Telephony and Telegraphy.

THE HOME TELEPHONE COMPANY'S SYSTEM, MOBILE, ALA.

A LARGE number of independent telephone companies throughout the country have been organized from time to time, and among them are to be found various kinds of equipments, some of which differ considerably from the familiar instruments of the Bell company. The Home Telephone Company, of Mobile, Ala., is one of the independent companies whose equipment is radically different from those generally seen. This system is the invention of Mr. Paul Minnis, the manager of the company, and as the instruments and appliances are extremely novel, we have described them in considerable detail.

Paul Minnis.

LINE AND STATION CONNECTIONS.

The general features of the system are clearly shown in Fig. 1, which represents a central station and two line stations, S and S′. The latter are in connection with the switchboard and with the main battery at the central station by means of one independent service wire, L, L′, to each line station, and by a common return wire, R, thus providing a complete metallic circuit, which is primary, being without induction coils. A single main battery, B, is connected in series with the line station and the central station which charges the line with a direct primary current. There is also a series of small batteries, T-B, one of which is directly connected with each pair of flexible cords at the central station, the indulations set up by the vocal vibrations being thrown upon the wires through the latter. A small incandescent lamp, D, is connected in multiple arc to the main battery, the lamp circuit being closed by devices operated by the current from small batteries, one of which is connected through one of the flexible cords with a circuit which is closed and opened at the line station. This closure is effected by the subscriber in using his telephone and the opening is automatic, whereby the signal, which is the equivalent of the "ring-off" now in use, is given to the central station the instant that conversation is at an end without requiring an action by the user of the telephone depending on his volition.

The series of small batteries is equal in number to the flexible cords in the central station, each cord being connected to one of the batteries by dividing it and connecting the severed ends directly to the opposite poles. These "talking batteries" are thus upon a normally open circuit, except at such times as the different service wires are brought into use. In this manner the common return wire is charged with as many separate direct primary currents as there are complete lines of communication in use, without the intervention of induction coils. There is thus obtained a common charge in the return wire having an amperage proportioned to the number of service wires in use at any given moment, the charge in the common return wire varying as the number of service wires in use increases or diminishes, the final object being to mass or combine the individual currents from the separate talking batteries in one common fund of electromotive force at a point where it can be equally drawn upon for the wants of each of the service wires in use without regard to whether the current used in any particular line station comes from the particular battery connected to the cord by which station is brought into communication with another station, or drawn from some other one of the series of talking batteries; or, in other words, from the aggregate or common charge of electromotive force present in the common return wire, a single main battery is provided to operate the annunciators and to light the lamps which denote to the operators at the central station that the service wires are in use.

THE CALLING APPARATUS.

The neglect of subscribers to "ring off" at the end of a conversation is perhaps as fruitful a source of annoyance and delay as any occurring in telephone service. In the new Mobile exchange the trouble has been entirely eliminated by an automatic ring-off system, which will be readily understood from the following: The arrangement is such that it leaves no act to be performed by the person using the telephone, except to release the handle of the instrument, by which the central station is at once notified that the line is no longer in use between the stations. The system of circuits is very clearly shown in Fig. 1. The call box shown in Figs. 2 and 3 consists of a casing provided with a hinged cover, which carries the bell-signaling mechanism. Arranged centrally within the casing, is a spindle, O, Fig. 3, to which is secured a stud that has a bearing in the lower end of a pedestal, rigidly secured to the cover and carrying the gong of the bell-signaling mechanism. Loosely arranged on the spindle, so as to rotate thereon, is a sleeve, c, and a reel is rigidly attached to this sleeve so as to rotate with it.

A coiled spring is disposed in a recess in the bottom of the

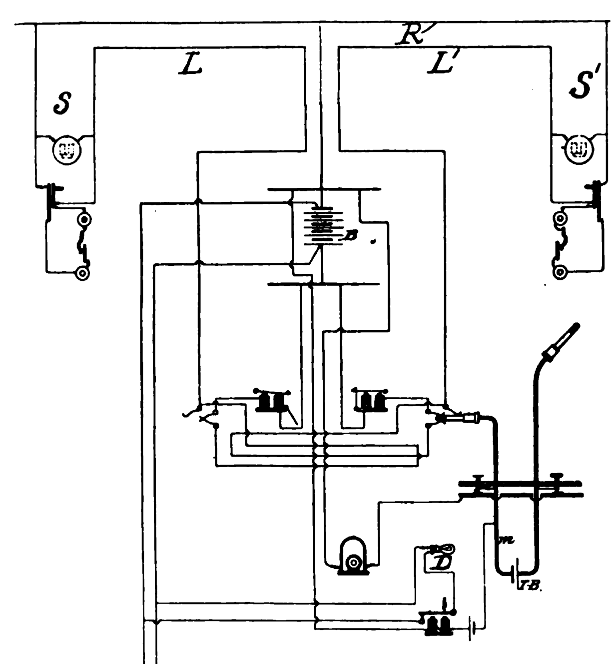

FIG. 1.—DIAGRAM SHOWING CONNECTIONS BETWEEN SUBSCRIBER AND EXCHANGE.

casing, one end of which is secured to the wall of the recess and the other end to the sleeve. On the opposite ends of the reel are discs, to one of which is secured a ratchet wheel, W, the teeth of which engage a bell crank shaped pawl, P, which is pivoted at one end to a bracket attached to the rim of the casing and at its other end is provided with a hook, H, upon which are

hung the receiver and transmitter. The coiled spring is interposed between the pawl and the rim of the casing and operates to normally hold the pawl in engagement with the teeth of the ratchet wheel.

The two conductors, A, lead from the receiver and transmitter through an aperture in the casing and are wound about the reel, the terminals being respectively soldered to the upper

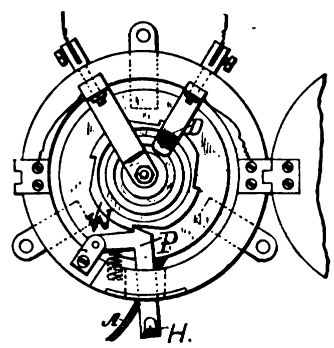

FIG. 2.—SUBSCRIBER'S CALL BOX.—PLAN.

flanged end of the sleeve and to an annulus attached to the disc. Resting upon the flanged end of the sleeve is one end of a spring contact, D, the other end of which is secured to a binding post that passes through the casing and is secured in place by a nut tapped over the inner threaded end of the binding post. The nut also serves to attach the spring contact to the binding post. A spring makes contact with the annulus and is connected with the other line wire.

The coils of the bell magnets are electrically connected to the

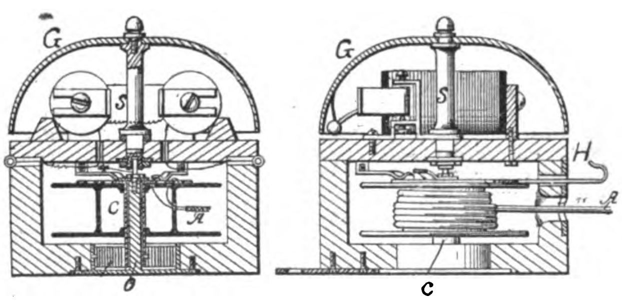

FIG. 3.—SUBSCRIBER'S CALL BOX.—SECTION.

hinges by wires and the gong is provided upon its inner edge with two shoulders arranged in proximity to each other, between which the bell hammer vibrates.

Let it be assumed that the device is supported in position with the lid or cover closed and all the parts in their normal position. To call up the subscriber, an alternating current of short duration is sent over the line wires from the central office by a magneto-generator in the ordinary manner and the circuit is closed through the contact wires and hinges through the bell magnets, and thence over the return wire to the central office.

Upon the subscriber removing the combined receiver and

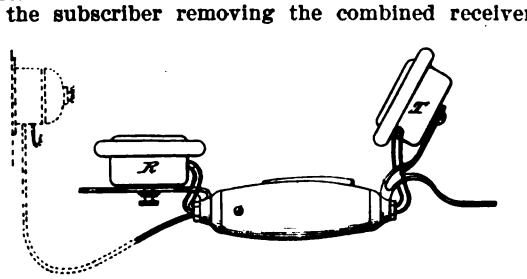

FIG. 4.—THE RECEIVER-TRANSMITTER.

transmitter from the hook, H, Fig. 2, the small coil spring forces the pawl into engagement with the teeth of the ratchet wheel; but the teeth are so arranged that the wires, A, may be unwound from the reel against the tension of the main spring to permit the receiver and transmitter being adjusted to the ears and lips. The pawl, however, prevents the reel from being rotated by its spring in the opposite direction to wind up the conductors.

Conversation may now be carried on between the two communicating parties, upon the conclusion of which the subscriber replaces the receiver and transmitter on the hook, and the pawl is thus retracted from its engagement with the ratchet wheel, upon which the main spring will rotate the reel and wind up the conductors. By this means the conductors are retracted within the casing at all times when the telephone is not in use, where they are out of the way and removed from all danger of accidental and forcible disturbance by which the telephone and its connections would be rendered liable to derangement.

COMBINED RECEIVER AND TRANSMITTER.

Fig. 4 shows the arrangement of the receiver and transmitter, which are mounted on a single handle in such manner that when the receiver is applied to either ear the transmitter will

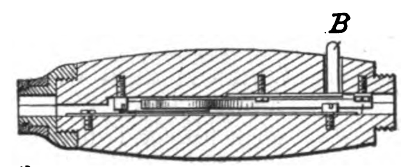

FIG. 4A.—SECTION OF HANDLE.

be in a proper position for conversation. The size and weight of the parts are small and their arrangement is such that they are easily manipulated and the convenience and ease of the user greatly promoted, as the telephone may be used while sitting or standing, or even by persons compelled to recline. Instead of employing a gravity switch use is made of a "palm-switch," A, shown in section in Fig. 5, which is closed by the mere grasp of the hand in holding the receiver to the ear. When the receiver is released this switch opens automatically, thus cutting the transmitter and receiver out of circuit with the line. There is also provided a second switch, B, Fig. 4A, which is normally open, in the handle of the telephone, whereby the subscriber may, by closing the switch, complete a call circuit through an instrument at the central station, thus avoiding the necessity of placing a magneto call generator at each line station. This second switch is closed by pressing a finger upon a push key, B, which projects through the handle, the arrangement being such, however, that the functions of this switch can, if necessary, be performed by the "palm-switch" already referred to.

In this system the whole apparatus at the line station is reduced to the call box and the telephone, shown in Figs. 2 and 4. This is not only a material reduction in the technique of the system, but it reduces the expense of installation, as well as the current expenses, there being no occasion for repairs, except, perhaps, upon rare occasions. There are no local batteries to be drained by careless persons who leave the receiver swinging by its cord and fail to "ring off," and the use of a gravity switch, which makes it necessary to hang the instrument up after use in order to cut the telephone out and switch the bell coils into circuit with the line, is avoided. Moreover, besides the evident ease and convenience to the user, who can assume any position within the range allowed by the length of the flexible

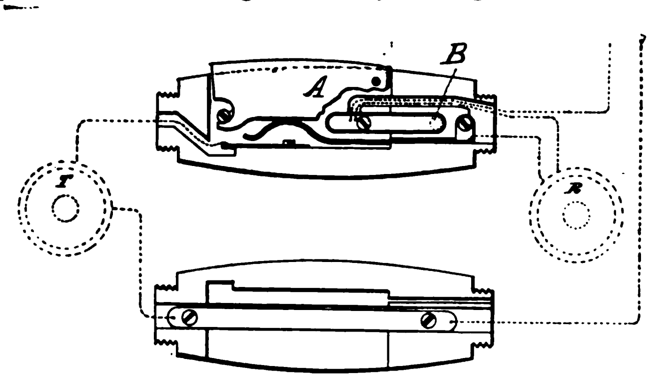

FIG. 5.—HANDLE OF RECEIVER-TRANSMITTER.

cord, there is no necessity for employing skilled labor in equipping a line station.

THE SWITCHBOARD CONNECTIONS.

The wire connections of the switchboard are shown in diagram in Fig. 6. Each line station, S, S′, is connected by a service wire, L L′, to the central station switchboard as shown, and connection is also made to a single return wire, R′, of such

diameter as to equalize the aggregate resistance of the service wires. This return wire forms part of the path traversed by the currents from all the service wires, and it is not connected to earth at any point.

The return wire is connected by a tap wire to one pole of a

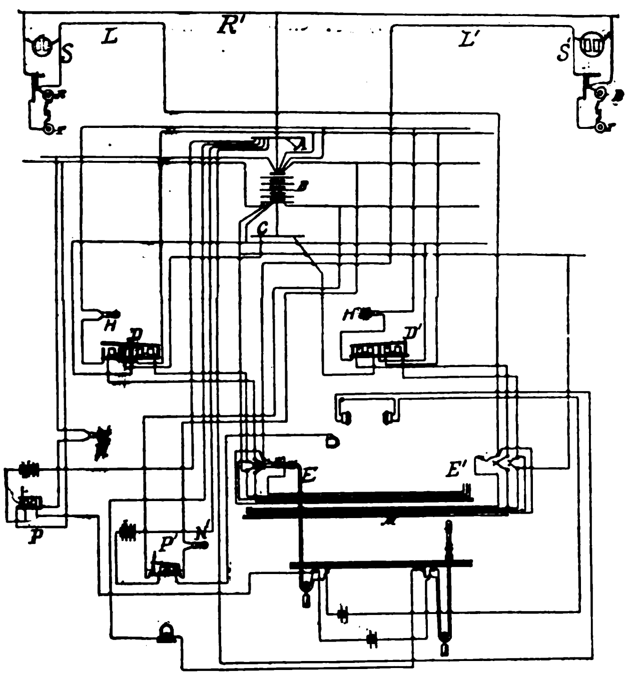

FIG. 6.—DIAGRAM OF SWITCHBOARD CONNECTIONS.

single main battery, B. This tap wire also connects electrically with a spread terminal, A, which lies between the return wire and the main battery. The other pole of the battery, B, is connected to a second spread terminal, C. From this latter a wire is carried to the first terminal of the helices of a pair of electromagnets, D D', and from the second terminal a wire is led to one of the line jacks of the switchboard at the central station, E E', which has two closed spring contacts, and to the former of which the wire is connected.

From the other spring contact a wire goes to the multiples,

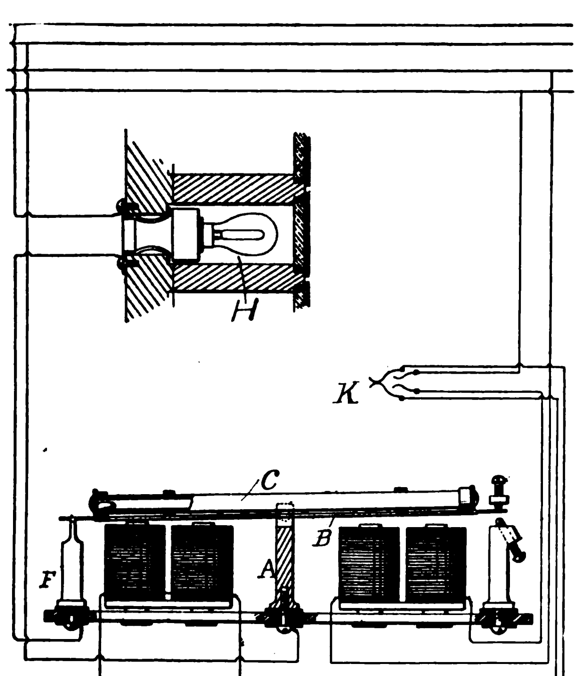

FIG. 7.—THE ANNUNCIATOR MAGNET AND LAMP.

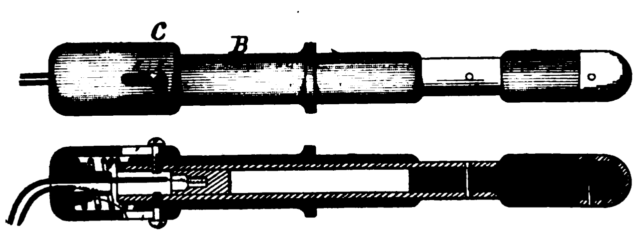
M, of the switchboard, and from these a wire is carried to a single spring contact which is in the same line jack with the closed contacts. From the single contact the service wire is led to the line station, where it forms a loop having two branches, between which the bell coils are placed in bridging connection. Beyond these coils the transmitter, T, and receiver, R, are connected in series, and from these parts of the telephone one branch of the loop is led to the return wire.

The circuit, which includes the service wire, single contact wire, multiples, M, closed contacts, and electromagnets, spread terminal, battery B, tap wire and common return wire, is normally complete at every point except at the line station, where the switch is placed in the handle supporting the receiver and transmitter, as described above. This switch is normally open, and by closing it the person using the telephone is able to send a current from the battery, B, over the circuit last described. The action of this current is as follows:

THE ANNUNCIATOR LAMP AND MAGNET.

The electromagnets, Fig. 7, are arranged at the central station in convenient proximity to the switchboard and the lamps, H, are in full sight of the operators. There are a pair of these magnets for each line station, the circuit in each being similar to that already described. By reference to it, it will be seen that the pair of electromagnets are mounted upon a base from which they are insulated. Rising from this base is a post of conducting material, A, on which is accurately balanced an armature, B. Upon this armature is mounted a small glass tube, C, which is also in equilibrium, so far as regards an equal apportionment of its weight upon both sides of the fulcrum on which the armature is balanced.

Within the tube, which is closed at both ends, is placed a globule of mercury, which is free to run from end to end of the tube when the latter is inclined even slightly. Mercury is the only substance suitable for this purpose, as it will move on a very slight inclination and with great swiftness, so that an instantaneous tip of the armature will be sufficient to enable the mercury to travel past the center and depress the end toward which it moves. The armature forms part of the derived circuit, the extremity which is adjacent to the magnets being prolonged to form a contact which rests upon the end of a second post. The wires go, as already stated, to the terminals of



FIGS. 8 AND 9.—THE SWITCH PLUG.

the magnets. From the fulcrum post a wire is led to a feeder and from the contact post, F, a wire is led to one terminal of a small incandescent lamp, H. From the second terminal of the lamp a wire goes to a second feeder.

These feeders are connected, respectively, to the opposite poles of the main battery, B, and are open, except through the multiple arc connections to the lamp. Each of these lamps is inclosed in a small housing, having a transparent wall, on which is displayed the number denoting the line station. Thus by merely closing the switch at the line station the lamp circuit is established and maintained after tne switch is released by the armature, overbalanced on one side by the mercury globule.

The end of the armature opposite that forming the contact has a prolongation which lies between two stops, both of which are adjustable in a post upon the base. This post is insulated and forms no part of any electrical circuit. Beneath the adjacent end of the armature is a pair of electromagnets, insulated on the base. The first terminal of the magnets is connected by a wire to a tap wire, which is led to one pole of the main battery, B. From the other pole of this battery the circuit of the magnets is by way of a wire to spring contact, K, one of a pair arranged in the same line jack with the contacts. The second contact of the pair is arranged over the first contact, but not in touch with it. From this second spring contact a wire goes to the second terminal of the magnets.

When the operator at the central station answers a call and inserts the plug on one end of the flexible cord in the line jack, the conducting cap upon the end of the plug engages the two contacts and closes the circuit, which includes the helices of the electromagnets. This attracts the corresponding end of the armature, drawing it down and causing the mercury globule to run to that end of the glass tube, C, thus maintaining the armature in the position it is caused to assume by the attraction of the magnets. The rise of the terminal contact breaks the circuit of the lamp and extinguishes it, its ignition being the call signal by which the central station was notified

that the line station desired to communicate with another station.

BUSY TEST.

It is well known that in most telephone exchanges the switchboard is divided into sections, each containing as many separate connections as can be served by a single attendant, and containing, moreover, multiples or duplicates of all the remaining connections. One purpose of these duplicate connections in each of the divisions of the switchboard is to enable any one of the operators to connect a line station served by that operator with any one of the line stations served by an operator having charge of another division, and to be able, more-

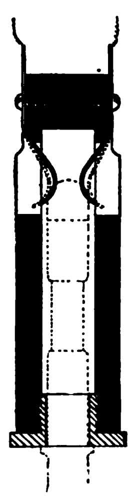


FIG. 10.—ARRANGEMENT OF LINE JACKS.

over, to ascertain easily and instantaneously whether the line station with which communication is desired is already using the service wire which connects that station to the switchboard. It is one of the special purposes of this system to provide means for accomplishing this with absolute certainty with the minimum expenditure of time, care and manual action on the part of the operators at the switchboard, and without the necessity of addressing a question to either line station and awaiting a reply. The means provided for this purpose are as follows: At the central station, in convenient proximity to the switchboard, so that the attendants can readily see the same without changing their position, are arranged a series of small lamps, N N', Fig. 6, each identified with one of the panels of the switchboard. Each lamp has its own independent circuit, which is closed and opened in the following manner. One lamp terminal is connected to a post which forms a support for the armature of a pair of electromagnets, P P', which are arranged, when energized, to attract the armature which is normally raised by a spring.

When attracted, the prolonged end of the armature is brought into contact with a post, and from this post a wire is led to a feeder. This feeder goes to one pole of the main battery, B, and the other pole of the battery is connected to a second feeder. From the latter a wire is led to the second terminal of the lamp.

The circuit, by means of which the magnets are energized, is as follows: From one terminal of the magnets a wire goes directly to one pole of a battery. From the other pole a wire goes to the spread terminal, from which point the circuit is by the tap wire, return wire, to the line station. Here, if the line is closed, the current passes through the telephone and over the service wire to the single contact in the line jack. Thence, a plug being inserted in the jack, the path of the current is through contact piece, bushing, face plate, conducting strip of the jack, and thence on by wire to the corresponding multiples and to their respective face plate through their respective contact strips. The circuit is completed by a wire from the second terminal of the electromagnets to a test thimble. This thimble is worn by the operator upon one finger. It is made of insulating material and has a metal tip to which the wire is attached. The pressure of this metal tip against the face plate of any line or multiple jack that is in use closes the test circuit, energizes the electromagnet, attracting the armature and drawing it into contact with the post, thus closing the circuit of the lamp by the lighting of which the operator is notified that the service wire thus tested is in use. Should the line be idle, the test circuit will be open between single contact and contact piece in the line jack and all of its multiples, and the failure of the lamp to light indicates that the line tested is free for use.

THE SWITCH PLUGS.

The two plugs, Figs. 8 and 9, are made in two colors, all those to which the head 'phone circuit is connected being of one color and designated as the "first plug" of the pair, and all the plugs to which the magneto-generator circuit is connected being of another color and designated as the "second plug" of the pair. The circuit for the head 'phone and the magneto-generator, respectively, are normally open in the caps of their respective plugs between the cylindrical bushing in the cap and the conducting body of the plug. When a subscriber calls the central office, the force necessary to insert the plug in that subscriber's jack telescopes the cap, C, on the body, B, of the plug, closing the contact between the cylindrical bushing of the cap and the conducting body of the plug.

The release of the plug by the operator cuts out the head-'phone circuit of the ringing circuit, as the case may be, by means of the spring which forces the cap back to its normal position, thus breaking the contact between cylindrical bushing of the cap and conducting body of the plug. Either of these circuits can, however, be instantly re-established by a pressure of the operator's finger upon the cap of either plug; but should it become necessary to ring the calling subscriber or speak to the called subscriber the plugs must be reversed. In other words, all talking or listening must be done by the operator by means of the first plug of the pair, and all ringing by means of the second plug of the pair. The simplicity, speed and certainty secured by this arrangement will be readily appreciated.

THE LINE JACKS.

Fig. 10 illustrates the line jacks used in this system. It will be observed that the insertion of the plugs in the line jacks not only breaks the call circuits, but it also completes the circuit of the magnets which restore the armature to its original position, thus cutting out the circuit of the lamp. The circuit of these magnets is completed through the contacts and the metallic cap on the tip of the plug.

The purpose of opening the call circuit by the insertion of the plug in the line jack is not merely for the prevention of short circuiting or leakage of the talking current, but is for the very essential purpose of disestablishing the connection between the line and the main battery, B. The heavy current from this battery must be removed from the talking circuit, because if it be present conversation would be practically impossible.

ARRANGEMENT OF THE SWITCHBOARD.

The relative positions of the various details of the switchboard are shown in Figs. 11 and 12, which represent it in front

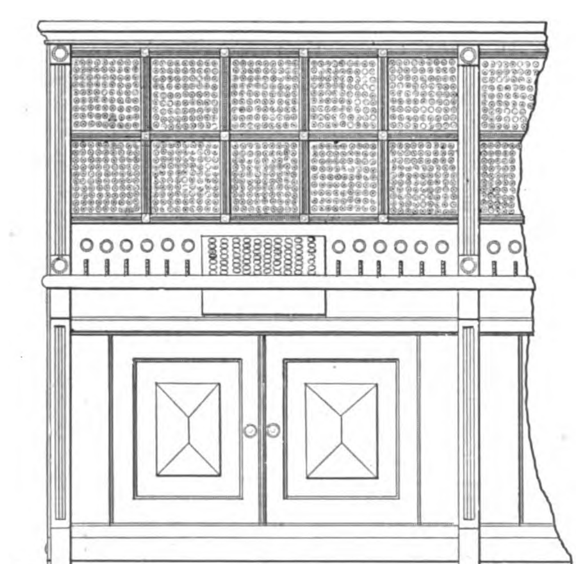

FIG. 11.—SWITCHBOARD.—FRONT VIEW.

and side view, respectively. It will be seen that the annunciators are placed at an angle on the apron of the switchboard below all the jacks, the relays operating them being racked up underneath the rear of the board. 100 annunciators occupying a space on the apron of the board less than twelve inches square. All the space above is thus left for jacks, it being possible to place a much larger number of subscribers in front of each operator, and also to add to the capacity of the board at

any time without reconstructing the portion already built. Such a board secures not only silence, but, it is claimed, a speed superior to anything heretofore attained, and adds greatly to the convenience of both the subscriber and operator. For example, if the former desires to speak to the operator, instead of hanging up his hand telephone on a gravity switch or operating the switch with one hand and the magneto in his box with the other hand, he simply presses the switch in his telephone handle several times in quick succession, thereby producing a series of flashes from the lamp which the operator instantly sees and answers.

The exchange is equipped with storage batteries, Crocker-Wheeler motor-dynamo chargers, Holtzer-Cabot direct and alternating motor-generators, reserve power generators, lamp resistance charging boards, etc., everywhere being in duplicate and in many cases triplicate, so that a complete breakdown is impossible.

THE COMPANY AND ITS BUSINESS.

One year ago Mobile, Ala., had only 300 subscribers to the old exchange. Their rates ranged from $50 to $150 per annum. To-day the Home Telephone Company has 800 subscribers, with

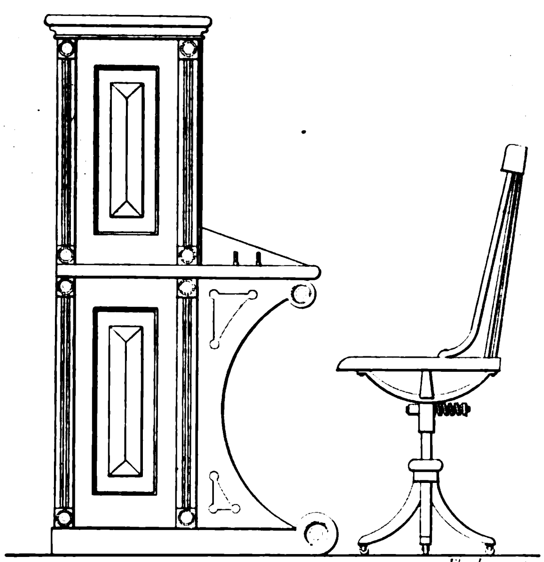

Fig. 12.—Switchboard.—Side View.

a prospect of 1,000 before they complete their construction. Their rates are $20 to $30 per annum.

The plant was constructed and installed under the personal supervision of Mr. Paul Minnis and the construction committee, composed of Messrs. Adam Glass, chairman; A. S. Lyons and W. H. Fitzpatrick, and is pronounced by experts to be the finest telephone plant in the South and one of the finest "overhead" plants in the country.

The officers and directors of the Home Telephone Company are: A. S. Lyons, president; J. K. Glennon, vice-president; Adam Glass, treasurer; W. H. Fitzpatrick, secretary; Henry Piser, A. H. Spira, P. J. Lyons, A. S. Benn and O. F. Cawthon, directors.

Literature.

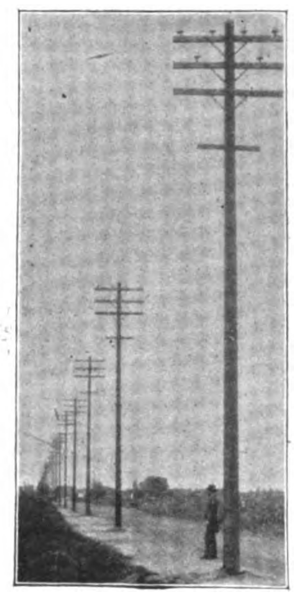
SYNOPSIS OF CURRENT ELECTRICAL LITERATURE, 1895, by Max Osterberg, E. E., A. M. New York, 1896: D. Van Nostrand Company. 143 pp., 7 x 10. Price $1.

This is an extremely useful and valuable publication, which we trust will be kept up. It contains an enormous quantity of well digested information and covers its ground thoroughly. There is little or nothing of importance that escapes Mr. Osterberg's dragnet, and the classification is remarkably good. Some of the more ephemeral items might perhaps have been dropped for the sake of more space on items of lasting utility, but, of course, it is difficult to get the real perspective from month to month. Mr. Osterberg indexes and digests here some fifty or sixty publications, so that even if his work had been done badly its mere bulk and scope would have given it a distinct value. The only trouble is there are now too many of these indexes; one really needs an index or synopsis of them. But Mr. Osterberg's work suffices for busy men and as a deposit of data should be supported by hearty encouragement.

Power Transmission.

THE 35-MILE ELECTRIC POWER TRANSMISSION AT FRESNO, CAL.

Fresno, the principal town of the great San Joaquin Valley, in California, was, during the last days of May, the scene of the completion of a great work, having for result the electrical transmission commercially over the longest distance yet attempted of power generated by an artificial fall of water unique in its creation and height.

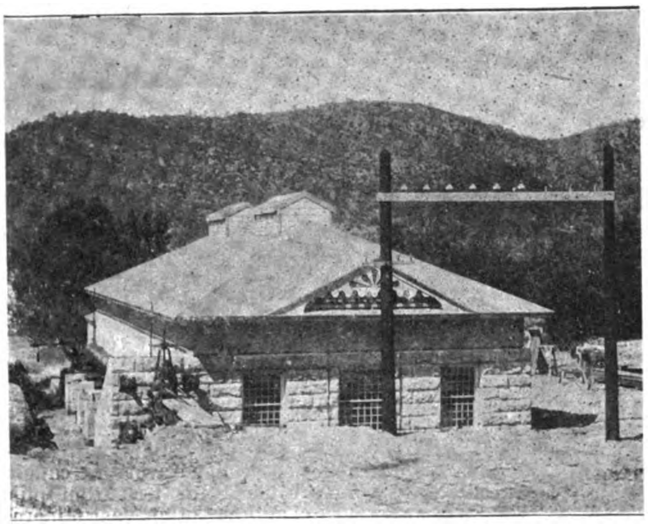


The city of Fresno stands in the valley of the San Joaquin River, in California, and was founded in 1872, when the Southern Pacific Railroad was first built in the valley. For thirteen years its growth was extremely slow, but in 1885 it received an impetus, and in the last ten years its population has risen to 15,000 persons. Its natural advantages are many: It is the center of a fertile agricultural region, overspread with a network of canals and ditches for irrigation purposes, and has other vast mineral resources as yet undeveloped. It is the commercial center of the San Joaquin Valley and would have become a manufacturing city had its aspirations in this direction not been subdued by the extremely high price of fuel and consequent heavy cost of power for manufacturing purposes. This handicap was felt severely by the city as a check upon its growth. All manufactured articles had to be purchased in the East, and when to their cost were added the

Pipe Line Descending Hill to Power House.

freight charges, prices on arrival at Fresno became almost prohibitive. The utilization of the difference of level of the San Joaquin River had been mooted, but not until the successful

solution of the problem of long distance power transmission had been reached did the utilization of the San Joaquin become possible. A company was formed, the San Joaquin Electric Company, to carry out the work, and the General Electric Company's project and three-phase system of transmission, by which power had already been successfully transmitted from Folsom to Sacramento, a distance of twenty-four miles, was adopted. The work, lacking a few details, is now complete and Fresno is on a par with any city of the East, so far as the cost of power and light is concerned.

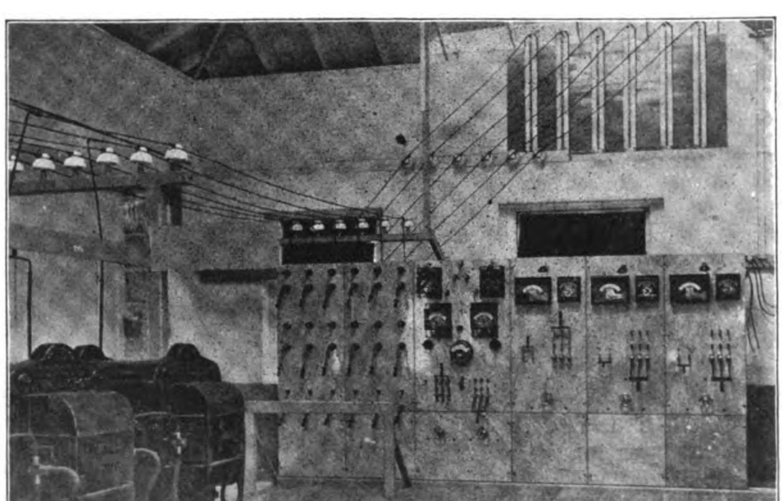


THE FRESNO ELECTRIC TRANSMISSION POWER HOUSE.

THE HYDRAULIC PLANT.

The source of the water power is the North Fork of the San Joaquin, which at the point of diversion runs through a narrow canyon with solid rock walls. The minimum low-water flow of the stream at this point is fifty cubic feet per second, which at the head used, will develop over 7,000 horse-power at the water wheels.

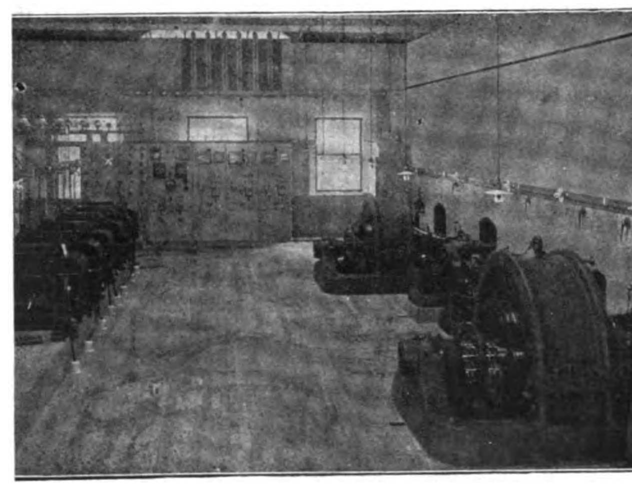
From the point of diversion, a flume has been built and a canal excavated and carried along the slopes of a hill for a distance of seven miles. They run along a right of way cleared of all obstructions for a width of 150 feet. The grade is 5.28 feet to the mile, and the lower bank forms a roadway for the inspection wagons. The entire system of headworks and canal is below frost line.



SWITCHBOARD IN FRESNO ELECTRIC TRANSMISSION POWER HOUSE.

At the end of the canal is a natural basin several acres in extent, surrounded for about three-quarters of its distance by a dyke of rock, which for an expenditure of less than $3,000 has been continued in an embankment for the remaining distance and a reservoir for storage water formed which at a maximum depth of only ten feet, will be sufficient to operate the plant at full load for several days consecutively. This provision will allow of the ditch and flume being shut off in case of repair or changes.

The reservoir is located at the top of a high hill, the river being some 1,600 feet below. From the pressure box in the reservoir the pipe line, 4,100 feet long, is brought down the mountain side and in this distance the difference in level between the water in the canal and the water in the river below is over 1,400 feet. For the first 400 feet the pipe is steel riveted; the balance is lap welded pipe, with lock joints, and at the lower end is ⅝ inch thick by 22 inches in diameter.



GENERATOR AND TRANSFORMER ROOM.

At the power house the pipe enters a receiver 57 feet long by 30 inches in diameter, of ¾-inch steel, with joints of the butt strap type. This receiver is designed to stand a working pressure of 800 lbs. to the square inch.

THE POWER HOUSE.

The power house at the bottom of the hill is built of native granite, with a wooden roof. It is 75 feet long by 30 feet wide and is built on solid bedrock. The receiver and water wheels are outside the main power house, the shafts passing through a heavy granite wall, which effectually keeps all water and moisture out of the dynamo room.

The water wheels are of the Pelton type, 57 inches in diameter, each capable of developing 500 horse-power at 600 revolutions per minute under an effective head of 1,410 feet, said to be the highest head ever used for power transmission purposes. The wheels are constructed with steel plate centers and bronze buckets and are fitted with flywheels, five feet in diameter. Separate wheels are provided for the exciters. The wheels which drive the generators are provided with Pelton differential governors.

THE ELECTRIC PLANT.

The electric plant consists of three General Electric three-phase generators, each of 350 kilowatts capacity, at a speed of 600 revolutions. The armatures are directly connected to the water wheels by insulated flange couplings. The exciters used are of the slow speed multipolar type. The current from the generators is delivered to six 125 kilowatt step-up transformers of the G. E. air blast type with secondaries wound for 11,200 volts, to which pressure the current in the transmission line is raised. Provision is left in the generator room for three more transformers of similar capacity. From the transformers the current passes to the switchboard, which is of Vermont marble highly polished, as are all the other switchboards used in the installation. The switchboard consists of six panels, three of which are generator panels, one exciter panel and the other two operate the combination of the six transformers and carry special high tension line switches.

THE TRANSMISSION LINE.

The 11,200-volt circuit, consisting of six bare copper wires, leaves the power house at the upper end, runs up the stream a few hundred feet, crosses the San Joaquin River, with a wide span of 275 feet, and is then led up the mountain for a distance of about 2,000 feet. The line continues for about ten miles through a rolling, hilly country, easy of access and at all times below the snow line; the rest of the line runs over a flat country and near Fresno passes through wheat fields and vineyards and follows a special right of way and wagon road for the entire distance.

The total length of the transmission line from the power house to the substation is little short of thirty-five miles, and is thus the longest commercial electric power transmission in the world.

The line is strung on special high-tension porcelain insulators made in the porcelain works of the General Electric Company, tested under 27,000 volts alternating before shipment. The poles are square redwood thirty-five feet long, set six feet into the ground and fitted with three heavy cross arms and one small cross arm for telephone wires. As a model of pole line construction, the Fresno transmission line can compare favorably with any pole line work done in the country.

THE SUBSTATION AT FRESNO.

The substation at Fresno is almost in the center of the business portion of the city, and is a brick structure 55 feet by 45 feet. The high pressure circuits entering the house are brought to nine step-down transformers, also of the air blast type. Three of these are 125 kilowatt capacity and reduce the pressure to 200 volts, three of 75 kilowatt capacity with secondaries of 1,000 volts, and three are of 40 kilowatt capacity, reducing the pressure to 3,000 volts. In addition to these transformers, the station also contains two 80-light Brush arc machines directly driven by two 60 horse-power, three-phase induction motors.

The system of distribution from the substation is divided up into three net works. The first a 200-volt, four-wire, low-tension network which covers the business portion of the town and having an initial capacity of 6,000 16 candle-power incandescent lamps. The second, a 1,000-volt, three-phase system, covering the residence districts of the town and having an initial capacity of 4,000 16 candle-power incandescent lamps. The third, a 3,000-volt, three-phase circuit designed to furnish current to the numerous vineyards and wineries within a radius of ten miles from the substation for both lighting and power purposes. Motors will also be furnished with current from both the 200-volt and 1,000-volt systems.

The policy of the operating company is of a broad gauge character, the end in view being the stimulation of the use of electric power. To effect this end prices are made which compare favorably with those charged for power where steam coal costs only $2 per ton. The result of this is that the demand has already taxed the resources of the company, although the plant has scarcely been running for one month.

THE UTILIZATION OF WATER POWER, ESPECIALLY WITH A SMALL FALL, WITH SOME EXAMPLES OF PLANTS FOR THE GENERATION OF ELECTRICAL ENERGY.—II.

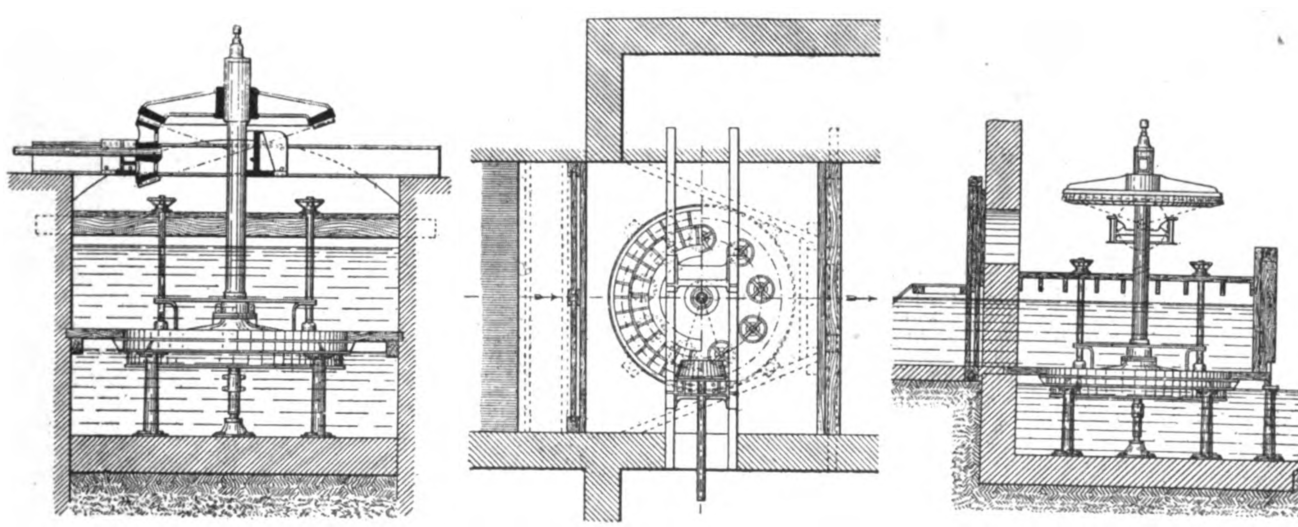
BY ALPH. STEIGER.

(*Concluded.*)

THE description of a Jonval turbine installation, which I supplied for the Brantham Mills, near Manningtree, in Essex, here illustrated, will show that a very small and varying fall can be utilized with great advantage to obtain nearly a constant power. The local conditions and requirements are most remarkable and interesting. The power is used to drive a modern flour mill, in which the maintenance of a regular speed is of equally great importance as for driving an electrical plant.

The River Stour is a tidal river, with a maximum fall at ebb tide of 4 feet 10 inches, while at high tide the fall is nil. The water is supplied partly by the river itself coming down from the hills of Cambridgeshire, and partly by the rising tide filling the river bed above the mill for a considerable length. The power required is 40 actual horse-power, and it was stipulated that this power should be maintained down to a fall of forty inches. On starting the turbine, it was shown, however, that it drove the mill at full capacity and at full speed under a fall reduced to thirty-two inches. The full power is available during sixteen hours of each day, while during six further hours the power corresponding to a fall reduced down to about one foot is still utilized for driving a part of the machinery. Comparing the useful power obtained from this varying fall by the new turbine during twenty-four hours with that obtained by the undershot water wheel previously working, it is nearly six times larger.

The turbine consists of only two concentric rows of buckets; the inner one is provided with gates, which are opened or closed by hand wheels, an automatic governor not being generally used in flour mills. The outer row of buckets is just large enough to give the full power required under the maximum fall. As the fall is decreasing by the rising tide, the gates of the inner row of buckets are gradually opened to make up the power by an increased quantity of water, and the more



FIGS. 5A, 5B AND 5C.—TURBINE AT BRANTHAM MILLS, ESSEX. CROSS SECTION, GROUND PLAN AND LONGITUDINAL SECTION.

water is passing through the buckets of the inner row, the more it acts on a reduced mean diameter, thus maintaining also the proper speed without perceptible loss of efficiency.[1] The power is transmitted from the turbine on to a horizontal main shaft by means of a pair of bevel wheels. This horizontal shaft is made to run at 75 revolutions, and is provided with a clutch by means of which the turbine is connected with the steam engine if the mill is required to work continuously. When the fall is reduced to more than thirty-two inches, the mill is, however, driven separately by the steam engine, and the power of the turbine is used to drive the wheat-cleaning machinery, and eventually some pairs of millstones which can work independent of the automatic roller mill plant. When the fall is reduced to fifteen inches, the power that is still obtained from this turbine is 7 horse-power, the turbine naturally running slower, but still this power is quite sufficient to be profitably utilized.

Assuming that the water power available at Brantham Mills

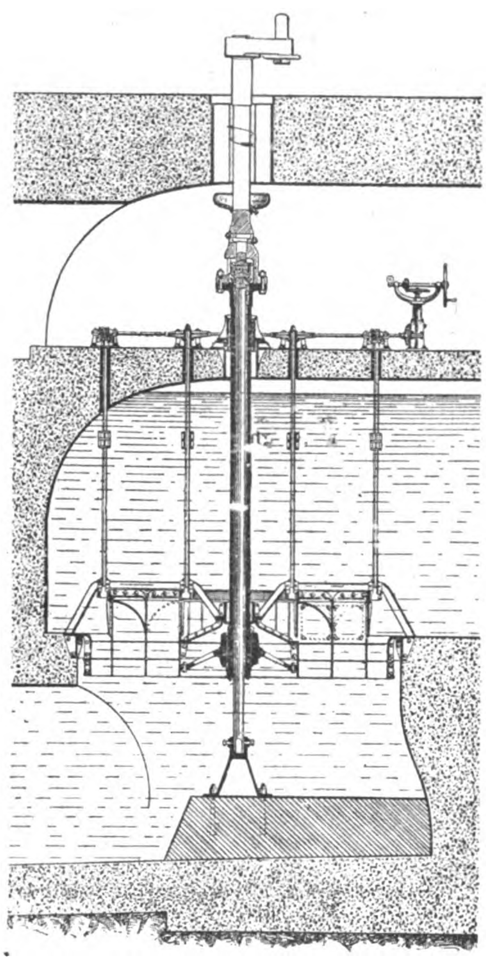


Fig. 6.—Turbines of the Waterworks, Geneva.

were applied for the generation of electric energy, it would, in the first instance, be necessary to obtain a conveniently high speed to drive an electrical generator without much intermediate gearing. A turbine similar to the one actually working could be made for exactly these conditions, running at thirty revolutions per minute, and a pair of bevel wheels put in of such proportions as to give the first motion shaft a speed of 150 revolutions per minute. This speed would be very suitable to drive a dynamo of 40 horse-power by means of a belt or ropes. A higher speed of the turbine than thirty revolutions would, for such a low fall, only be obtainable at the expense of efficiency. As in this special case the fall, and consequently the power, varies with the rise and fall of the tide, the full power of the turbine can of course only be relied on during fifteen or sixteen hours every day. The power produced during the time when the fall is diminished beyond the limit at which it is 40 horse-power, and at less than the normal speed, could probably be applied to charge electrical accumulators.

The construction of the turbine shaft deserves some notice. The space underneath the turbine being always filled with water, and, therefore, inaccessible, the pan for the footstep is placed on top of a column round which the hollow cast iron shaft revolves. The upper part of the turbine shaft is widened, and contains an adjustable steel pin which revolves in the pan or cup, filled with oil. Although a well-constructed footstep will last for years without requiring repairs, an easy access to it is of great advantage.

Similar turbines were erected by me in other mills near Norwich, Reading, and Lewes. In all cases the fall varies between two feet six inches and six feet, the reduction of the fall being caused by floods, while the water supply varies in the proportion of about 1 to 4. In each case the local conditions were carefully investigated and the turbine constructed accordingly. The good results obtained in each case are due to the careful adaptation of the turbine to the conditions. The importance of a careful consideration of local conditions is evidenced by several failures which were recently brought under my notice. In one of these instances, the turbine—which in itself is a very good motor—gives very poor results, owing to the disregard of the actual conditions of the locality. Even the construction of some details of a turbine depends sometimes on these conditions; and in several cases now under consideration I have had to depart from the general practice of designs of turbines, in order to secure the highest results when most required.

How varied the construction of a Jonval tube may be, will be shown by the following examples. The turbines of the Geneva waterworks, built by Messrs. Escher, Wyss & Co., of Zurich, work under a maximum fall of twelve feet during the winter season, when the water supply is shortest, while during the summer season the water supply stored up in the mountains, in the shape of snow and ice, is abundant. The large summer supply reduces the fall, however, to 5 feet 7 inches. The power of each turbine, of which there are now seventeen at work, is 210 actual horse-power, and they run at a uniform speed of thirty-six revolutions per minute, whether the fall is 5 feet 7 inches, or 12 feet. The cost in this case was a secondary question; the turbines have, therefore, been provided with the best possible arrangements to suit the large variations of the fall and quantity of water. The drawing shows three concentric rows of buckets. The outer row alone will develop 210 horse-power under the maximum fall of twelve feet—its outside diameter is fourteen feet. Each of the two inner rows of buckets is provided with a revolving gate, working separately. Each turbine drives a pair of double-acting plunger pumps direct, the crank common to both pumps being fixed on the vertical turbine shaft, Fig. 6.

An interesting turbine installation, under a fall varying from 10 feet 9 inches to 8 feet 10 inches, in connection with electrical generators, is that at Baden, in Switzerland. It was described in "Engineering" of November 1, 1895. This plant was erected to supply the town of Baden with electric light, and the necessary driving power to the new works of Messrs. Brown, Boveri & Co., the well-known electrical engineering firm. The fall had to be created by a weir, and a canal about 2,500 feet long, which added considerably to the cost of the plant. Each of the three turbines is of the Jonval type, giving off 200 British horse-power. It is impossible to build a turbine of that power for the fall available in this case, which would run with a speed high enough to drive a generator direct. The turbines run at forty revolutions per minute, which speed is maintained under the varying fall by means of gates for the inner row of buckets. The generators—two-phase dynamos of the horizontal type, made by Messrs. Brown, Boveri & Co.—run at 200 revolutions per minute, and are driven direct off the turbine shaft by means of a pair of bevel wheels. The exciter dynamos, of which there are three of 10 horse-power each, are driven each by a separate turbine. These small-power turbines naturally run at a higher speed—namely, 180 revolutions per minute—and drive, therefore, the exciter dynamos without any intermediate gearing.

In most cases in this country where a good water supply is available, the fall will be rather lower than 10 feet or 12 feet; it will therefore require intermediate gearing to drive a high-power generator, and it will even not often be possible to connect it direct with the first main shaft driven off the turbine by bevel wheels. Belt drives are very convenient to get up the necessary speed of dynamos, but for large power they are very expensive, and absorb a considerable amount of the power in friction. The ordinary round hemp and cotton rope is objectionable, on account of requiring frequent repairs and resplicing. During an inspecting tour in Switzerland last summer, I came across a new kind of hemp rope, which seems to supply just what is wanted to drive large power dynamos.

It is a plaited rope of extreme pliability, which does not stretch. I found this rope working at the generating station of Schaffhausen. The power at the generating station is transmitted from the countershafts, driven off two turbines of 300 horse-power each by means of bevel wheels, on to the gener-

[1] Outside diameter of this turbine is about 10 feet, and it runs at 24 revolutions per minute.

ators by means of ten such ropes, one and three-quarter inches thick. The rope pulleys on the dynamos have a diameter of five feet, running 300 revolutions per minute. The rope pulleys on the countershaft have a diameter of 13 feet 6 inches, and the distance between the centers of shafts is fifty-one feet. The power is electrically transmitted to a spinning mill about half

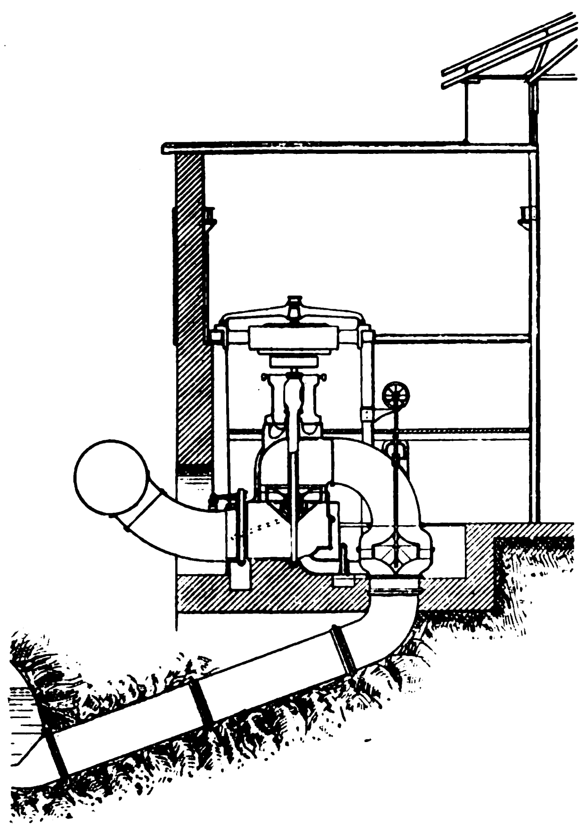

FIG. 7.—TURBINES OF THE ALUMINUM WORKS AT NEUHAUSEN, SWITZERLAND.

a mile distant from the generating station. The secondary station consists of an electromotor of 200 horse-power, coupled directly to a main line shaft, and two electromotors of 190 horse-power each, coupled together. The latter, running at 300 revolutions per minute, carry a rope pulley of five feet diameter with fourteen grooves. One hundred horse-power are transmitted by four such ropes to a shaft twenty-one feet above the electromotor, at an angle of 51 degrees, while the remaining 250 horse-power are transmitted to another shaft on about the same level and 17 feet 8 inches distant, running with 130 revolutions per minute. In spite of the unfavorable relative position of the shafts these ropes work with extreme regularity and easiness, and their adoption has, according to the manager of the spinning mill, put an end to the trouble and frequent stoppages caused by the breaking of the round ropes which were previously used.

Returning to the description of water-power plants proper, two more examples in connection with the generation of electricity deserve to be mentioned, showing how certain objects can be attained by a special construction. One of these is the installation of five new turbines for the aluminum works at Neuhausen, on the Rhine fall, in Switzerland. One of these turbines is here illustrated. Each of these turbines gives off 610 British horse-power under a fall of sixty-six feet, with a quantity of water of 6,500 cubic feet per minute. With the high fall a high speed suitable for driving the dynamo direct is naturally obtained—an arrangement which has also been adopted in this case to economize space. On the other hand, the load on the footstep of a turbine of the power mentioned by the pressure of the water, in addition to the weight of the armature of a generator of corresponding dimensions, is so great that a special arrangement had to be adopted to release the footstep of at least a part of that load. In order to overcome this difficulty, the turbine has been reversed, the water passing through the turbine upward, acting, therefore, in the opposite direction to the weight of the machinery. The boss of the turbine wheel is, moreover, formed into a piston, working in a cylinder, to which water under the pressure corresponding to the fall is admitted, thus counteracting again the weight of the moving parts of the turbine and dynamo. The water, after passing through the turbine, is conducted to the tail-race through a suction tube, the turbine being placed 15 feet 9 inches above the tail water. It runs at 150 revolutions per minute, and is a single Jonval turbine. To regulate its speed, if required, a ring gate is inserted in the suction tube, while it can be stopped by a throttle valve in the wrought iron tube taking the water to the turbine. The total power now utilized by these aluminum works is 4,550 horse-power. The turbines were constructed by Messrs. Escher, Wyss & Co., of Zurich, and the dynamos by the well-known electrical works at Oerlikon. Each dynamo is of 7,500 amperes and 55 volts.

The last turbine installation here illustrated is that at Zufikon-Bremgarten, also in Switzerland. The drawing shows another arrangement to counteract the weight carried by the footstep, and at the same time an arrangement by means of which the necessary speed to drive a dynamo of large power direct under a medium fall is obtained. The plant consists of four sets of double Jonval turbines of 325 British horse-power each, running at 115 revolutions per minute, and a smaller Jonval turbine of 34 British horse-power, driving two exciter dynamos, running with 210 revolutions per minute, and was erected to supply electric light to the neighboring town of Wohlen and driving power to the new works of Escher, Wyss & Co., in Zurich, and a large flour mill close by these works. The distance over which this power is transmitted is about eleven miles. The fall is 17 feet 6 inches, and was obtained by building a dam across the River Reuss, and a tunnel about 1,100 feet long across a hill round which the river flows at a rather high speed. The water is divided between two Jonval turbines fixed on one common shaft, so that it passes upward through the lower wheel and downward through the upper wheel. By distributing the water in this manner, the diameter of each turbine is reduced, and the speed consequently increased. At the same time the pressure of the water, which would otherwise act on the footstep, is entirely counterbalanced. The central part of the lower wheel, is, moreover, formed into a disc, on which the water presses from below, releasing the footstep also partly by the weight of the revolving parts of the turbine and the dynamo. The space between the two turbines on each shaft is connected with the tail-race by a flume formed

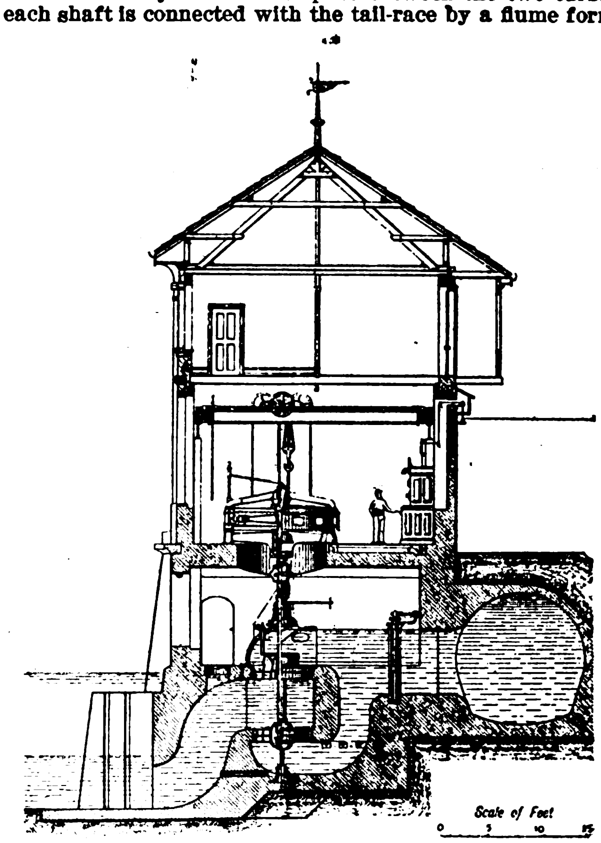

FIG. 8.—TURBINES AT ZUFIKON-BREMGARTEN, SWITZERLAND.

of concrete, which acts as a suction tube. This turbine plant was also erected by Messrs. Escher, Wyss & Co., and the dynamos were built by the Oerlikon works.

The examples given above of the utilization of water power may be considered as representative types of successful installations, under different conditions. They are sufficient in number and variety to prove the necessity of a selection from mo-

tors which are different in principle, and of the careful adaptation of the turbine selected to the local conditions and requirements.

A turbine installation under a low fall will be more costly than one under a higher fall; it is, consequently, of special importance to obtain the highest possible efficiency, even at an extra expense, under a low fall. The cost of the turbine itself is only a fraction of the total outlay for the plant, including foundations, connection with the machinery to be driven, and sometimes a weir and a canal. The cost of these permanent structures exceeds that of the motor; it is, therefore a penny wise and pound foolish policy, after putting in the permanent structure, to try and cut expenses by putting in a turbine of insufficient capacity or inferior efficiency. The commercial value of a water power depends rather more on the annual outlay on the same than on the first cost, and the annual outlay for the work obtained from the power is the smaller the higher the efficiency of the plant.

The efficiency of a turbine which can be obtained and honestly guaranteed, even if the fall is low, is about 75 per cent. Eighty per cent. and a little over is sometimes obtained under favorable conditions, and has been proved by careful tests made by responsible experts; but an efficiency of 85 and 90 per cent., sometimes claimed, is never reached, if the quantity of water be accurately measured during the test. If the efficiency of the turbine is guaranteed at all, it should be stated not only for the most favorable conditions, but also for a reasonable minimum of the fall or the quantity of water.

In many instances within my own knowledge, water power, in itself sufficient to drive the machinery of a factory, but improperly utilized, is supplemented by artificial power, produced by steam, gas, or oil engines. The loss of money caused by the waste of the cheap power from a running stream in this manner amounts certainly to a big sum in this country alone. The annual cost of such auxiliary power, calculated for 3,000 working hours, may be put at three to four times the cost of water power, and calculated for 6,000 working hours, four to eight times the cost of water power. A judicious utilization of the water power in such cases would not only result in an enormous saving of money, but in a gain of a large amount of power now unutilized. Most factories are closed at night time, when the water is allowed to run away without being made use of. Assuming that the water power is insufficient to drive all the machinery in the daytime, while it is wasted during the night, electrical storage batteries in connection with a generator might very advantageously, and perhaps with greater economy, be used instead of auxiliary steam, gas, or oil engines.

It seems probable that in the near future the electrical transmission of power will take the place of shafting and belt drives in factories, when certainly the waste of water power would be prevented in the manner suggested. Owners of factories driven by water power might even find that by improving their water power they obtain spare power which could be profitably applied by the generation and distribution of electrical energy in the immediate neighborhood. I may add that the majority of large-power central stations now being erected in Switzerland for the generation and distribution of electrical energy are mostly utilizing small or medium falls varying between 10 to 30 feet. The storage of water in the shape of snow and ice on our mountains provides us with a good water supply during the summer, but the low temperature in winter reduces that water supply very considerably. The water power there is just as variable as in other countries, and those falls which can be advantageously utilized on account of being situated in the inhabited and industrial districts are often not any higher, or not much higher, than in this country; the only difference being that such small falls occur more frequently, rendering a concentration of large power in one place easier, and perhaps less costly. Still, it is my conviction that concentration of water power for the distribution of electrical energy, or for the generation of a large amount of electric current, as required for electro-chemical and electro-metallurgical processes, is possible in many places in this country without going into prohibitive expenditure for canals, etc.

In conclusion, I hope to have succeeded in my endeavor to show how water power under low falls can be, and is, very advantageously and economically utilized for the generation of electrical energy; and that a very large amount of water power is now running to waste which could, in conjunction with electrical machinery and apparatus, be turned to profitable account by such a hearty co-operation of the electrical and the water-power engineer as has resulted in such success of commercial enterprise in my native country.

THE RAILROAD COMMISSIONERS of New York report that while in 1893 but 25 per cent. of the street railways in the State were electrically equipped, in 1895 about 94 per cent. were so equipped.

ROENTGEN RAYS.

ON THE BLEYER PHOTO-FLUOROSCOPE.[1]

BY J. MOUNT BLEYER, M. D., F. R. A. M. & of N.

SUFFICIENT of the practical value of the application of the Röntgen rays to medicine and surgery is already known for us to pronounce them, and the wonderful screen that reflects them, as among the greatest triumphs won in the modern history of discovery.

I am happy to say that after much experimenting in this field, I have been enabled to produce the photo-fluoroscope.[2] This invention enables the eye and the photographic sensitive plate to record simultaneously images as we are desirous of putting them on record.

The photography of luminous objects has been for some years an important factor in astronomical studies, as, for example, in the mapping of stars, and the recording of solar and stellar spectra and the phenomena of eclipse, but of late it has been made to embrace a broader range of subjects. Several of the most reputable photographers and scientists have of late given this special branch much thought and study; and among them I cannot pass by without mentioning a most beautiful set of pictures made by Wallace A. Levison and by Nikola Tesla, whose illustrations of luminous objects have given me much pleasure and fruitful recompense. I owe to the study of them the invention of the instantaneous fluoroscopic photography of luminous objects taken directly from the fluorescent screen.

The invention bears my name (Bleyer's photo-fluoroscope), and is very simple.

It is practically an adaptation of the fluoroscope to the needs

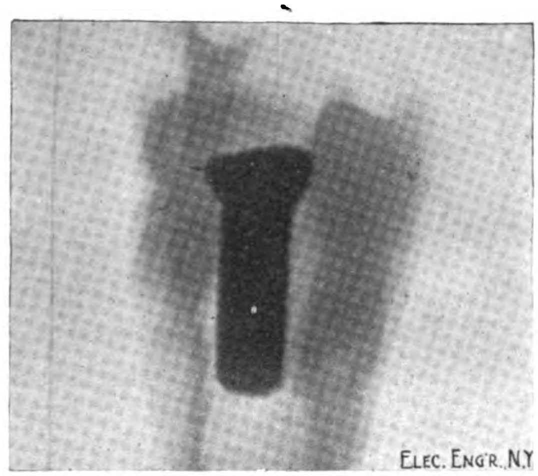

FIG. 1.—A PHOTO-FLUOROSCOPE PICTURE.

of the physician and surgeon, and consists in the combining of direct and instantaneous photography of the shadow thrown on the fluorescent screen. In other words, it is simply a combination of an ordinary copying photographing camera, and a fluoroscopic screen of special make carefully fitted into the camera. Several other types of camera can be adapted also for this purpose. The screen receives the object fully outlined in its detail, while the camera is so arranged as to take time exposure of the object made visible on the screen.

By this means the object can also be seen and studied and the trouble located before the photograph is taken. Then the proper focus is taken by means of the camera arrangements, and a direct photograph is obtained. The sensitive plate is then removed to the dark room and is there prepared like any other photograph.

The photo-fluoroscope has the advantage over other methods of revealing the object on the screen, either to be seen directly by the eye or to be reproduced on a sensitive plate. This renders it of peculiar advantage to physicians and surgeons for positive diagnosis. The photograph is necessary only for recording purposes, as the object can be seen plainly by the naked eye, the phosphorescence making it possible to see the

---

[1]Original Communication to the Royal Academy of Medicine and Surgery of Naples, Italy, for 1896.

[2]I am indebted to Mr. A. A. Hamerschlag and to Mr. F. J. Harrison (editor of Anthony's "Photographic Bulletin") for most valuable suggestions during the progress of this investigation. The electrical apparatus employed by me is manufactured by A. A. Hamerschlag & Co., 26 Liberty street, New York.

object plainly in darkness. Necessarily, this is more advantageous to physicians than the general method of shadowgraphing by the ordinary plateholder, with the object placed thereon, without the assistance of the camera.

As far as we know at present in regard to the Röntgen rays, the laws applicable to light are entirely disobeyed, and consequently no lens or camera can be taken into consideration. This light does not admit of being, so to say, refracted or reflected in the same manner as ordinary light, so that there is no possibility of direct use of the camera with the Röntgen rays. But the onward march has added the fluorescent screen, by means of which the eye can follow the rays through hitherto impenetrable substances, and with its assistance I have succeeded in establishing the method illustrated, which for the use of physicians and surgeons is simpler and gives infinitely more satisfying results than any other method of which I know at present. The difficulty in accomplishing this can be appreciated only by those who have followed up the subject, and worked in the laboratory side by side with companions in the race for priority and with full knowledge of the thousands of difficulties that beset the endeavors of the experimenter.

One of the most important advantages that the photo-fluoroscope presents over the Röntgen method of photographing, is that curves, corners, and angles are no obstacle to it, while an object in the Röntgen photography must always be in direct contact on a flat plate containing the sensitized plate, the reason being that the Röntgen rays must be applied directly on the surface of the object, while with the photo-fluoroscope it may be taken at a short distance. This is due to the fact that the laws of light applicable to photography have been applied by photographing the luminous shadow from the screen and by the use of lenses.

To the left of the illustration, Fig. 2, is seen the camera fully equipped and its accessories mounted on a table, and its fluoroscope attached, showing on its screen a hand ready to be photographed by this process directly from its luminosity. The screen is arranged so that any size object can be taken in. The fluoroscopic box is very light, made of cardboard and fitted close on to the camera, encircling the lens with zinc, thus preventing stray Röntgen rays from reaching the sensitive plate through the wood portion of the camera. On the right side is a Crookes tube attached to a Ruhmkorff coil which is operated either by a spring break vibrator, or preferably by a wheel. The entire picture shows the full operation of photo-fluorographing. The latest model has many other detail attachments and advantages over this one.

Practical Points in Photographing by Means of the Photo-fluoroscope.—Above all things in photo-fluorography, a dark room is required for good results. Here the object to be photographed should first be located with the fluoroscope, in order to fix its exact position. This done, the screen on the photo-fluoroscope must light up the object until every detail shows clearly. Now shut off the X-rays before introducing the sensitive plate into the camera, to avoid any possibility of fogging the plate.

After these preliminary steps have been attended to the X-rays are turned on, and an exposure ranging from one to two minutes is allowed, depending upon the density of the object. Good strong X-rays are required, and it will be found that a coil giving a spark of from six to eight inches will answer all purposes for good ordinary work. In fact, all accessories should be in first-class working order; much experience is also necessary, and the best teacher, for obtaining good results by this method or by the Röntgen. A focus tube is the best.

The plates should not be removed until the X-rays have been shut off. Upon these few and simple injunctions depends the success of the photo-fluoroscope.

I succeeded as early as April 7 in locating a tube in the larynx, and another that had slipped down into the trachea, and recorded them, as shown in the accompanying picture, Fig. 1, in the early trials and undeveloped stages of my photo-fluoroscope, and before the Crookes tubes were brought up to standard make. I, nevertheless present them herein, knowing that they will create curiosity, and induce others to follow my footsteps in the use of the X-rays in laryngology.

In my lecture, April 15, 1896, before the Medico-Legal Society, I referred to this fact, notes of which were also published at the time. I refer to these dates now in confirmation of the priority of the objects located and photographed by me over those recently obtained by Dr. Levy, of Berlin, and others in England, and mistakenly accorded the priority in several of our dailies only.

At present much of my time and work with the photo-fluoroscope is being spent in shadowing out tumors, growths, foreign bodies, and various diseased conditions of the larynx and bones of the face and their accessory cavities, and the lungs with their many complicated ailments. In these experiments I have so far been very successful in obtaining first-class definitions of the varying shadows, illustrating many interesting clinical conditions of these organs. Many fine specimens which I made are in my possession, to which the above can testify.

The results of my further experiments will be taken up, with their technical points, in a later communication.

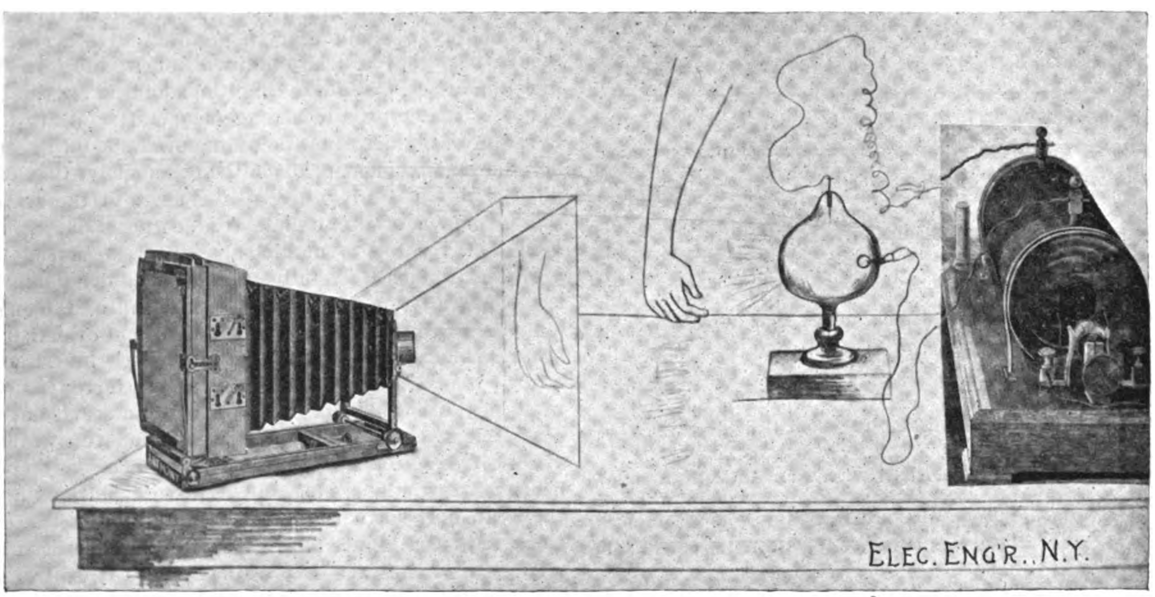

FIG. 2.—ARRANGEMENT OF THE BLEYER PHOTO-FLUOROSCOPE.

AN ELECTRIC RACE TIMER.

An electric chronograph, on which Professors Crehore and Austin have been working for some time, was put into operation recently in the races of the Interscholastic Association, of Boston.

The clock records the time from the report of the starting revolver to the breaking of the tape. Falling weights set in motion a heavy frictionless, rotating wheel. The record of time is made by a pencil on a roll of paper wound about the shaft cylinder. The explosion of the pistol releases the weights and sets the wheel in motion, and at the same time presses the lead on the paper. When the winner breaks the tape the circuit is made and broken, and the pencil point makes a notch in the record. The instrument is calibrated by an astronomical clock, the recorded revolutions all read by tables and the time deduced in seconds and fractions with the greatest possible accuracy.

VOL. XXII. NEW YORK, JULY 1, 1896. No. 426.

CONTENTS.

MUNICIPAL OWNERSHIP OF ELECTRIC PLANTS.

During the recent meeting of the Street Lighting Convention in New Haven, there was considerable discussion on the subject of the municipal ownership of electric lighting and other plants which are operated under municipal franchises, and both the friends and opponents of government control were heard. The question has for some time been a burning one in this country, and almost every time a community becomes dissatisfied with its lighting service, municipal control is suggested by its adherents, as the only remedy for securing a perfectly satisfactory service at a minimum price. In opposition to this view Mr. Allen R. Foote discussed the subject in a very able paper read at the convention, in which he analyzes the situation as it presents itself in relation to electric lighting. It is difficult to find any convincing arguments or data favoring the municipal ownership of electric lighting or any other industrial enterprises, and if we look to the experiences of a number of cities where municipal lighting has been attempted the conviction that business undertakings are properly matters of private enterprise will be considerably strengthened.

Starting from the standpoint that the best interests of any municipality demand that its lighting or other service shall be the best that can be obtained and at the lowest cost, the question arises, Can these conditions be best obtained under policital or under private management? It appears too obvious to require argument that no public need should be supplied under the management of a political monopoly, that can be supplied with equal advantage to the users of the service, under the management of an industrial corporation. Much of the opinion favorable to municipal control is caused by a very prevalent but entirely unjustifiable prejudice against corporations generally, and this prejudice has caused the enactment of many laws governing the management and direction of corporations, which, to some extent, render such investments uncertain or unprofitable, except at a largely increased cost to the users of the service. In order to supply a service at the lowest cost it is necessary that the corporation furnishing the service be free as far as possible from unnecessary obstructions, charges, restrictions, etc., and if these conditions are imposed they can only have the effect of maintaining the cost to the consumers at a higher figure than it otherwise need be.

In spite of the fact that we have a great deal of restrictive legislation against corporations, which thus increases the cost of their services, the fact remains that in most cases where private and municipal services have come into competition the private corporations are generally more successful, both as to the cheapness of the service and the profits to the stockholders. When a municipality invests in a plant for carrying on any business it must secure the necessary funds by selling bonds. In the case of an electric plant for the distribution of light, heat and power for both public and private uses, if the charges for service are made high enough to produce a profit, this profit increases the cost to the consumers of the service for the benefit of those tax payers who are not consumers, and who may even be non-residents. On the other hand, if no profits are produced, then the non-users pay a certain amount of extra taxes for the benefit of those who use the service. It is also a generally acknowledged fact that money obtained by taxation is never expended by municipal politicians as economically as are the funds invested in private enterprises by the parties who have been obliged to earn their capital and who feel the necessity of disbursing it cautiously. Aside from the theory that commercial enterprises of this nature belong properly to the sphere of the private manufacturer or the merchant, experience has shown in a large number of cases that cities that have taken the action of purchasing electric light plants have, instead of gaining any advantage either as to the improvement of their lighting or the cost of the same, taken a step backward, and after a few years of presumably fair trial under municipal management a number of cities have found it to be their

best policy to sell out their municipal plants and allow the business to revert to private management. Among the cities that have passed through this experience are Greenville, S. C., Carrolton, Ga., Stockton, Kan., Lyons, Ia., Marceline, Mo., Marietta, O., Michigan City, Ind., Portland, Ore., Tipton, Ia.; Titusville, Pa., and Moline, Ill. The city of Chicago furnishes an example of the cost of electric lighting under municipal management. The cost per arc lamp per year was found after careful study to be $153.48, exclusive of taxes and insurance. A test of the value of this plant to the city lies in the fact that private companies are ready to contract to furnish the same amount of lighting at considerably less cost to the city than it can produce them for from its own plant. Another municipal plant which has been prominently mentioned as an example of the benefits of municipal ownership is that of the city of Detroit, Mich. In this case the plant was estimated to cost $600,000, and the cost per lamp per year was figured at $84. In addition to the issue of $600,000 of city bonds, $50,000 additional was required to be raised by direct taxation to complete the plant, and the annual cost per lamp already reaches $100 with a new plant in perfect order. Only 5 per cent. depreciation per annum is included in this cost and this we certainly know to be too small a figure. As the plant grows older the renewals will constantly increase the price per lamp, which already has been found to be higher than what private companies are charging in many places.

It is generally necessary to make considerable allowance in the figures quoted as the cost of lighting by municipal plants, as several items which should be included are frequently omitted by political financiers. One of these, just mentioned, is the depreciation, which should be fully included in estimating the cost of operation. This is just as necessary to include as the cost of coal, and if omitted at first, to make a brilliant showing of economy for the plant, must nevertheless be paid for eventually. In comparing the cost of city and private lighting the item of taxes is entirely neglected, though without reason. If the municipal plant were to be operated by a private company the cost of lighting to the city would be reduced by the amount that company would be obliged to pay over to the city in taxes.

Through improvement in machinery and by competition which naturally takes place in any commercial business the cost of lighting has been gradually reduced during the last ten years to less than half the original figure in many cases. In the city of New Haven the price per lamp was at first $237.25, while at present it is only $98.55, and this latter figure is considerably lower than can be found in the case of almost any municipal plant in the country. A number of these plants quote lower figures than this, some of them claiming the cost to be as low as $40 or $50 per year; but in every case where these phenominally low estimates are given, some important items of the real cost are invariably omitted.

Mr. Foote maintains that there is not a municipally-owned gas or electric light plant in the United States which private capital will not be willing to take over and operate under contract at the same price the service is now costing the municipality, all items of cost being correctly and fully considered and all franchise rights enjoyed by the municipality being assigned to the private corporation. This being the case, it shows that the general feeling among capitalists is, that there is always room for earning a profit by economizing the management of municipal plants. From the number of public plants which have already reverted to private ownership it seems probable that this will be the ultimate outcome of the majority of such plants after the cities have had sufficient experience in the line of municipal management.

ROENTGEN RAY WORK.

THE Röntgen X-ray still continues to be the subject of research and speculation among physicists, and, though much has been added to the general literature on the subject, it stands to the credit of Professor Röntgen that comparatively little has been added to our knowledge beyond what was contained in the discoverer's first announcement, and, again, that subsequent investigators have only confirmed the truth of his deductions. The search for the best methods and apparatus for producing the rays has resulted in several types of tubes, each one having its peculiar advantages. A recent practical development, specially worthy of notice, is the photo-fluoroscope of Dr. J. Mount Bleyer, which the inventor describes in another page. By its use the value of the fluoroscope cannot fail to be largely extended and work accomplished which was heretofore impracticable.

REVIVAL OF THE THIRD RAIL.

THE details of electric railway operation have now been pretty thoroughly worked out, and it would almost seem as if little more could be accomplished as long as the present general methods employed remain in vogue. But it would be a grave mistake, we think, to cling to the idea that no great changes will be made in the near future, and more particularly that methods found successful in street railway work are to be necessarily closely copied in the broader suburban and interurban traffic which is rapidly developing, and in which category must be included the hanging over of steam roads to electric. The most recent striking example of this newer development in methods is the equipment of the Nantasket Beach branch of the New York, New Haven & Hartford Railroad, with the insulated third rail as a supply conductor.

This reversion to the very earliest form of electric railway current supply system must be considered as of more than ordinary significance from more than one point of view.

In the first place, it answers the criticism of the steam railway advocates, that an overhead system of supply for heavy traffic in order to stand the wear and tear which would be put upon it would be prohibitive in cost and otherwise introduce difficulties of such a nature as to make it troublesome to operate, if not entirely prohibitive on a large scale. No such objection, of course, can be urged against the third rail as such, and it remains now only to be seen whether the system will stand up in actual use.

The only question, apparently, which remains to be solved is that of insulation. On this point we are satisfied that if a pressure no greater than 500 volts be used the system will be found workable and that the loss by leakage even in wet weather will not reach a prohibitive point. We are encouraged in this belief by the results obtained with high potentials on long-distance transmission lines in this country and abroad. If it be urged that a wire not suspended in the air is not comparable to rails laid on insulators close to the ground, it may be said that the potential in electric railways fed from one source will be proportionately less, and hence the leakage coefficient reduced in like ratio.

Apropos of the introduction of the third rail it would seem that the hold which the trolley has maintained on street traffic is by no means as strong as it was some time ago. Whether this be due to the fact that patent litigation on the under-running trolley has caused uneasiness among railroad companies, or whether the overhead system has been found to possess peculiar troubles of its own, the fact remains that conduit railway systems, and latterly more particularly surface contact systems, have found much more favor in the eyes of railroad companies than for a long time past. This is probably also largely traceable to the vast improvements in these systems and their demonstrated fitness to accomplish what their inventors have claimed for them. We may, therefore, look for their early extended application. The more one contemplates the situation the stronger grows the conviction that the time will be very short, indeed, when the overhead trolley will disappear in all of our large cities, and with it will begin a new era in the prosperity and stability of the electric railway, both as a system of transportation and as an investment.

Electric Transportation.

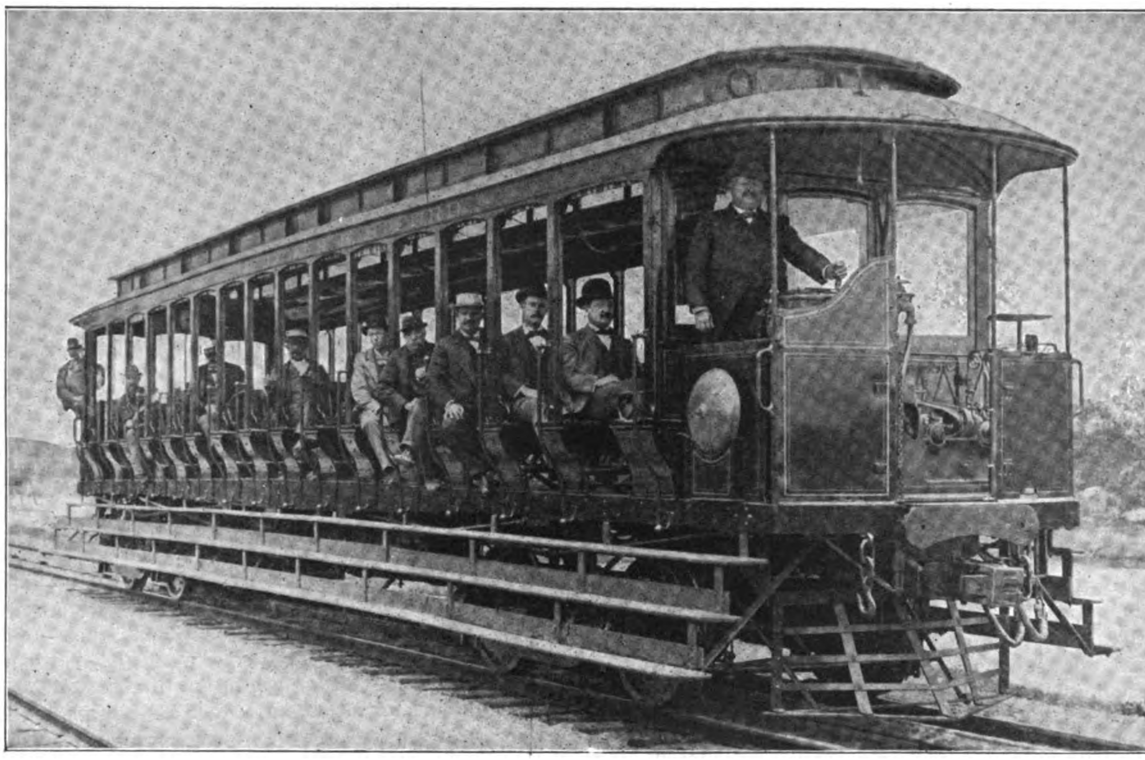
THIRD RAIL ON THE NANTASKET BEACH ROAD.

THE second step toward the operation of its main lines by electricity was made June 26 by the New York, New Haven & Hartford Railroad Company in the extension of the electrical equipment of the Nantasket Beach line as far as East Weymouth, 3½ miles along the main line of the South Shore Branch of the Plymouth Division, of which Mr. J. C. Sanborn is Superintendent.

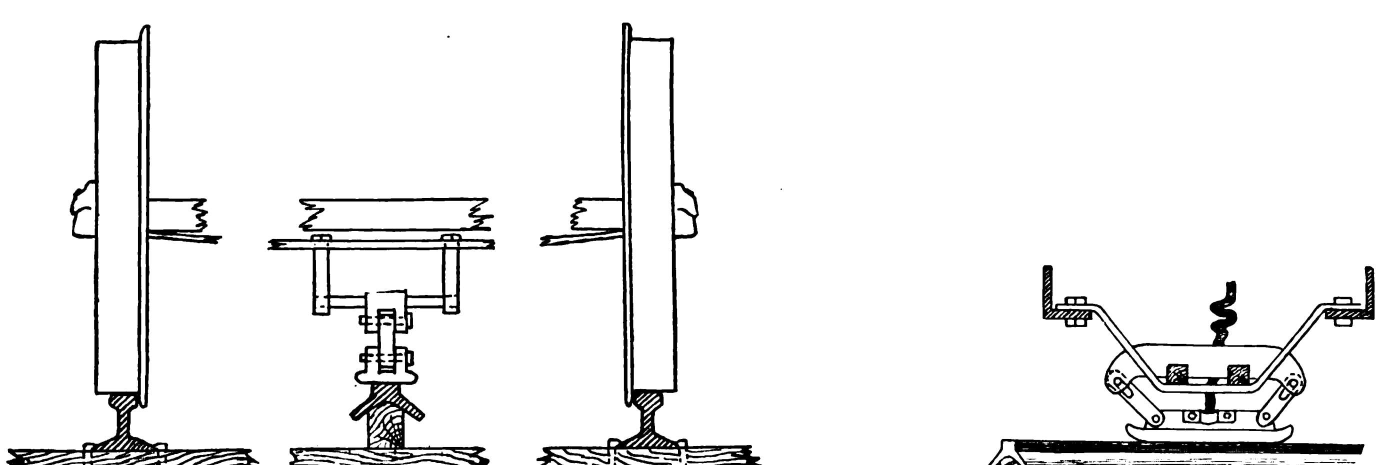
In determining upon this extension the overhead trolley system in use on the Nantasket Beach Branch was abandoned and the third rail method of contact chosen as the most readily adaptable to ordinary railroad requirements. While the third rail system for electric roads is not new, it being in use on the West Side and Lake Street Elevated Railways in Chicago, the rail being set outside the track, this is the first instance of a third rail being laid upon the permanent way of a trunk steam road, between the rails of the service track.

The current for the third rail section is brought from Power House No. 1, on the Nantasket Line, over two insulated feeders of copper cable laid along the tops of the poles which carry the overhead wires of the Nantasket Line. At the Nantasket Junction station the feeders are dropped to the ground, and each is connected to its own third rail.

The third rail is of peculiar shape—the end view resembling a flattened A, Fig. 1. It is laid midway between the two service rails of each track. Each section of third rail is 30 feet long, and weighs 93 pounds to the yard. It is supported by three ash blocks to each section, the blocks being let into the ties. Before use these blocks are boiled in vacuum pans with a tar compound, and thus each pore is filled with insulating and preservative material. The insulation is almost perfect. The continuity of the third rail circuit is secured by attaching each end of one rail to that of the next by means of two heavy copper bonds. The line between Nantasket Junction and East Weymouth is absolutely distinct electrically from that between the first-named stations and Pemberton. It is fed by its own feeders and is provided with its own automatic safety appliance which, in case of carelessness or accident to the third-rail section, enter into action and cut all current off from it, rendering it nothing more than a peculiarly laid stretch of track.



Electric Car on Nantasket Beach Railroad, with Third Rail Conductor.



Figs. 1 and 2.—View of Third Rail Conductor and Contact Shoe, Nantasket Beach R.R.

The electricity is taken from the third rail by two sliding shoes, Fig. 2, hung loosely from the car, one suspended between the axles of each truck immediately under the king pin by two links which allow it to slide easily over the top of the third rail and make perfect contact with it all the time. The current is brought to the motors through the controllers ond circuit breakers, and returns to the track rails by the wheels. The continuity of the return circuit is secured by using a short, thick bond of copper cable to join together the ends of each pair of track rails, the ends of the bond being fastened into the flange of the rail. The distance between each of the two shoes on the car is 33 feet. No third rail is laid at the crossings, the circuit continuing between the broken end by means of lead-covered cables. At the crossings, less than 30 feet wide, one of the shoes is always in contact; at wider ones the inertia of the moving car brings the shoes into contact again before the car can come to rest.

The baggage cars in use last year, each equipped with four motors, have been abandoned, and the large sixteen-bench open cars are alone employed as motor cars or locomotives. Sixteen of these cars will be put into service, each equipped with two General Electric "2,000" motors, two series parallel controllers, two automatic circuit breakers—the safeguards from accident to the rest of the electrical apparatus—and an air-pump and motor for the compressed air for the whistle and brakes. The air-pump combination is automatic in its action. As soon as the pressure in the main air-tank falls below ninety pounds to the square inch a small knife switch is closed by a spring and the motor starts. The switch is forced open by the air pressure as soon as that in the tank reaches the normal.

The cars leave Pemberton and run with the trolleys as far as Nantasket Junction. The trolley is then pulled down and hooked and the shoe strikes the third rail, the passengers being unaware of the change in the method of contact. The regular schedule of the electric trains between Pemberton and East Weymouth has been in force since June 14, but owing to the non-completion of the third-rail section the trains have been hauled from Nantasket Junction to East Weymouth, 3½ miles, by two steam locomotives.

A good idea of the advantage of electricity as a motive power compared with steam may be gathered from the fact that the two locomotives burn each four tons of coal per day, while not more than four tons per day burned in the power house serves to generate sufficient power to operate the whole seven miles of line between Pemberton and Nantasket Junction by electricity. The construction of the new section has been carried out under the personal supervision of Col. H. H. Heft.

During a recent test with the officials of the railroad on board, a speed of from 70 to 80 miles an hour was attained. On arrival at East Weymouth, the car was switched over and the return trip was made from East Weymouth to Pemberton in about eleven minutes, the distance being about 10½ miles. Should the operation of this road prove successful it is probable that the third-rail system will be extended as far as Braintree, a station 10 miles out of Boston, and if the success of the new method under the ordinary conditions of constant travel, fulfills all expectations, suburban service throughout the country will probably undergo a change.

HENRY'S RESISTANCE DETECTOR FOR RAIL JOINTS.

THE object of this instrument, invented by Mr. John C. Henry, of Denver, Col., is to make an examination as to the conductivity of the joints connecting the track rails. Heretofore the only method of testing the bonds when any trouble occurred was to open the pavement and replace all the bonds, both good and bad.

By the Henry method an electrician, with the assistance of a couple of boys, is enabled to examine the condition of the

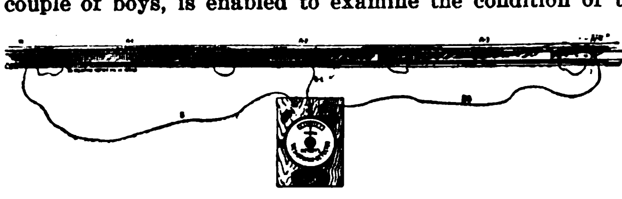


FIG. 1.—HENRY'S RESISTANCE DETECTOR.

joints on several miles of road in a day, and can mark the defective ones for repairs. The theory on which the method works is as follows: The instrument, Fig. 2,, which is called a "resistance detector," is a specially designed differential ammeter, which is so arranged that opposing magnet coils influence the needle. Those coils are connected to the portable flexible conductors, B and B2, Fig. 1. The other terminals are laid to the track rail in a central position, through the flexible conductor B-1. The tests are made when the cars are running. A portion of the current from the track rails is shunted through the instrument. If the conductivity of the rails is alike on both sides of the instrument the needle will

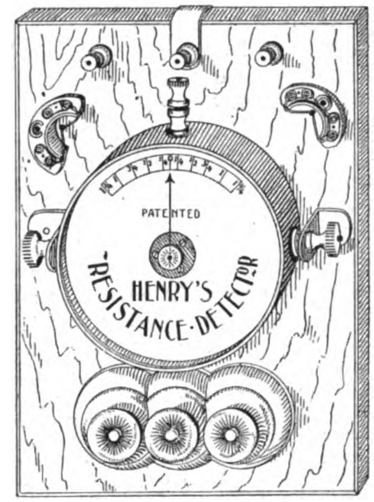

FIG. 2.—HENRY'S RESISTANCE DETECTOR.

stand at zero. Should there be a defect or a poor connection at the joint, A-4, for instance, more current will flow around that joint through the right hand coil of the instrument, and the lead, B-2. In consequence, the instrument becomes unbalanced and the pointer shows the direction of the cause. By closing in with the conductors, B and B-1, the bad joint can be located and marked for repairs.

THE AMERICAN STREET RAILWAY CONVENTION AT ST. LOUIS.

INDICATIONS are not wanting leading to the belief that the next convention of the American Street Railway Association to be held at St. Louis, Oct. 20, will be one of the best thus far held. The National Republican Convention Auditorium has been secured for the purpose, and our engraving

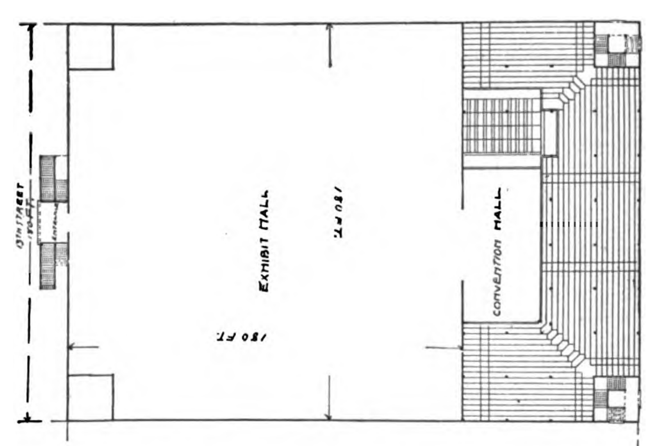

EXHIBIT HALL, STREET RAILWAY CONVENTION, ST. LOUIS.

shows the arrangement adopted. The exhibits will occupy a space 180 x 180 feet, thus giving ample room for the most elaborate displays of apparatus. The convention hall will be situated at the rear end of the building and will be completely separated from the exhibits. The entrance will be on Thirteenth street, so that delegates will pass through the exhibits before entering the convention hall.

"BREAD AND MEAT."

That standard sheet, known and read of all electrical men, The Electrical Engineer, is bread and meat to every station manager. Were he to lose it, his lights would go out.—"Kansas City Architect."

ELECTRIC LIGHTING.

CHARGING FOR CURRENT.

BY JOHN F. GILCHRIST, CHICAGO EDISON CO.

I have read the article on "Charging for Electric Lighting Service," in The Electrical Engineer of June 3, carefully and with great interest, as well as the editorial upon it, and am from my experience prepared to corroborate the statements made by Mr. Farnsworth and The Electrical Engineer as to the importance of some systematic basis of charge for electric current to customers of different classes, according to the quantity of light consumed and average consumption through a twenty-four-hour day.

My first impression in reading the article is that the writer does not lay much stress upon things which our experience has led us to believe are extremely important conditions, viz., the questions of business policy both as regarding quantity of light consumed and in competing with opposition companies. The conditions of the plant in which I have had my experience are also probably very different from conditions in the plants where there is in all probability the greatest amount of irregularity and poor judgment which Mr. Farnsworth intends particularly to reach. I realize it is rather narrow to criticise the honest suggestions of another without being able to offer suggestions borne out by good reasons as to a plan to be substituted. However, I will give a little outline of our method of dealing with these questions which may afford your readers some information on the subject under discussion.

In the first place, the system suggested would, it seems to me, be somewhat unsatisfactory in starting dealings with a customer, as the information necessary to classify the customer must be obtained from actual tests of the way the customer burns his light, and his average consumption as compared with the maximum capacity connected. This would, of course, require some little time, and it would be rather annoying to a business man and also prejudicial to the interests of the company not to be able to make some definite statements as to the exact charges before going into the matter. In addition to this, it is possible that many a customer would vary so in his consumption from month to month that he would be constantly changing from one class to another, and dispute would arise as to the class, which would necessitate intricate explanations as to methods which would be beyond the comprehension of many of the consumers, particularly in the large cities, and would, I believe, lead to dissatisfaction and suspicion.

The principal criticism I have to offer would be, that the cost of supervision necessary to keep the system properly enforced when established, without which it would be useless—would hardly be justified by the results obtained.

In our experience the cost of items included in class A, when figured out upon the basis of kilowatt capacity connected, is extremely small, so inconsiderable, in fact, that in the majority of cases a small minimum bill, such as the smallest consumer would not object to, would entirely cover it. Class B is not so easily disposed of, but as the great majority of consumers use current in much the same way, and during practically the same hours of the day, it seems to us the most practical to adopt a list basis of charge which would be fair for this class of customers, which may in this connection be the poorest class, and therefore entitled to the least consideration in the way of low price; and to take up separately the cases of consumers whose large consumption or consumption through a large portion of the day would entitle them to more consideration, and make discounts from the regular rate to these, which, in accordance with the business obtained viewed from every standpoint, would seem just. In this, as I have already stated, many times, in fact, in the majority of cases, questions of business policy with regard to certain customers would necessarily influence the company, and really in the long run represent as much to it as does the slight difference in the price of its product between the regular rate for that particular class of service and what it could get the business and hold it satisfactorily to the consumer for.

This method, while it seems beyond the reach of any system, is certainly not guesswork, as the conditions of each separate customer who is outside of the regular rule are taken into consideration, and the discount is made with due reference to the quantity of business actually assured either by minimum bill or agreement as to the use of electricity to the exclusion of other methods of illumination; to the relation of average to average maximum load and possibly extreme maximum load; to the hours of the day during which greater portion of current will be consumed; to duration of agreement, as tendency in all growing stations is to reduce cost of production, and to the effect which the use of current for illumination by a customer will have upon other prospective customers.

This arrangement covers all kinds of business, except, perhaps, cases which on any station will be few in number, viz., those that are glaringly unprofitable, such as emergency connections to the isolated plants, palatial residences or audience rooms which for purposes of large entertainments are equipped with enough lamp capacity to use several hundred times the normal amount of electricity, current being used in large quantities, however, only three or four times per year; and electric elevators of large capacity in apartment buildings where 80 per cent. of the work is done during two hours, morning and evening. These should be taken care of by a guarantee of a certain minimum income to the company, representing a fair interest on the company's investment necessarily maintained to furnish the customer with sufficient current to supply him at the maximum of his capacity or stipulation as to hours when use of current will be permitted, notification to be given the lighting company, or turning on of current to be controlled by them in some effective way.

Further than looking after all of its business in the above way, which, by the way, is a comparatively simple matter, to be certain that none of it is unprofitable, our company does not attempt to follow any absolute system, and as I state above, on account of the ever-increasing economy we rest secure in the assurance that any arrangement which is profitable at the time of making will be at least as profitable at any future time.

The question of difference of cost per kilowatt hour of output at different hours of the day, touched on in the article in The Electrical Engineer is attracting at the present time a great deal of attention, especially in direct-current stations, and many are experimenting with accumulators or watching with great interest the plants in which they are in practical operation, believing that they offer possibilities of greatly increased economy, by affording sufficient load to machinery throughout the entire day to admit of equally favorable operation at all times.

RULES OF THE PITTSBURG BOARD OF ELECTRICITY.

THE Bureau of Electricity of the Department of Public Safety, Pittsburg, Pa., has issued a circular letter to electrical contractors relating to an ordinance recently passed in that city. The ordinance provides for the appointment of electrical inspectors to overlook the construction and appliances used for electrical purposes.

Among the rules it is provided that hard drawn copper wire will not be approved and not more than six lights can be placed on any branch circuit, except by special permission. None but white porcelain insulators and bushings will be approved and all concealed work must be left open until examined by the inspectors.

MR. FALK'S X-RAY PICTURES.

We publish below an item appearing in the New Orleans "Times-Democrat," at the request of Mr. H. L. Falk, who asks it as a personal favor to him:

"New Orleans, June 15, 1896.

"To the Editor of the 'Times-Democrat:'

"This is to certify that we, the undersigned, have investigated and tested thoroughly Mr. Hilbert L. Falk's claim of being able to photograph the soft and hard tissues of the human body. With his special plates and screens, we have put him to the severest of tests, and we, the undersigned, do now hereby declare Mr. Falk's claim to be genuine in every respect. Hoping you will publish this, we are, very respectfully, (Signed) L. C. Ferell, Dr. J. M. Ferguson, J. A. Rehage, A. V. Fazende, T. P. Flaherty, Dr. F. Loeber."

We have no personal acquaintance with any of the above gentlemen, nor are they known to us by reputation.

PERSONAL.

PROFESSOR CHARLES W. CARMAN, of the Lewis Institute, Chicago, left on June 27 for Europe, on a tour of inspection preparatory to the equipping of the physical and electrical laboratories at the Lewis Institute. Professor Carman intends to visit the principal laboratories of England and the Continent.

MR. ALEX DOW, formerly city electrician of Detroit, has declined a reappointment to that office and accepted the position of manager of the Edison Illuminating Company, of Detroit.

NEWS AND NOTES.

THE KELVIN JUBILEE CELEBRATION.

As announced briefly in our last issue Lord Kelvin's jubilee was celebrated with much enthusiasm. The first public function took place on Monday, June 15, consisting of a conversazione in Bute Hall, at the Glasgow University. Over 2,000 persons gathered there in the evening and were received by Lord and Lady Kelvin. In the library there was an exhibition of Lord Kelvin's instruments, and here the Anglo-American Telegraph Company, the Commercial Cable Company, and the Eastern Telegraph Company received messages of congratulation to Lord Kelvin from all over the world, and sent the replies. A number of messages were also sent around the world. It was here that Lord Kelvin spent the greater part of the evening with much delight.

On Tuesday morning the presentation of addresses from the universities and scientific bodies took place. Among the large number of delegates who presented addresses were the following:

M. Lippmann, University of France; M. Henri Moissan, University of France; M. Picard, University of France; M. Mascart, Collège de France, who presented the Arago Medal of the Académie des Sciences to Lord Kelvin; M. Violle, Ecole Normale Supérieure; Professor Heinrich du Bois,University of Berlin; Professor Quincke, University of Heidelberg; Professor Woldemar Voigt, Royal Society of Science, Göttingen; Mr. T. C. Martin, American Institute of Electrical Engineers and National Electric Light Association, U. S. A.; Sir George G. Stokes and Professor J. J. Thomson, Cambridge; Professor Carey Foster and Sir Henry E. Roscoe, London; Professor Oliver J. Lodge, Victoria University; Professor Burdon Sanderson, Oxford; Professor Andrew Gray and Principal J. Viriamu Jones, University of Wales; Professor Stroud, Yorkshire College; Professor W. G. Adams, King's College; Professor Ramsay, University College; Professor Osborne Reynolds, Owens' College; Sir Frederick Abel, Society of Arts; Mr. A. A. Common, Royal Astronomical Society; Professor A. W. Rücker, British Association; Professor John M. Thomson, Chemical Society; Sir Benjamin Baker, Institution of Civil Engineers; Dr. John Hopkinson, Institution of Electrical Engineers; Major P. A. MacMahon, Mathematical Society; Captain W. de W. Abney, Physical Society; Sir Joseph Lister, Royal Society; Professor Schuster, Manchester Literary and Philosophical Society; Professor Silvanus Thompson, Finsbury Technical College, and Mr. H. A. C. Saunders, Eastern Brazilian Submarine, and Allied Cable Companies.

After the presentation of addresses the degree of Doctor of Laws was conferred on Lord Kelvin, who then conferred honorary degrees on a number of foreign scientists, among them Professor Cleveland Abbe, of Washington, and Professor Simon Newcomb, of Johns Hopkins University; Professor Lippmann, Professor Moissan, Professor Mascart, and Professor Quincke.

This ceremony was concluded by an address by Lord Kelvin, in which he thanked the university and the assembled guests for the honors showered upon him, concluding as follows:

"My fifty happy years of life and work as Professor of Natural Philosophy here, among my students and my colleagues of the university, and my many friends in the great city of Glasgow, call for gratitude; I cannot think of them without heartfelt gratitude. But now you heap coals of fire upon my head. You reward me for having enjoyed for fifty years the privilege of spending my time on the work most congenial to me and in the happiest of surroundings. You could not do more for me if I had spent my life in hardships and dangers, fighting for my country, or struggling to do good among the masses of our population, or working for the benefit of the people in public duty voluntarily accepted. I have had the honor to receive here to-day a gracious message from His Royal Highness the Prince of Wales and addresses from sister universities in all parts of the world; from learned societies, academies, associations, and institutions for the advancement of pure and applied science; from municipal corporations and other public bodies; from submarine telegraph companies, and from their officers, my old comrades in their work; from students, professors, and scientific workers of England, Scotland and Ireland, and other countries, including my revered and loved St. Peter's College, Cambridge, and my twenty Baltimore coefficients of 1884. The term coefficients is abused by mathematicians. They use it for one of the two factors of the result. To me the professor and his class of students are coefficient fellow-workers, each contributing to whatever can possibly be done by their daily meetings together. I dislike the term lecturer applied here. I prefer the French expression—"conférence." I feel that every meeting of a professor with his students is rather a conference than a pumping in of doctrine from the professor, perhaps ill understood and not well received by his students. The Scottish universities have enabled us to carry out this French idea of conference. I think in every one of his classes the professor is accustomed to speak to his student sometimes in the form of vivâ voce examination, and oftener, I hope, in the manner of interchange of thoughts, the professor discovering whether or not the student is following his lecture, and the student pointing out his own view on the subject, and helping the professor through his treatment of the subject. I have had addresses also from my old Japanese students of Glasgow University, now professors in the University of Tokio, or occupying posts in the Civil Service and Engineering Service of Japan. I wish particularly to thank my Baltimore coefficients for their address. They have been useful to myself in my own keen endeavor—unsuccessful, I must say—nevertheless keen—to find out something about—to know something about—light and ether and crystals. The addresses which I have received to-day contain liberal and friendly appreciation of all my published mathematical and physical papers, beginning in 1840, and ending—not yet, I hope. The small proportion of that long series of writings which has led to some definite advancement of science is amply credited for its results. The larger part, for which so much cannot be said, is treated with unfailing and sympathetic kindness as a record of persevering endeavor to see below the surface of matter. It has been carried on in the faith that the time is to come when much that is now dark in physical science shall be seen bright and clear, if not by ourselves, by our successors in the work. I am much gratified by the generous manner in which these addresses have referred to the practical applications of science in my work for submarine telegraphy; my contributions to the advancement of theoretical and practical knowledge of the tides; my improvements in the oldest and next oldest scientific aids to navigation, the sounding plummet and the mariner's compass, and my electric measuring instruments for scientific laboratories, for the observation of atmospheric electricity and for electrical engineering. I now ask the distinguished men who have honored me by presenting to me these addresses to accept for themselves personally, and for the societies represented by them, my warmest thanks for the great treasure which I have thus received—good-will, kindness, friendship, sympathy, encouragement for more work—a treasure of which no words can adequately describe the value. I thank all present in this great assembly for their kindness, which touches me deeply, and I thank the city and University of Glasgow for the crowning honor of my life which they have conferred on me by holding a commemoration of the jubilee of my professorship."

The festivities terminated with a banquet in St. Andrew's Hall, in which 600 guests took part, and in response to a toast Lord Kelvin made a brief address, in the course of which, he said:

"I might, perhaps, rightly feel pride in knowing that the University and City of Glasgow have joined in conferring on me the great honor of holding this jubilee, and that so many friends and so many distinguished men, friends and comrades—day laborers in science—have come from near and far to assist in its celebration, and that congratulations and good wishes have poured in on me by letter and telegram from all parts of the world. I do feel profoundly grateful. But when I think how infinitely little is all that I have done I cannot feel pride; I only see the great kindness of my scientific comrades, and of all my friends, in crediting me for so much. One word characterizes the most strenuous of the efforts for the advancement of science that I have made perseveringly during fifty-five years: that word is failure. I know no more of electric and magnetic force or of the relation between ether, electricity, and ponderable matter, or chemical affinity, than I knew and tried to teach to my students of natural philosophy fifty years ago in my first session as professor. Something of sadness must come of failure; but in the pursuit of science, inborn necessity to make the effort brings with it much of the certaminis gaudia, and saves the naturalist from being wholly miserable, perhaps, even allows him to be fairly happy, in his daily work. And what splendid compensations for philosophical failures we have had in the admirable discoveries by observation and experiment on the properties of matter, and in the exquisitely beneficent applications of science to the use of mankind with which these fifty years have so abounded! You, my Lord Provost, have remarked that I have had the good fortune to remain for fifty years in one post. I cordially reply that for me they have been happy years. I cannot forget that that happiness of Glasgow University, both for students and professors, is largely due to the friendly and genial city of Glasgow in the midst of which it lives. To live among friends

is the primary essential of happiness; and that, my memory tells me, we inhabitants of the university have enjoyed since I first came to live in it in 1832, sixty-four years ago!"

STEVENS INSTITUTE OF TECHNOLOGY.

At the commencement exercises of the graduating class of '96 from the Stevens Institute of Technology, Hoboken, N. J., held June 18, the degree of Doctor of Engineering was conferred upon Commodore George W. Melville, Engineer-in-Chief of the United States Navy, in appreciation of the excellent engineering work performed by Commodore Melville for his country and the advancement of the science of steam engineering, well illustrated in the famous "White Squadron."

Only once before in the twenty-five years' history of the Stevens Institute has the degree of Doctor of Engineering been conferred, and then upon Professor R. H. Thurston, who formerly occupied the chair of Mechanical Engineering in Stevens Institute, and is now director of Sibley College, Cornell University.

SOCIETY AND CLUB NOTES.

CONVENTION OF RAILWAY TELEGRAPH SUPERINTENDENTS.

The fifteenth annual convention of the Association of Railway Telegraph Superintendents was held at Hygeia Hotel, Fortress Monroe, Va., from June 17 to 20 inclusive. The meeting was well attended, many of the members being accompanied by their wives and daughters, whose presence added greatly to the social features of the convention.

After the transaction of the regular business and the reading of a number of papers the selection of a place for the next annual meeting was discussed. Niagara Falls was decided upon and the date was fixed for June 17, 1897.

The following officers were elected for the ensuing year: President, George M. Dugan, Superintendent Illinois Central Railroad, Chicago; vice-president, J. W. Lattig, Lehigh Valley Railroad, South Bethlehem, Pa.; secretary and treasurer, P. W. Drew, Wisconsin Central Railroad, Milwaukee, Wis.

MISCELLANEOUS.

ELECTRICITY DIRECT FROM CARBON.[1]

BY DR. ALFRED COEHN.

THE problem of the direct production of electricity from carbon would find its simplest solution if we could succeed in dissolving carbon in a fluid, just as we do metals. This question is formulated thus by the theory of electrolysis: Can carbon form ions?

In attempting to find an answer to this question, I started from an observation made by Bartoli and Papasogli, that when dilute sulphuric acid was electrolyzed between carbon electrodes, the carbon anode takes part in the electrolytic processes in such a way that, besides oxygen, both carbonic oxide and carbonic acid make their appearance at the anode. I commenced my experiments by varying the important factors, viz., concentration, temperature, and current density, in order to discover whether it was possible to obtain the products of combustion without admixture of oxygen on the anode. I have not succeeded in obtaining carbonic acid or carbonic oxide alone, but a mixture of the two, containing only 1 per cent. of oxygen. In this mixture about 70 per cent. was carbonic acid and 30 per cent. carbonic oxide.

In these experiments it was observed that at low temperatures a disintegration of the carbon anode took place, small particles of carbon being seen suspended in the acid. At higher temperatures, on the contrary, no such disintegration of the carbon took place, but a distinct coloration of the acid was produced—at first yellow, then later dark red and red brown. If this is a solution of the carbon brought about by the current, the carbon is presumably contained in it, in the form of ions, i. e., in a form capable of being influenced by the directing power of the current. Such a solution must be capable of giving up carbon to the cathode, since carbon does not decompose water. (A series of platinum plates, coated with carbon, was shown, and a dish, such as is used by Classen for quantitative electrolytic analysis, was shown coated inside with a dense layer of carbon.) The solution and precipitation could readily be obtained with different kinds of coal as anode. Ordinary coal ground smooth, and arc lamp carbons, were found specially suitable; the experiment also succeeded with coke.

That the precipitate was really carbon, and not metal derived from impurities in the coal, was shown by treatment with acids. It was not attacked by hydrochloric acid; in hot nitric acid traces were dissolved—as in the calorimetric test for carbon in steel. In the flame, even the densest precipitates completely disappeared immediately. Finally, a direct proof was obtained by oxidizing the precipitated carbon by chromic acid, and absorbing the resulting carbonic acid in alkali. A number of analyses were made, and these always showed, in addition to carbon, a little hydrogen. The residue—reckoned as oxygen—was sufficient to convert the hydrogen found into water. Either, therefore, in addition to the carbon, a solid, conducting carbohydrate was separated, or some kind of crystalline water which adhered strongly to the carbon was produced. The presence of water in the precipitate is indicated by its behavior with concentrated sulphuric acid. If the acid is dropped on the precipitate it is immediately loosened and blackened, reminding one of the behavior of sulphuric acid with a carbohydrate.

It was now of interest to attempt to construct an element whose soluble electrode consisted of carbon. The only question now was to place a more electro-negative element opposite the carbon. The peroxides stand still nearer even than carbon to the negative end of the potential series. Lead peroxide was used in the practical form of a charged accumulator plate. If this is placed opposite a carbon in sulphuric acid of the proper concentration, temperature, etc., an element is formed of which carbon is the soluble electrode. The element supplies a strong and constant current. Through an external resistance of 100 ohms it shows an e. m. f. of 1.03 volts.

There arises here the question whether any share in the production of the current is due to the reaction on the carbon, and if so, what share? Platinum also, when placed opposite a peroxide plate under the same conditions, shows a current in the same direction as the carbon. But it never comes to a visible development of oxygen; as soon as the platinum is charged with oxygen, the current becomes exceedingly small. If the carbon was an insoluble electrode, it would behave in the same way. But this is not the case. The current lasts till the accumulator plate is discharged. A second charged peroxide plate may then be substituted, and the current is again produced as strong as before.

The results of my investigation may be summarized as follows:

1. It is possible by electrolysis to produce a solution of carbon.
2. From such a solution, carbon may be separated as a cation.
3. An element may be formed of which carbon is the soluble electrode.

EFFECT OF TEMPERATURE ON INSULATING MATERIALS.[1]

BY CHAS. F. SCOTT.

IN the discussion of this paper, I referred to certain tests made by Mr. C. E. Skinner, who has kindly furnished the following statement of some results which he has obtained in his work in this line:

Some time ago a series of tests were undertaken to determine the effect of temperature on the insulation resistance and braking down e. m. f. of various insulating materials and of completed apparatus. A large number of insulating materials, including paper, cloth, etc., both in the treated and untreated forms, were tested.

(1) Tests on Insulating Materials.—Various methods of making these tests were tried. The apparatus illustrated in Fig. 1 was finally adopted for standard tests as being best suited for practical work. This piece of apparatus consists of two similar parts, the two parts forming the plates between which the insulating material is placed when tested. These plates are ten inches in diameter and are carefully surfaced. Each part is made of two separate pieces of castiron, fastened together, as shown, and wound with a coil of asbestos covered wire. The heating of the apparatus is effected by sending an alternating current through the two coils in series. The heating results from the eddy current and hysteresis loss in the iron as well as from the copper loss in the coil. The rate of heating can be controlled easily by means of a suitable rheostat in circuit with the coils, the mass of iron in the heater being sufficient to prevent sudden changes of temperature from outside causes. The

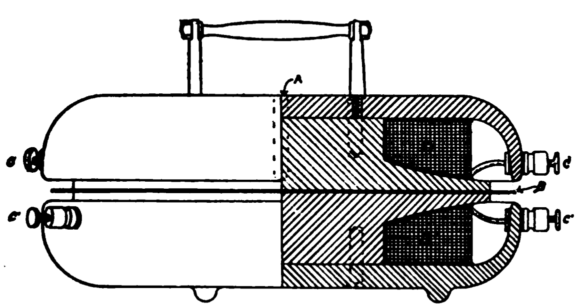
[1] Communicated after adjournment to the A. I. E. E.—Abstract.

insulation resistance of the samples was measured in all cases by means of a high resistance voltmeter on a 500-volt circuit, all wires of the heating circuit being disconnected when the insulation measurements were made.

A curve was obtained from tests on a piece of untreated paper. The minimum resistance was reached at slightly below 100 degrees C. From this point the resistance rises rapidly until it reaches a point too high to be measured with the apparatus used. The absolute value of the insulation resistance of any material of this class depends on the amount of moisture in the material at the start, the rate of heating and the chance for the escape of moisture during the test. The absolute value of the insulation resistance of treated material depends largely on the drying of the material before treatment. Samples of cloth which were treated with linseed oil after being thoroughly dried and then the oil baked on, do not at any time show a very low insulation resistance, even at a temperature of 150 degrees C.

A test of a sample of 0.15" calendered pressboard was maue as follows: The temperature was maintained constant at 120 degrees for thirty-one hours. At the end of this time the temperature was increased to 280 degrees. At the end of thirty minutes the insulation resistance had fallen from 85 megohms to less than one megohm and again risen to about 12 megohms. The lowest point reached was .032 megohm. At the end of seventy minutes the insulation resistance had become too great to be measured by the apparatus at hand. Frequent readings were taken during the thirty-one hours' run at 120 degrees C., but at no time was it possible to measure the insulation resistance.

(2) Tests on Completed Apparatus.—A curve was obtained from tests on a motor armature which was wound without previous drying of any of its insulating materials. The motor was run with an overload and measurements were made at frequent intervals. The temperature could not be taken until the end of the run, when it was found to be about 110 degrees



Apparatus for Testing Insulating Materials.

C. The drop in the curve at the points a and b is accounted for by the fact that the load was increased at these points, thus increasing the temperature of the armature. The lowest insulation resistance reached in this test was 4,500 ohms. At the end of seventy hours the insulation resistance on the armature had become so high that insulation resistance measurements could not be made.

(3) Relation Between Breaking Down E. M. F. and Insulation Resistance.—An attempt was made to establish the relation between the breaking down test of insulating materials and their insulation resistance. For this purpose samples of paper which gave a very uniform breaking down test in the normal state were heated up until the insulation resistance reached a certain predetermined amount, when the breaking down test was quickly made. It was found impossible to establish any definite relation between the two, even for a given material. It was found, however, that a low insulation resistance usually meant a low breaking down test, but a low breaking down test did not necessarily mean a low insulation resistance.

(4) Conclusions.—(a) The insulation resistance of all ordinary fibrous insulating materials, such as paper, cloth, etc., decreases upon being heated up and then increases again when the moisture is expelled.

(b) Continued heating of thirty-one hours at 120 degrees C. does not lower the insulation resistance of paper.

(c) The insulation resistance of completed apparatus shows the same characteristics as the insulation resistance of materials taken separately.

(d) A low insulation resistance is not necessarily an indication of poor insulation, but probably an indication of the condition of the apparatus in regard to moisture.

(e) A high e. m. f. should not be applied to apparatus when the insulation resistance is low.

(f) Material which is badly deteriorated mechanically by heat may still have a high insulation resistance, but very poor insulating qualities.

RIFLE BULLETS DEFLECTED BY ELECTRICITY.

A RECENT discovery seems to indicate that modern steel projectiles may be deflected from their course by means of electricity. It was noticed by the committee of the Federal Rifle Meeting at Winterthur, Switzerland, that the greatest number of hits on the target fired from the right side of the range were marked on the right of the bull's-eye, while those fired from the left of the range were almost exclusively on its left. Moreover, all projectiles partly or wholly constructed of steel had become magnetic. These facts suggested various theories, and among them it was suggested that the diversion of the bullets might be due to the numerous electric and telephone wires extending along both sides of the range at Winterthur. Fresh experiments at the ranges of Berne and Thun confirmed this conclusion.

At Thun there was used parallel with the rifle range, at a distance of a little more than forty yards, an electric current of 8,000 volts, carried along four steel cables. With a view of tracing the whole effect paper circlets were placed at every ten yards. The first experiments were made with the Swiss model rifle of 1889. With this the influence of the electric current was at once apparent. In a distance of 260 yards the bullet took a lateral deviation of twenty-four yards, and after that the curve of the trajectory was still more marked. The second experiments were made with the Japanese 3.3 mm. rifle of Colonel Yamagata, and they were still more decisive, the bullet being rapidly attracted to the electric wires and following their course. Further attempts were made with artillery. The range selected was one of 3,000 yards and 200 yards in front of the targets, but forty yards to the side, was placed the electric circuit. Every shot was diverted by its influence far to the side of the target. The deviation was one of 14 degrees.

THE COST OF WIRE.

In an address by Thomas Morris before the Staffordshire, England, iron and steel works' managers on the remarkable achievements that have been reached in the manufacture of fine wire, the interesting fact was mentioned that the lecturer had been presented by Warrington, the wire manufacturer, with specimens for which some $4.32 per lb. were obtained, or more than $8,600 per ton—drawn wire, largely used in the construction of piano and other musical and mechanical instruments. Among these specimens also was pinion wire, at a market price of $21.60 per lb., or $43,200 per ton—it took 754 hairsprings to weigh an ounce of 437½ grains. 27,000,000 of these were required to make a ton, and, taking one to be worth a cent and a half, the value of a ton of these cheap little things ran up to over $400,000. The barbed instrument used by dentists for extracting nerves from teeth was even more expensive, representing some $2,150,000 per ton.

THE HÆMOSTAT.

Demonstrations have been given lately by Mr. Lawson Tait, in London, of his electric hæmostat, an instrument which, as the name denotes, is intended for the arrest of bleeding in surgical operations. A platinum wire, arranged to carry a current, is inclosed in the blades of a pair of steel forceps, or any other requisite instrument, the wire being isolated by a bed of burnt pipeclay. A current of suitable voltage is turned on, the artery seized and compressed, and in a few seconds the tissues and arterial walls are so agglutinated that the passage of blood is rendered impossible. The temperature employed is about 180 degrees F., so that it will be seen that the principle is fundamentally different from that of electrical cauterizing instruments. It is stated that by Mr. Tait's instrument the necessity for a ligature is removed, and a new and completely effective method is placed in the hands of the surgeon for the treatment of surface oozing.

NEW OPEN CIRCUIT CELL.

A new cell is described in "L'Electricien," the main feature of which is the short distance between the plates. It is a carbon-zinc combination. The carbon is channelled down one side and filled in with a paste made of powdered carbon and manganese dioxide. The zinc plate is amalgamated in the usual way, but is only separated from the carbon by a piece of coarse felt of small thickness. The liquid is a solution of two parts by weight of sal-ammoniac to one part each of common salt and chloride of zinc. It is stated that a cell about 6½ inches high will give four amperes at 1.5 volts.

CONNECTING LIGHTHOUSES AND LIGHT SHIPS WITH THE SHORE.

THE fourth report has been submitted by the Royal Commission appointed to inquire into the question of connecting lighthouses and light ships with the telegraph system of the United Kingdom by electrical communication, for the purposes of reporting vessels in distress, casualties at sea and transmitting storm warnings. The following is an abstract of the report:

In the last report, issued in April, 1895, the hope was expressed that, after visiting Denmark and inspecting the system of electrical communication with lighthouses and life-saving stations in that country, the Commission would be in a position to prepare the way for their final report. In consequence, however, of the serious difficulties which continue to be experienced in maintaining electrical communication with certain light vessels on the system now employed, it has been decided to postpone the final report until attempts have been made by further experiments to overcome these difficulties.

Connections Which Have Been Effected.—There are at present five light vessels, six island, pile, or rock lighthouses, and forty short lighthouses around the coasts of the United Kingdom, which have been placed in electrical communication with the general telegraph system of the country at the national charge.

The Danish System.—In August last the Royal Commission visited Denmark and inspected the system of electrical communication with lighthouses and life-saving stations in that country. The system of electrical communication with lighthouses in Denmark is described at some length. Briefly, the system is practically an extension of the general telegraph system of the country. The use which is made of the wires for private and business purposes far exceeds the use to which the connections are put for the purpose of affording assistance to vessels in distress. Much of the important work which is done in the United Kingdom by the Coastguard, the Postoffice, and various other agencies is carried on in Denmark by the lighthouse authorities. At Hanstholm, Hirshals, Skagen and Hammeren lighthouses in Denmark, to which signal stations are attached, messages of any nature, made by means of the International Code of Signals, are received from passing ships, and are forwarded by wire to their destinations, and telegrams can also be sent to the lighthouses to be signaled to passing vessels.

The Royal Commission was unable to ascertain what has been the cost to the State of establishing electrical communication with lighthouses in Denmark, or what the annual expenses and receipts are, but the latter, they understand, are not sufficient to counterbalance the expenses.

Working of Cables Already Connected.—Kentish Knock light vessel.—(1) On May 18, 1895, the veering (electric) cable was found to be broken. (2) On July 12, 1895, communication was interrupted, the veering (electric) cable having been broken by the lightship riding to it. (3) On December 7, 1895, the veering (electric) cable parted, the sheathing having become damaged some time previously.

Goodwin (North Sand Head) light vessel.—(1) On January 30, 1895, the veering (electric) cable was reported to be broken. (2) The cable laid on April 10, lasted until October 24, 1895, when it broke.

Hasborough light vessel.—(1) On May 18, 1895, the first cable to the lightship parted. (2) On November 19, 1895, the veering (electric) cable broke. (3) Communication was again interrupted on December 8.

Shipwash light vessel.—The first cable to the lightship broke on August 20, 1895. No further interruption in communication occurred during the year, but as the result of a heavy gale, the outer sheathing of the veering (electric) cable was damaged, and some repairs were effected on December 2.

Formby light vessel.—Electrical communication with this lightship in Liverpool Bay was established on October 20, 1895. This vessel has been supplied with a new form of veering (electric) cable of a more flexible nature, and protected with rings of lignum vitæ, in order to save it from being chafed by the mooring chains, and by the light vessel herself. No interruption in communication had occurred up to December 31, 1895.

Gunfleet pile lighthouse.—No interruption in electrical communication had occurred since the cable was laid in October, 1893.

Tuskar lighthouse.—Telephonic communication with this lighthouse had not been interrupted since it was established on September 10, 1894, although the cable was slightly injured in October last.

Fastnet lighthouse.—In our first report we recommended the establishment of electrical communication with this lighthouse, which is situated about seven miles off the southwest corner of Ireland. The precipitous rock on which the lighthouse is built is exposed to the full force of the Atlantic seas, and is unapproachable except in calm weather. In 1885 electrical communication by a continuous cable was established with the lighthouse at the instance of the Committee of Lloyds, but it was abandoned at the end of eighteen months, after several lengthy interruptions in communication had occurred. Having regard to the difficulty of maintaining electrical communication with the Fastnet by means of a continuous cable, it was recommended that a non-continuous system should be tried, and effect was given to the recommendation on July 18, 1895.

Caldy Island lighthouse.—This lighthouse, in Carmarthen Bay, was electrically connected on July 29, 1895, and no interruption in communication occurred during the year.

Maplin pile lighthouse.—Electrical communication was effected with this lighthouse, off the north entrance to the Thames, on September 5, 1895, and no interruption had occurred up to the close of the year.

Conclusions.—It is seen that, as far as lighthouses are concerned the cables which have been laid have worked satisfactorily. The first outlying lighthouse which was connected with the mainland was the Gunfleet pile lighthouse, which was placed in electrical communication with Walton-on-the-Naze on October 2, 1893. Since that date four more outlying lighthouses (excluding that on Lundy Island) have been connected, and, although some of these stations are in very exposed positions, communication has not been interrupted with any one of them except the Fastnet.

As regards the cables to the light vessels the returns are not so satisfactory as was anticipated, but there is reason to believe that many, if not all, of the interruptions have been due to remediable causes, and endeavors are being directed to remove those causes and also to experimenting upon a system of communication by induction as suggested in the last report. Under this system the cable running from the shore is laid in a circle on the bottom of the sea immediately under the light vessel, the circle having such an area that the vessel will always be within the circumference of it. Round the deck of the light vessel a number of turns of insulated wire are coiled, which are in connection with a telephonic receiver on board the ship. An intermittent vibratory current is sent through the cable, and is made and interrupted by a Morse key. The vibrations act by induction on the coils of wire on the light vessel and produce buzzing sounds in the telephone, which, being intermitted by the Morse key, are read as in the ordinary Morse code. By means of a special arrangement a call bell can be rung. In the same way messages can be sent from the light vessel to the shore. This system has not yet been subjected to a practical test at a lightship; but the commission regard it as offering greater chances of success than any of the other inventions of the same nature which they have had before them, and meanwhile defer recommending the establishment of electrical communication with any further light stations, awaiting the result of the experiments which are about to be made.

NITRIC ACID PRODUCED FROM AIR.

It is reported that Messrs. Siemens & Halske, of Berlin, have patented in Germany a process for producing nitric acid from air. It is found that if air is mixed with ammonium gas and subjected to a discharge, obtained under certain definite conditions from an induction coil, ammonium nitrate is formed in large quantities, from which nitric acid is readily obtained. A mixture which has shown good results contains 100 parts by volume of air with one or two parts of ammonium gas. An excess of ammonium gas does not interfere with the reaction and can be recovered.

THE BABCOCK ELECTRIC SOUNDER.

An electric sounder has been invented by Dr. J. F. Babcock, of Bangor, Me., for use as a substitute for the hand lead upon vessels approaching a coast or shoal in darkness or fog when the position of the vessel is doubtful. Briefly stated, the apparatus consists of a metallic cylinder having a water-tight chamber, partially within which chamber a piston works longitudinally. Upon the outer end of the piston is a heavy ball, the weight of which, when the apparatus is swinging clear in the water, keeps open an electric circuit which, when the apparatus rests (in any position) upon the bottom, is closed by the action of a powerful spring.

When the sounder takes the bottom and the circuit is closed, the current, conveyed by wires running in the cable by which the sounder is attached to the ship, rings a bell in any desired part of the ship, giving immediate notice.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JUNE 23, 1896.

Alarms and Signals:—

AUTOMATIC RAILWAY SIGNAL. H. V. Miller, Bloomington, Ill., 562,639. Filed May 1, 1896.
In combination with the rail and ties a cross-bar, two blocks, a lever and its frame provided with standard and contact springs.

ALARM. R. W. J. Kraus, New York, 562,731. Filed Jan. 30, 1896.
A cage, a barokinetic circuit closer, and a guide for directing the falling of an unconscious body within the cage upon the circuit-closer.

Secondary Batteries:—

SECONDARY BATTERY. R. J. Gulcher, Charlottenburg, Germany, 562,396. Filed Feb. 29, 1896.
A fabric made of lead threads as warp and glass or quartz threads as woof, and a frame of lead.

PROCESS OF UTILIZING MATERIAL OF WORN-OUT SECONDARY BATTERIES. W. L. Silvey, Dayton, O., 562,776. Filed Nov. 19, 1895.
Consists in first washing the plates in water to eliminate the sulfuric acid, then subjecting them to the action of heat, then melting the plates and converting them into finely divided lead and oxids of lead, then adding a quantity of low oxid of lead, then forming the material into a paste and applying the paste to a grid, and finally hardening the plates.

Conductors, Conduits, and Insulators:—

WIRE HOLDER. L. M. Hakansson, Mason City, Ia., 562,528. Filed April 23, 1896.
Provided with arms on its upper end, under which a wire is forced into a locked position by turning the head of the holder.

Distribution:—

SYSTEM OF ELECTRICAL DISTRIBUTION. L. K. Oppenheimer, Cincinnati, O., 562,647. Filed Dec. 21, 1895.

Dynamos and Motors:—

ALTERNATING CURRENT MOTOR. E. Arnold, Zurich, Switzerland, 562,365. Filed Jan. 11, 1893.
The field coils and some of the armature coils are connected with the source of alternating currents, and establish induced currents in locally-closed armature coils, whereby two distinct moments may be produced varying with, and regulated by, the speed of the motor.

ELECTRIC MOTOR AND DYNAMO. E. Arnold, Carlsruhe, Germany, 562,366. Filed April 5, 1895.
An armature commutator and brush therefor, with resistances introduced in alternate commutator connections.

ALTERNATING CURRENT MOTOR. M. J. Wightman, Lynn, Mass., 562,686. Filed July 26, 1888.
An effective rotation is produced by parallel circuits formed upon a ring core, one of which is closed on itself and armature and an interposed copper conductor.

Electro-Metallurgy:—

ELECTRIC FURNACE. W. R. King and F. Wyatt, New York, 562,400. Filed Jan. 24, 1896.
Provided with a centrally located hollow movable electrode, whereby the length of the electric arc is regulated, an inner tube extending downward inside said hollow electrode and serving as a central feed, and mechanism, whereby the material to be smelted is fed into said furnace through said inner tube and deposited within the field of said electric arc.

PROCESS FOR FORMING CALCIUM CARBIDE. W. R. King and F. Wyatt, New York, 562,402. Filed April 14, 1896.
Consists in the heating of the vertical center of a mound composed of pulverized coke and ground lime to a white heat by the passage of an electric current along a conductor core.

ELECTRIC FURNACE. W. R. King and F. Wyatt, New York, 562,403. Filed April 21, 1896.
Employs the incandescent principle in distinction from the arc principle.

ELECTRIC FURNACE. W. R. King, New York, 562,404. Filed Feb. 1, 1896.
Employs more than one arc.

PROCESS OF REDUCING ALUMINUM. H. F. D. Schwahn, Kansas City, Mo., 562,785. Filed Jan. 31, 1895.
Details of process.

Lamps and Appurtenances:—

ELECTRIC ARC LAMP. D. Higham, Boston, Mass., 562,609. Filed March 31, 1896.
Embodies a close fitting hood stationary with the lamp frame, and inclosing the arc.

Measurement:—

ELECTRIC METER. A. G. Waterhouse, Hartford, Conn., 562,680. Filed March 25, 1895.
The combination of an ammeter having a movable part actuated by the electric current to be measured and a compensator and registering device worked by one or more derived circuit currents.

Miscellaneous:—

CIGAR LIGHTER. A. C. Gruhlke, Waterloo, and W. F. Kessler, Auburn, Ind., 562,395. Filed Dec. 6, 1895.
A device automatically lighted by an electric spark when the lighter is pulled toward a person, and extinguished when released.

ELECTRICAL ADVERTISING APPARATUS. C. E. Skinner, Pittsburg, Pa., 562,429. Filed Feb. 28, 1894.
Two sets of insulated conducting bodies disposed to display advertising letters or designs, in combination with a source of alternating currents.

ELECTRICAL RELEASING DEVICE. C. A. Stearns, Watertown, Mass., 562,431. Filed April 15, 1896.
An electromagnet and an armature therefor normally locked with apparatus to be released thereby; and a cushion or spring interposed between the armature and its resisting-contact.

AUTOMATIC OPERATION OF ELECTRIC GENERATORS. F. E. Kinsman, Plainfield, N. J., 562,541. Filed June 23, 1893.
The combination of a locomotive boiler, a dynamo and engine for operating the same and an interposed valve set to open connection there between at ordinary blow-off pressure.

ESCAPEMENT MECHANISM. C. E. Allen, Washington, D. C., 562,561. Filed May 28, 1894.
An escapement wheel provided with movable arms mounted thereon, and controlled by means of the electric current.

BANK OF ELECTROMAGNETS. C. E. Allen, Salem, Mass., 562,564. Filed Oct. 28, 1895.
Consists of a number of iron-clad magnets, arranged in such manner that the magnetic pull of two or more magnets is converted into one mechanical thrust.

MEDICAL ELECTRODE. W. P. Horton, Jr., Cleveland, O., 562,765. Filed Dec. 30, 1895.
A plate having a flange on the front face, thereby forming a cavity for the reception of absorbent material, forwardly bent loops at its ends, and a binding post on its rear side.

ELECTRIC LIGHTER. H. E. Rider, Brooklyn, N. Y., 562,775. Filed May 2, 1895.
Comprises a torch and means for electrically lighting said torch through the movement of taking it from its support.

APPARATUS FOR GENERATING ACETYLENE GAS. William R. King and Francis Wyatt, New York, N. Y., 562,401. Filed Jan. 29, 1896.
Consists of a generator revolubly mounted on a shaft and provided with means whereby the solid material and the liquid material may be introduced at opposite ends of the generator and may be brought together at the middle thereof.

Railways and Appliances:—

ELECTRIC RAILWAY. H. Brandenburg, Chicago, Ill., 562,453. Filed March 11, 1895.
Employs an I-shaped rail having the integral laterally recessed flange on one side of the head of the trolley conductor seated in and closing said longitudinal recess.

TRAVELING CONTACT OR PLOW FOR UNDERGROUND ELECTRIC RAILWAYS. S. L. Phillips, Washington, D. C., 562,483. Filed Jan. 21, 1896.
An insulating cover comprising two sections, clamps for securing said sections to the plow, and fastenings for detachably engaging the ends of the sections.

TRAVELING CONTACT FOR UNDERGROUND ELECTRIC RAILWAYS. S. L. Phillips, Washington, D. C., 562,484. Filed Jan. 21, 1896.
Similar to above.

TROLLEY. H. A. Seymour, Washington, D. C., 562,494. Filed Feb. 20, 1896.
Employs an electromagnet for forcing the trolley into contact with the conductor.

ELECTRIC CONTROLLER. E. A. Sperry, Cleveland, O., 562,501. Filed Feb. 20, 1895.
A main moving element of the controller for each circuit, in combination with means for dissimultaneous operation of the moving elements.

ELECTRIC LOCOMOTIVE. I. E. Storey, Boulder, Colo., 562,502. Filed June 29, 1892.
Method of mounting motor.

TROLLEY DEVICE. H. A. Gray, New Haven, Conn., 562,523. Filed Aug. 1, 1895.
Oppositely located, antifriction devices, supported upon the head above the wheel and capable of both an axial and a rising and falling movement, and means for causing said devices to approach each other in their upward movement.

APPARATUS FOR OPERATING TROLLEY ARMS. P. J. Dowling, Waterbury, Conn., 562,591. Filed July 23, 1895.
Provides a releasing mechanism in connection with the trolley pole whereby the pole will be prevented from striking the guy wires when thrown out of its operative position with the line wire.

ELECTRIC LOCOMOTIVE. John C. Henry, Westfield, N. J., 562,398. Filed April 22, 1895.
A motor having an armature shaft centrally located therein and extending laterally through bearings in the truck frame and a track wheel on each end of shaft.

ELECTRIC LOCOMOTIVE TRUCK. William P. Henszey, Philadelphia, Pa., 562,607. Filed Oct. 4, 1895.
The combination in a car truck, of the side frames, the top plate extending from one side frame to the other, openings in the top plate, with a bolster having a center plate and side bearing blocks extending through openings in the top plate.

ELECTRIC RAILWAY. Rudolph M. Hunter, Philadelphia, Pa., 562,766. Filed Sept. 23, 1896.
A switch, electrically operated from the car.

Regulation:

RHEOSTAT FOR ELECTRIC HEATER. W. S. Hadaway, Jr., New York, and W. E. Davis, Malden, Mass., 562,527. Filed July 18, 1895.
The resistance conductor is combined with a suitable non-conducting core in such a manner that if the conductor is broken the broken ends will be supported by the non-conducting core and short circuiting prevented.

CONTROLLING MECHANISM FOR ELECTRIC MOTORS. R. C. Smith, Yonkers, N. Y., 562,745. Filed Jan. 25, 1892.
A reversing switch, an auxiliary switch, a safety resistance in the armature circuit, and a resistance in the field magnet circuit.

Switches, Cut-Outs etc.:—

OUTLET BOX AND FIXTURE SUPPORT. C. O. Mailloux, New York, 562,633. Filed Feb. 20, 1895.
A seat formed in the bottom of box, a removable bushing fitted to said seat, and a bolt passing through said bushing for securing the box in place.

ELECTRIC SWITCHBOARD AND CIRCUIT MAKER. A. L. Pratt, Kalamazoo, Mich., 562,658. Filed April 9, 1896.
Provides means to lock the switch at each shift from one set of terminals to another.

Telephones:—

SYSTEM OF CURRENT SUPPLY FOR TELEPHONE CIRCUITS. J. S. Stone, Boston, Mass., 562,435. Filed April 23, 1896.
The central source of current may be used for signaling purposes.

THE NASSAU COMPANY, OF BROOKLYN, AND THE UNDERRUNNING TROLLEY PATENT—SUIT DISCONTINUED.—The suit of the Thomson-Houston Electric Company against the Nassau Electric Company, of Brooklyn, for alleged infringement of a certain trolley appliance was last week stricken from the calendar in the United States Circuit Court, by order of Judge Lacombe. The Nassau Company agreed to pay $20,000 for the appliances now in use and $100 for each additional one used. In a similar suit against the Union Railway Company the motion set down for argument was also temporarily removed from the calendar.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

GUNNING FOR ORDERS.

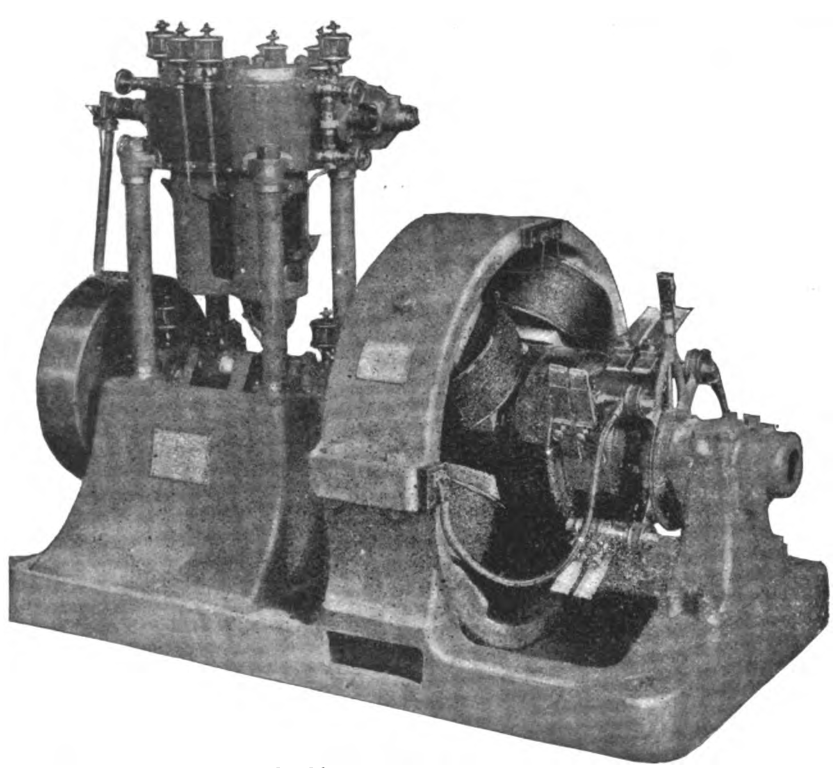
THE usual peace and quiet of our sanctum were rudely disturbed last week by the arrival of a suspicious-looking box, which upon opening was found to contain a full-size Winchester repeating rifle. As we are at peace with all the world the murderous weapon is of no use to us; but a legend on the butt of the gun serves to remind us that the American Electrical Works, of Providence, R. I., are asking all their friends to join in the celebration of the glorious Fourth of July.

"Our Goods Hit the Mark," which is proclaimed by a card on the magazine of the rifle, is an axiom in connection with 'Gene Phillips' wares, and his neat method of making the fact known is in consonance with his well-known modesty.

THE G. E. MARINE COMBINATION PLANT.

One of the most important requirements in an electric plant for shipboard lighting and power is the smallness of space in which both engine and dynamos can be set up consistent with efficiency of operation and satisfactory service. In marine electric practice, the General Electric Company has had a wide and most varied experience, and having installed a large number of marine plants on all classes of vessels both merchant and governmental, has full knowledge of the necessary requirements. It has brought down the marine dynamos to their smallest practical size and in order that they may be operated most efficiently, has also developed a line of steam engines to which the dynamos may be coupled directly. The capacities of the engine range from two kilowatts to fifty kilowatts.

They are of simple design and noteworthy on account of the few parts which enter into their construction, while every part is easily accessible. The sets occupy a minimum of floor space, the engine bed being carried out to support the dynamo. While this construction gives a massive appearance, the bed is so carefully cored out that the capacity is approximately only 3½ watts per lb. The generators are of the four-pole type with ironclad armatures, a special armature winding being adopted to reduce the height and length of the sets to a minimum.



THE G. E. MARINE GENERATOR COMBINATION.

PREMIER BATTERIES AND MOTORS.

MR. M. R. RODRIGUES, manufacturing electrician, of 17-19 Whipple street, Brooklyn, N. Y., has issued a pamphlet describing his well-known "Premier" products. These include the Premier motors, batteries and induction coils, besides which Mr. Rodrigues manufactures medical batteries, phonographs and electrical novelties and supplies of all kinds. The Premier motors are made up in several sizes, the smallest being but three inches high. This size is made for driving small mechanical toys, etc., and is run with one battery cell. The largest size is used as a fan motor and is run with two or three cells. It carries a ten-inch fan, runs at about 1,000 revolutions per minute and is well and substantially made of the best materials.

The Globe ironclad fan motor is manufactured by Mr. Rodrigues for use on 110-volt circuits. This is adjustable for two speeds and is provided with a wire guard.

A. K. WARREN & CO.

Mr. A. K. Warren, of A. K. Warren & Co., 465 Greenwich street, has recently taken into partnership with him Mr. J. R. Steers, of this city. Mr. Warren started in the electrical repair business under the title of the "New York Electrical Repair Company" on a small scale about three years ago, and has been obliged, in order to take care of the work and insure prompt deliveries, to constantly increase his plant and facilities, until his shop has become one of the recognized repair shops for all classes of electrical work in the Eastern district.

A few months ago Mr. Warren began the business of electrical maintenance, as, from his repair business and shop facilities, he was in a position eminently fitted to take up that line and furnish quick work and low estimates. In addition to this, some of the largest electrical manufacturing companies, having found it more economical to turn over to him the erection of all their large generators and machines in this vicinity than to send their own men from the factory, the business has grown beyond all proportions of what was anticipated. It was found that still more room, plant, and increased capital were required to handle the work. Mr. Warren also found that he could not attend to the outside work, making out of estimates, and all the business details and still give the time and attention he desired to the work in the shop.

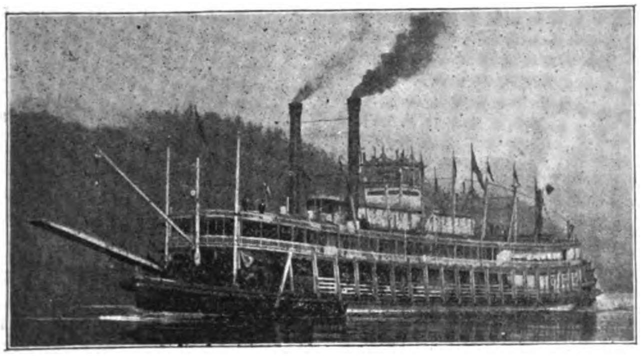
Mr. Steers has put into the firm all the capital that is required for the necessary increase of plant, and for working capital. Two more floors, fully equipped with all the necessary machinery and appliances, have been added to their factory; and he will have charge of all the office work and the finances of the company. The old title of A. K. Warren & Co. will be continued.

ELECTRICITY ON AN OHIO RIVER BOAT.

The most recent addition to the fleet of steamboats plying on the Ohio is the "Virginia," of the Pittsburg and Cincinnati line, launched last November, from the ways of the Cincinnati Marine Railway Company. She is of the flat-bottomed, stern wheel type, 235 feet long, 40 feet beam and 7 feet depth of hold in the clear. The cabin is full length and is 190 feet long, with fifty staterooms opening upon it.

The machinery consists of a double set of tandem compound condensing engines with high pressure cylinders of 15 inches diameter, low pressure of 33¼ inches diameter and 84 inches stroke. Steam at 186 lbs. is supplied by one battery of four externally fired steel boilers, 42 inches in diameter and 20 feet long. The "Virginia" is lighted by electricity throughout, the General Electric Company furnishing the entire equipment.

The generator is a 25 kilowatt multipolar machine directly



ELECTRICALLY LIGHTED OHIO RIVER STEAMBOAT.

connected to a 40 horse-power automatic engine. The plant is set up on the lower deck, in the main engine rooms, and furnishes current for 250 incandescent lamps, two arc lamps and one searchlight. One hundred incandescent lamps are used in the main cabin, one in each stateroom, and 100 more in the texas and elsewhere. The searchlight is one of the regular General Electric 12-inch projectors, fixed to the crane mast forward and controlled from the pilot house.

The switchboard is of the skeleton type and carries a voltmeter and ammeter, rheostat and switches controlling seven circuits. Each switch and junction box located at different points in the vessel is of the G. E. marine watertight type and everything has been done to make the installation perfect.

The "Virginia" now plies regularly between Cincinnati and Pittsburg, and is the handsomest and most perfectly equipped boat ever seen on the Ohio River.

MICANITE SPECIALTIES.

We are in receipt of a sample of the latest production in micanite made by the Mica Insulator Company, 218 Water street, N. Y., and 153 Lake street, Chicago. The sample consists of a plate of extra flexible micanite and is built up of pure India sheet mica. It is especially adapted to be used as an insulation for armature slots, armature cores, field magnet coils, etc., as, on account of its extreme flexibility, it can be bent into almost any desired shape. It is furnished in sheets up to 36 x 36 inches in size, and of any desired thickness from 10-1,000 of an inch upward.

Besides the plates, micanite is manufactured in a great number of forms. These include segments, rings, cylinders, tubes, rheostat linings and others too numerous to mention. The company reports the demand for micanite specialties on the increase both here and in Europe, and their Schenectady and London factories are both kept very busy filling orders.

ELECTRIC RAILWAY PROSELYTING LITERATURE.

The Brooklyn Heights Railroad Co. has begun the publication of a 24-page paper to be issued monthly, called "The Trolley." This is said to be the first publication of its kind ever put out by a street railway company and the company expect it to prove of value in advertising their special car service as well as the pleasure resorts reached by their lines, and to increase general traffic. Twenty-five thousand of these will be distributed each month throughout the Greater New York.

THE AMERICAN ORDNANCE COMPANY, of Bridgeport, Conn., are about to install electric lights in their extensive shops and are in the market for supplies for 1,500 incandescent and 30 arc lamps. Catalogues, price lists, etc., should be sent to Mr. E. O. Crocker, the company's electrical engineer.

WESTERN NOTES.

THE VALENTINE CLARK COMPANY, dealers in poles for overhead wiring purposes, have changed their headquarters in Chicago from 704 The Rookery to 804 and 805 Gaff Building, La Salle street.

THE BALL ENGINE COMPANY, of Erie, Pa., have removed their Chicago office from 506 The Rookery to 1526 Monadnock Block. The office will be in charge of their sales agent, Mr. W. A. Kreider.

CALIFORNIA NOTES.

The Electric Specialties Company, of Oakland, Cal., have just installed a 90-light system in the pumping station of the Oakland Water Company, at Alvarado. The plant consists of a 5.62 k. w. 125-volt Westinghouse generator, driven by a ten-horse-power Racine engine. The works are wired for 1½ per cent. loss and no expense has been spared to make the plant the most complete of its size in the country.

The same company are now installing a 500-light plant at the suburban residence of Mr. William J. Dingee, three miles from Oakland. The current for this system is taken from the Piedmont and Mountain View Railway, one and one-third miles distant, and at the residence reduced to 110 volts by a "Robbins direct-current converter," which admits of 40 per cent. variation in current. The system has been in operation for several weeks in part and has proved very satisfactory. This is the first application of this converter on so large a scale, and it is being watched with considerable interest by local railroad men.

The Piedmont and Mountain View Railway have just ordered another 150-kilowatt generator of the General Electric Company. The new machine is expected to be running within thirty days.

Ground has been broken for the new electric road between Monterey, Cal., and Pacific Grove, and the work is being pushed rapidly forward. We are not advised as to the names of contractors for the electric equipment.

NEW YORK NOTES.

THE ELECTRO-CYANIDE GOLD AND SILVER EXTRACTING COMPANY, of New York, has been formed by Henry Wetjen, of Brooklyn; John Meyer, of New York City, and others, with a capital stock of $25,000.

THE C & C ELECTRIC CO., of New York, have secured the services of Mr. J. Holt Gates, who will push the sale of C & C appartus in Chicago hereafter. Mr. Gates requires no introduction to the electrical trade, being one of the best known electrical men in the West.

MESSRS. STANLEY & PATTERSON, of 32 and 34 Frankfort street, have made arrangements to act as sole selling agents in the United States, for Fleming's woven wire dynamo brushes. With increased facilities for manufacturing, there will be no delay in the future in filling orders for any size of brush, or any quantities that may be required.

The Pioneer lamp has won the confidence of several parties having a capital of over $2,000,000, who are now backing up the Electric Arc Light Company in the fullest manner. A firm and aggressive policy has been adopted by the company, manufacturing on a large scale, advertising freely, and establishing agencies throughout the country. Elegant offices have been fitted up at 687 and 689 Broadway, and a fine laboratory at 250 and 252 Mercer street, New York City.

THE GLEN FALLS PAPER COMPANY, of Glen Falls, N. Y., are making extensive alterations and additions to their plant, and on all their new buildings they are placing roofs supported by steel trusses. This form of construction is especially adapted for buildings devoted to the manufacture of paper, and wherever new buildings are put up, or old ones remodelled, steel is almost invariably used. The trusses for the work which they are now doing, will be furnished by the Berlin Iron Bridge Company, of East Berlin, Conn.

THE MATTHEWS-NORTHRUP COMPANY, Buffalo, N. Y., have just issued the eighth edition of their "Postal Dictionary," an alphabetical handbook of postal rates, laws, and regulations. It has been compiled from official sources with the utmost care, and will be found thoroughly accurate, complete, and up-to-date in all particulars. Business men and others who use the mails can refer to the Postal Dictionary with profit and pleasure in the numerous cases of doubt that arise in the course of correspondence and of merchandise mail. The book fits a desk pigeon-hole snugly, and is substantially and neatly bound in tough manilla paper. The price of single copies is 15 cents, which includes postage.

WESTERN NOTES.

THE C. E. WOODRUFF COMPANY, 235 Lake street, gave a bill of sale of all their effects to the Joliet National Bank, Joliet, Ill. Mr. Mason, the manager of the Bank, is in possession of everything on the premises.

THE WESTERN TELEPHONE CONSTRUCTION COMPANY, Chicago, report the following contracts, which they have secured recently: 1,000 drop switchboards at Sea Crosse, Wis.; 100 telephones, Sandersville, Ga.; 200 telephones and 200 drop switchboard, Winchester, Ky.

GARTON-DANIELS ELECTRIC COMPANY, of Keokuk, Ia., with the approach of summer are beginning to receive orders for their new type lightning arresters, which were described in our pages last week. Among the recent orders is one for the entire equipment of the Hamilton (Ont.), Radial Railway, with their improved pole type.

THE JEFFREY MANUFACTURING COMPANY, of Columbus, O., inform us that Mr. Cyrus Robinson, of their mining department, has resigned his position with their company, to take effect July 1. All correspondence pertaining to their mining appliances, will be taken care of from the Columbus office as heretofore.

THE METROPOLITAN ELECTRIC COMPANY have taken the Northwestern agency of the Missouri Telephone Manufacturing Company, St. Louis, Mo., and are carrying a full line of their celebrated telephones, switchboard apparatus and patent gravity hooks. All telephones are guaranteed. Correspondence will be answered promptly.

THE ELECTRIC APPLIANCE COMPANY are carrying in Chicago a well assorted stock of Electra carbons, and are prepared to fill orders at manufacturers' prices. They claim that the Electra carbon is the cleanest imported carbon on the market, burning with the least possible amount of dust, hence giving a longer life than would otherwise be possible.

THE CYCLE ELECTRIC LIGHT COMPANY, at 20 West Randolph street, Chicago, has confessed judgment for $11,-036.42 in the Superior Court. The judgment was made in favor of Thomas A. Snider, president of the company, and was rendered on a demand note made May 6 last. The company has been engaged in the manufacture of electric bicycle lamps. The officers of the concern are Thomas A. Snider, president, and W. A. Crowdus, secretary.

THE ELECTRICAL APPLIANCE COMPANY have taken the general Western agency for the already far-famed Armorite iron-armored interior conduit, which is creating a very great deal of favorable comment, on account of its many unique and desirable features. One of the great points claimed is that the conduit can be bent cold into almost any shape, thus saving the expense of elbows and greatly reducing the time required to install the conduit. The Electric Appliance Company consider Armorite a "winner."

THE SUNBEAM INCANDESCENT LAMP COMPANY, Chicago, has recently purchased a new factory, located at Desplaines, Ill., a few miles west of Chicago. The factory is a substantially built brick structure, and will give the Sunbeam company about double the floor space of its present factory. It will be fitted up with all of the very latest devices used in the manufacture of lamps, which will give the Sunbeam company facilities that are second to none, and a largely increased capacity.

ALTHOUGH the demand for china insulating material and batteries has fallen off for the present, the Peru Electric Manufacturing Company, of Peru, Indiana, are running their factory full time, making up stock. This firm have been established in business since 1892 and are now employing about 100 men steadily, both on china insulating material and batteries. Their goods, throughout, are exceptionally well made, which accounts for their growing demand, both in this and in foreign countries. We are informed that large shipments were recently made by the Peru Electric Manufacturing Company to Nova Scotia and the City of Mexico. They anticipate a brisk trade for the fall.

THE CUTLER HAMMER MANUFACTURING COMPANY have removed their plant from 128 South Clinton street, Chicago, to more commodious quarters in the Dunn Building, at 71 West Jackson street. The business of this company has recently increased so rapidly that it was found to be absolutely necessary to secure more space for manufacturing, as their old quarters were utterly inadequate for the purpose of carrying on their trade. To aid them still further they have purchased the plant of the Gates Electric Manufacturing Company, and when they get their new factory in full working order they will be enabled to turn out a large quantity of rheostats, which they intend to manufacture exclusively. They have also secured the services of quite a number of extra hands who are experienced in the business, thus making their factory thoroughly complete in every respect.

NEW YORK NOTES.

THE CLONBROCK STEAM BOILER WORKS, of Brooklyn, are having so large an accession of orders recently that the shops are running on full time, with a large number of orders ahead. The outlook is particularly bright for work of other kinds.

MESSRS. H. E. & C. BAXTER, Bedford, Division and Canton streets, Brooklyn, N. Y., report a satisfactory business, especially on their No. 7707 electric bell. Their full force is still kept busy on these, as well as on annunciators, push buttons, switches, burglar alarms, springs and other specialties.

TEN HOURS' a day steady work is the schedule time at the New York office of the Joseph Dixon Crucible Company, 68 Reade street. Mr. John H. Baird, the genial manager, with efficient help, is very busy filling orders for resistance rods, ranging from 1-5 to 25,000 ohms, graphite pencils and many other articles made of graphite.

THE LECLANCHE BATTERY COMPANY, East 131st street, New York, are now putting on the market and pushing the sale of their zinc holder. It is an ingenious device for holding the zinc in the spout of any battery jar, and preventing it leaning against the porous cup with a possibility of short-circuiting. The device is the invention of Mr. Brewer, president of the Leclanché Battery Company. The company will take pleasure in mailing samples to any one free upon application.

THE PALERMO MICA CO., 27 Peck Slip, New York City, who are dealers in mica exclusively, are sending out to the trade a new price list of all grades of mica for electrical purposes. Besides their sheet mica, this firm supplies segments and rings for commutators of all makes, cut to pattern and built up to any desired thickness. The company can furnish mica in any quantity and of any quality desired.

THERE is a race for first place in public favor between the old short-hour and the new long-hour arc lamp. The Pioneer guarantees a run of 100 to 150 hours, while the old lamps give between 8 and 10 hours. This is prettily illustrated by the cartoon of the Electric Arc Light Company. In all the large orders recently placed, the long-hour lamp has received serious and favorable consideration. In addition to the money saved by using only one pair of carbons a month instead of one a day, the annoyances of daily trimming and the scattering of carbon dust are avoided.

MR. GEORGE FINK SPENCER, is at present on a combined pleasure and business tour through Europe and is expected to return about the middle of July. Mr. Spencer is the manager for I. P. Frink, reflector manufacturer, 551 Pearl street, New York, whose goods have been installed in such places as the Metropolitan Art Gallery, Central Park, Carnegie Library and Art Gallery, Pittsburg, and many other well-known galleries, churches, etc. Frink's improved reflectors are highly recommended for use in connection with electric, gas and oil light.

MR. D. S. PLUMB, 24 Boudinot street, Newark, N. J., whose advertisement appears on another page, established himself in 1881, originally as a manufacturer of very fine clocks. The thorough knowledge of how to make these delicate and intricate mechanical devices and the like, gradually led him into the business of making specialties of this nature for manufacturers of heavy machinery, who have not the facilities nor employés to turn out delicately adjusted clock mechanism. Mr. Plumb's steadily growing business is the result of the demand he created, the electrical line largely coming in for its share. Among the many specialties manufactured are electric meters, clockwork arrangements, automatic devices, intricate mechanical instruments, etc., also special screw machine work. Mr. Plumb caters more to manufacturing special devices for other manufacturers, and solicits correspondence on the subject.

NEW ENGLAND NOTES.

THE BERLIN IRON BRIDGE COMPANY, of East Berlin, Conn., have secured a contract for a steel rolling mill building, 103 feet wide and 112 feet long, from the Pennsylvania Bolt and Nut Company, of Lebanon, Penn. The building will have a steel frame, and roof and the sides will be of corrugated iron.

MR. JOHN BECKER, of Fitchburg, Mass., is making a number of sales, particularly among electrical people, of his milling machines. A little pamphlet, which he has just issued giving some of the users of this machinery, presents a number of names well known either as being directly interested in the electrical field, or connected with it in some way.

Department News Items will be found in advertising pages.

THE

Electrical Engineer.

Vol. XXII. JULY 8, 1896. No. 427

Electric Lighting.

ON THE CAUSE OF CONTINUOUS SPECTRA IN EXHAUSTED TUBES.

BY DR. W. H. BIRCHMORE.

Among my exhausted tubes is one, a bulb-tube, which presents remarkable phenomena when subjected to the action of an electric current. These phenomena are light relations and are of so interesting an order that I describe them in detail.

The Tube.—This is an ordinary exhausted bulb, containing two electrodes of aluminum; one a wire, the other a disc. These are separated by about 20 mm. and the disc has a diameter of 30 mm. The degree of exhaustion is not known. This is unfortunate, but unavoidable, as the tube was made by an electric lamp maker who "exhausted it perfectly," but left no small volume of gas within, as, indeed, is the usual condition in electric lamps.

The phenomena observed when the current from a coil is passed divide themselves variously according to the amount of the primary current, the arrangement of the condenser of the coil and the behavior of the current under the influence of the secondary condenser. The influence of this last mentioned apparatus depends very largely on the amount of surface, but also in its relation to the amount of surface in the primary condenser.

The coil used in these experiments was provided with a "striking apparatus" so arranged that the length of spark could be varied from ⅛ inch by 1-16ths to the full length obtainable. The length most suitable for experimentation depended on the tubes in use. A spark ⅝ inch long in dry air represented the electrical stress required for the phenomena in series A; while 1½ inches was the stress employed in series B; and ¾ and 2 inches the proportions in series C and D.

The battery used for excitation in experiments series A and C was 7 amperes under 1.5 volts. While for B and D it was 11.5 amperes under the same pressure. Amperage and voltage were measured by instruments from J. W. Queen & Co.

Experiments, Series A.—These consisted in studies into the spectra of the tube (bulb-tube) just mentioned. Under the electrical stress mentioned, 7. amperes and 1.5 volts these spectra were bright lines on a black ground, when no secondary condenser was used. In effect they were the spectra shown in the cut of spectra published in The Electrical Engineer of March 25, 1896, as of the first exhausted bulb.

There was no luminosity to the ground spectrum, not even a green cloud; the spectrum was, and is whenever the experiment is repeated, a spectrum of bright lines and of but few of them. It is of importance to remember in this connection that the current of the coil is always in one direction; there is no return current and that this phenomenon is a regular criterion by which gases of various kinds are investigated.

The slit of the spectroscope was placed in the middle distance between the two poles, and the width of the slit was less than 1-5 mm. Therefore it may be safely stated that all the light was produced within the inter-electrode space by the electrical stress, and none of it by the possible radiation from the electrodes within the bulb.

Experiments, Series B, were identical in all respects with those of Series A except that a Leyden jar was introduced as a condenser.[1]

The introduction of this jar quite changes the conditions of the experiment and produces a correspondingly great change in the results. In the first place, the discharge is not of the same kind. It no longer has a definite direction, but discharges in waves, which are of inverse direction each to its predecessor. In other words, between each make and break from the coil an immense number of short time waves pass. This is easily proved by passing the spark from an apparatus thus arranged between electrodes of different substances when the spectra formed are confused mixtures of those of the two metals, showing that the current passes back and forth between the two electrodes in alternate directions.

Under circumstances such as these a line spectrum is still produced, but behind it appears a continuous spectrum extending from about the wave length of line A to far beyond that of line G. In other words, there is produced without the intervention of any red-hot material a spectrum containing nearly all the wave lengths of the one familiar to everybody. But while the wave lengths are all present, the number of waves of the various lengths differ entirely from those of an incandescent body, say a piece of white hot lime.

Indeed, the spectrum intensities may almost be said to be reversed. The maximum of light, that is, sense-perceived undulation is in the blue and violet, while the green is less intense and the yellow and red more indistinct in the order given. It is well known that when a body is heated, the first sensible undulation is in the green, and it appears as a sheen without perceptible hue. This same phenomenon appears in the case of the exhausted tube under electrical stress, but its location is the space midway between F and G, say, in the violet near the blue. It is also well known that the heat rays begin the scale in the ordinary light, while in the exhausted tube the chemical (actinic) rays take this place. The carbon molecule will begin radiating heat long before it begins to radiate light, but the tube will begin actinic undulations before light waves are given off, and I have taken photographs with tubes whose only visible spectrum was "the four bright lines." That the real efficient radiation here was an F—G radiation extending out beyond the H limit was shown by photographs of colored objects, diagrams in color and the like.

As was mentioned, in these series a bulb-tube was used, in which were electrodes so placed that the current passed within the tube from one electrode to the other under a condition of stress whose measure was the length of the spark in dry air. For if the stress within the tube exceeded the resistance of the air space, the spark would pass here and the tube would not increase in its luminous phenomena to the same degree, if at all. This method of arrangement therefore constituted a gauge of the minimum stress required to produce a given phenomenon.

If for this bulb-tube is substituted an exhausted tube with no internal electrodes and experiments series C and D are performed, results much as follows are reached.

Construction of the Tube.—The most satisfactory results in these two series were reached by the use of a tube 1 inch (25 mm.) in diameter, and 15 inches (325 mm.) long. Around this tube at equal distances from the middle (150 mm.) were placed two bands of tinfoil (25 mm. wide) stuck fast to the glass with fish glue. Around the pieces of foil was coiled copper wire, almost as if to form a band, to which were connected by proper contacts the wires from the coil. The exhaustion of the tube was controlled by a Sprengel pump.

The battery used is that for experiments C and D, and the extremes of the electrical stress are those given. The conditions were those of choice and were usually successful; it being understood that in series C the direction of the stress was always from band A to band B on the tube, no secondary condenser being used, while in the series D the stress alternated in direction, being in waves whose direction was alternately from A to B, and from B to A. The conditions which interfered with uniformity in the experiments were dampness and dust. These, by interfering with the insulating action of the glass between the bands, caused the most surprising variations in the stress needed at the "striking apparatus" to produce a given result, and to obtain a reasonable uniformity it was needful to wipe the tube with a warm dry cloth, sometimes, and to dust it always.

In experiments, series C, the Leyden jar was not used; in series D the Leyden jar was in circuit.

[1] This series seems more suited for discussion in this preliminary mention than the more elaborate ones with the Becquerel apparatus, which may be discussed later.

The Phenomena Observed During the Passage of the Current.—It is desired to insist upon the distinction between these experiments and those of De la Rue, in that the electrodes were internal in the De la Rue tubes, but in these experiments there was absolutely no connection by current between the vacuum within the tube and the current outside. The phenomena were those of induction and were experimentally proved to be of a very different order from ordinary induction phenomena.

Series C.—In these experiments the current had a distinct polarity and there was a definite make and break. Under these circumstances there was a striation, an alternation of dark and light spaces, so to say, within the tube. At first sight, these appeared to be the well known "striæ" of Spottiswood and De la Rue, but by carefully managing break, resistance and current condenser, it was possible to prove the luminous bands to be true vortices.

The direction of motion of the rotation was against the direcsight, these appeared to be the well known "striæ" of Spottisdirections; they are in the center of the tube from A to B, the other close to the inner surface of the glass from B to A; or perhaps the simile would be better, to say that there seemed to be friction between the surface of the glass and a current within producing the vortical rings.

A very slight disarrangement of the conditions—rapidity of break was the most effectual—caused a luminosity, a sort of indefinite sheen coincident with the axis of the tube surrounded by a "black space" parting the central sheen, which showed no striæ, from the rolling rings. There is sometimes a curious variation of this order. The "sheen" is not only axial, but fills the middle of the tube like a double-spindle, the thickest part in the middle, and the vortical rings then surround it at both ends, becoming less distinct towards the middle, where they merge into the luminous cloud. The precise conditions of the current and stress needed to effect this I do not know, but I seem to be able to produce it at will by passing a copper ring, insulated with hard rubber, over the tube.

This ring is 1 cm. wide, of copper foil, and has a diameter twice that of the tube. This sheen is most intense and luminous when a very long wire of small relative resistance is used to connect the poles of the coil to the tube, say, 500 feet of No. 16 wire—ordinary electrical bell wire with an insulating winding in place of the ordinary 3 feet of electric light flexible cord. This is probably the agent in producing the sheen, acting as a Leyden jar, and yet in not by any means the same degree, the current rushing backward and forward violently between each break and make. For the exact relation standard works give many details of observations and the results of many speculations and much study.

When the Leyden jar was inserted as a secondary condenser, and the stronger current used, a condition of luminosity was obtained by which good print could be distinctly and easily read. A watch held 500 mm. from the eyes and 3 metres from the tube, could be read to seconds, and colors were distinguished, not by their true hue, but as presenting differences. Crimson and indigo could not be distinguished, but blue and green, or green and yellow, could be easily parted. The distinction between yellow and blue was very distinct; yellow was evidently the critical color. Aureolin (cadmium sulphide), which by daylight and all ordinary light is an intense yellow, by this light is white. Cobalt blue shows true, as does the manganese violet, while indigo shows almost black. No combination of colors which I could make showed as a true gray. The reflection spectrum was equally anomalous, the brightness of the violets and very light blues being surprising.

These experiments seem to prove two things—first, that if the undulations of electrical force are sufficiently rapid, and of sufficient amplitude, wave lengths in the ether are produced which answer in all respects to light, in fact, are light; second, that the excitation produced in a closed tube differs in some way from that produced in one with electrodes inside it. Examination into the rationale of this thing gradually led to the following experiments: Disconnect the condenser of a small coil—¼ inch spark seems to be quite sufficient—but leave the breaking apparatus alone. Connect the primary current to the battery in the usual way. Now connect the exhausted tube to the coil as follows: Coil, bobbin of 500 feet No. 16 wire insulated, exhausted tube as described, another bobbin, coil. This makes a circuit of very large capacity in proportion to the coil, and the fluctuations are most enormous, and rapid.

The battery needed to work the coil is small; two dry cells have been found to be ample. The exhaustion being determined by experiment and the pump stopped at the point of election, the luminous cloud appears in perfect development, and with a continuous spectrum.

These facts being established, the questions involved are as follows: 1. Does this tube give as much, more, or less light than an incandescent lamp requiring the same battery power? This question I cannot answer yet as I have had no time to make the needed analyses.

2. How does the actinic power of the lamps compare? To this question a definite answer can be given. The exhausted tube is many times more efficient than the other

3. How is the luminous sensation produced? The prima facie answer is by undulations of the ether; but why not of some definite wave length, as can be shown to be the case under known conditions of current and exhaustion, instead of such a multitude of waves evidently discordant?

It is very plain by certain observations made by Hertz that the induction currents rushing through dry air have a limited relation, but these currents on the surface of a tube of glass neither clean nor dry may have a quite definite one, and it is the influence of the currents without the tube which produce the disturbance of the ether within, and yet the relation be quite unlike the relation of Hertz's experiments.

Still further, we do not yet know that the other undulations to which we refer have origin in the direct action of the current. It is quite contrary to all experience. Currents of high tension going definitely in one direction produce in a vacuum definite discontinuous spectra of bright lines. Why should a rapidly oscillating current produce another sort of spectrum which is really continuous and of so different an order. The doctrine of the degradation of vibrations seems to apply somehow, but in the present state of the theory it certainly does not definitely apply. A modification is possible.

One thing may be set down as certain, the light produced is not emitted by gases. These in all cases would give non-continuous spectra. If we can imagine water to be in such a condition that the heat of formation could exactly equal that required to expand the formed water under the conditions stated, we might imagine the heat produced to make a very minute amount of water incandescent. This explanation has been suggested by two well-known experimenters, but it presents difficulties; an explanation that dust may play a part is possible.

But it is also possible that the real agent is a precipitated carbon. To free any space like this from carbon dioxide without special precaution is very hard, and from experiments I am inclined to think combinations of carbon and hydrogen, as well as of carbon and oxygen, are present in nearly all these tubes in various combinations, and therefore I am inclined to believe the continuous spectrum to be that of carbon under a very peculiar physical condition. I am the more inclined to think this, because my declaration that the spectrum of the light of certain exhausted tubes was continuous was immediately after followed by the declaration from various others of similar observations, which, while in a way coinciding with those I made, seem rather to have been of the order of fluorescent overlapping spectra than to have been faint continuous ones.

At any rate the continuous spectrum is there. I have offered a speculation as to its possible origin, namely, the heat produced by the union (precipitation) of gaseous atoms, perhaps carbon, which heat is instantly dissipated by their return to the gaseous condition. This is an interesting field for speculation and may be one of valuable scientific discovery.

ELECTRIC WAVES.

Some experiments made by Cole's method on the refractive index and reflective power of water and alcohol for electric waves have been described in the "Annalen der Physik und Chemie," from which it would appear that for waves of 300 cm. to 600 cm. length the refractive index for water was 8.95 and for alcohol 5.20, which is in agreement with the figures obtained by other observers. With waves of 5 cm. length the two Fresnel formulæ give the same value of the refractive index from the observed reflective power; for water it was 8.8 and for alcohol 3.2; for alcohol the refractive index for long waves is appreciably greater than for short ones. It also appears that waves 5 cm. long pass only with great difficulty through even very thin layers of water of 0.04 cm., although long electric waves readily pass through the water and both traverse with ease wood, paper, rubber and many other opaque materials. With these waves reflection is total from metals when the oscillations are at right angles to the plane of incidence and only partial when they are parallel to this plane. It will be seen that all these values are exceedingly high compared with those for the longest known light waves.

MR. WALTER D. STEELE has been appointed city electrician of Detroit to succeed Mr. Alex Dow, resigned. Mr. Steele will have charge of the engineering department and of the operating and construction forces. Mr. Will F. Conant has also been appointed secretary and general manager of the city plant for the ensuing year.

SOME CENTRAL STATION ECONOMIES.[1]

BY P. G. GOSSLER.

IT is well known that many central stations which have not been operating on a paying basis have been turned into profitable investments by prompt measures having been taken to modernize them, and to put them on a footing to meet competition either from companies already in the field or contemplating entering it. To do this, it has generally been necessary to reconstruct the entire electrical part of the plant from the generators to the lines and transformers, replacing the old generators and transformers by the more efficient apparatus now manufactured; rebuilding and re-designing the switchboard, and last, but certainly not least, the re-arrangement of the feeders and mains, to give economical distribution, to overcome the inductive effects, and to bring the feeder losses within the limits of good practice.

The following gives results obtained from the partial reconstruction of one plant. It does not give a full idea of what will be accomplished by complete reconstruction, inasmuch as that part so far carried out has been confined to transformer and line changes.

To proceed with a systematic reconstruction, the first things necessary are reliable records, at least of what the plant and lines to be reconstructed consist. For the plant herein referred to it was necessary to establish pole line and circuit maps as well as transformer maps. It may be said that such a system of records in detail and kept up to date is necessary for the economical operating of an electrical lighting station.

For the pole line records a card catalogue was arranged, each card having a number corresponding to a pole; in connection with this card catalogue there is a map on which each pole is located with its number; also, for further convenience in making out reports and locating poles, each pole itself was numbered.

Fig. 1 represents a form of pole card which was found to answer the purpose very well.

On the card representing a particular pole all of the wires are shown in their relative positions on the pole by numbers placed over the pins to which the wires are attached, the numbers indicating the circuits of which the wires form a part. By means of this card the positions of the wires forming the different circuits were clearly shown, also what changes in the relative positions of the wires were necessary to overcome existing inductive effects, the latter being a source of much annoyance. In fact, the pumping on the circuits due to mutual induction, prior to their rearrangement, when circuits supported on the same pole were running from dynamos on different engines, was so serious and caused so much fluctuation of the lights that it was necessary to rearrange the relative positions of the feeders of all the circuits to counteract these inductive effects. Very satisfactory results were obtained when the rearrangement of the wires had been carried out. Prior to this change, to overcome fluctuation, it was necessary to feed all circuits on the same pole line from one set of dynamos operated by one engine, which was very often not convenient and only possible with a large loss in operating expenses.

In connection with this pole catalogue, circuit maps were arranged, which consisted of diagrams for each circuit, showing the streets upon which the circuit ran, and the size and length of each section of wire or wires.

At the same time these records were being made out, transformer charts were prepared, which consisted of maps for different sections of the city covered by the different circuits. On these maps each transformer was located by a small square stamped on the map, and within this square was written the name of the customer being served from this transformer, the number of lamps installed, the revenue per year, the revenue per lamp per year, the estimated number of hours burned per lamp per day, and the probable number of lamps burning at any one time. There is also indicated on these charts the size and length of secondary wires from the transformer to the customer's cut-out. All this information was found necessary for the proper "bunching" of customers on the transformers and for the loading of the transformer.

Wherever possible, secondary systems were established, to which several transformers were connected in parallel, in which case the size of the secondary mains between the transformers was such that the drop in these mains was small compared to the drop in the transformers themselves; in this way the transformers were made to share, more or less, the load equally between them. When a secondary system of distribution was not economical, single transformers were located. In determining whether a customer was to be included in a bunch of customers, all of whom were to be fed from one transformer, or whether it was more economical to place a separate transformer, it was necessary to make an approximate estimate of the cost of locating the transformer for each case. When the interest on the cost of placing a separate transformer, plus the cost of maintenance of the transformer, was more than the interest on the cost of connecting a customer to a transformer feeding other customers, the connection in question was made to the transformer feeding the "bunch." However, even if the difference in annual cost was small in favor of a separate transformer, connection was made to the "bunch." In making these calculations a fixed drop in the secondary mains was allowed, and the load, i. e., the probable number of lamps burning at any one time, for calculating this drop was determined from the records on the transformer charts; of course the character of the service goes a great way in making this last determination. A separate transformer was placed only when the total annual cost for the placing and maintenance of such transformer did not exceed the sum of the two following costs—the interest on the cost of placing and maintenance of wire necessary to connect the customer to the nearest "bunch" transformer, and the increased cost due to necessary increase in size of transformer. The annual cost of a transformer on the lines was considered to include the cost of the iron losses, figured as costing the electrical lighting station at an assumed rate of one-tenth (.1 cent) per lamp hour of 55 watts, a 5 per cent. interest on the cost of the transformer and the high rate of charge of 10 per cent. depreciation. To faciliate the bunching and loading of transformers in conjunction with other data, the following table is useful:

Capacity in lamps.	Cost of transformers.	Interest on cost at 5%.	Depreciation, 10%.	Leakage.		Cost of leakage at .1 cent per lamp hour, 55 watts.	Total annual cost of transformers on lines 24 hours service.
				Watts.	Watt hours per year.		
10	18.00	.90	1.80	29	254,000	4.62	7.32
15	22.00	1.10	2.20	30	262,100	4.78	8.08
20	26.00	1.30	2.60	32	280,000	5.10	9.00
30	32.00	1.60	3.20	35	306,400	5.58	10.38
40	39.00	1.95	3.90	37	324,000	5.88	11.73
50	47.00	2.35	4.70	51	446,000	8.10	15.15
75	68.00	3.40	6.80	65	569,000	10.33	20.53
100	80.00	4.00	8.00	77	674,500	12.25	24.25
150	112.50	5.62	11.25	85	744,000	13.50	30.38
200	150.00	7.50	15.00	125	1,093,000	19.90	42.40
300	225.00	11.25	22.50	150	1,312,000	23.85	57.60
400	300.00	15.00	30.00	160	1,400,000	25.00	70.00
500	375.00	18.75	37.50	170	1,488,000	27.05	83.30

The principal factor in determining the size of a transformer is the character of the service, a more liberal allowance being made for an overload in a residence than could be made in a commercial district. A good transformer should stand an overload for several hours of at least 25 per cent., and for a shorter period of 50 per cent., or even more.

The lightest load registered during the year preceding the commencement of the reconstruction was 380 amperes. Ten months later, with about 8,000 more lamps wired on the service than at the time of the 380 ampere load, above referred to, the lowest load recorded was 245 amperes, or a decrease in the load line of 135 amperes, this decrease in leakage load being due to transformer changes. The leakage of the 229 new transformers was 19 amperes, which means that the 473 old transformers had a leakage of 154 amperes, or an average leakage of .325 ampere per transformer removed, which figure has been verified by leakage tests made on the old transformers which have been removed from the lines. Thirty-six of the 135 amperes reduction was due to the removal of the 110 old transformers, and placing the customers served from these on other old transformers, making secondary distribution systems. From this is deduced the fact that by replacing the 345 old by 187 new transformers, a saving was effected of 99 amperes. The average saving for the 187 changed is then .529 amperes per change, which with coal at $2.75 per ton, means an annual saving of $25.58 per change in coal alone. The average cost of the 187 changes, including the cost of new transformers, all extensions of wiring for secondary mains and all labor, crediting these orders with old transformers as scrap only, was approximately $65. As stated above an annual saving per change in cost of coal would be effected of $25.58, therefore at this rate the new transformers will pay for themselves, if the saving in coal only is considered, in about two and a half years.

When the 1,160 transformers above referred to have been replaced by new transformers, and the bunching of customers

[1] Abstract of a paper read before the Canadian Electrical Association.

has been carried out, it is estimated there will be but 636 transformers required, and the total leakage will be less than 75 amperes.

Fig. 2, Curve a, represents the average load on the station during the twenty-four hours for seven days, the highest point reached being 760 amperes, and the lowest 380 amperes.

Curve b represents the average load that would have been on the station for the same period had the 917 transformers

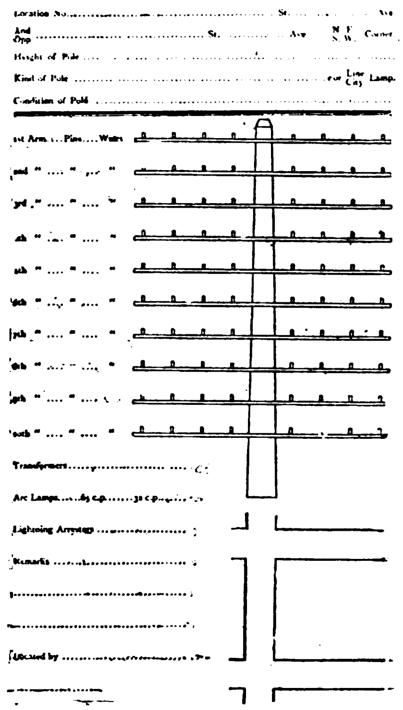


Fig. 1.—Pole Diagram.

been on the lines instead of the 1,160, and the saving of 135 amperes been accomplished.

A decrease in transformer leakage of 135 amperes means a decrease in load of 135 amperes for every hour of operation, which represents a saving in coal, at $2.75 per ton, of about $7,348 per year, that is, for a station running twenty-four hours per day. Apart from this increase in capacity, there is also the saving due to running a smaller engine for the day load, and the consequent saving in labor, oil, etc.

As so much of the advantage to be gained by this decrease in transformer leakage depends upon the kind of transformer used, it would only seem safe and wise to insist on all transformers coming within guaranteed limits for leakage and regulation. The only way to know that transformers come within the prescribed limits is to get them from manufacturers who are known to build the very best transformer, or, better still, test each transformer as it is received from the factory. Inasmuch as transformers made by different manufacturers, and apparently alike in every respect and seemingly identical in construction, are known to vary from 25 per cent. to 100 per cent. from each other, the advisable plan appears to be to test each transformer as it is received. This plan of testing transformers is followed out in many stations and is the only sure means of keeping the leakage within the calculated limits.

The reduction in leakage load so far obtained in the reconstruction under consideration has not been accompanied by any sacrifice of transformer regulation. The type of new transformer used is one giving the best all round results, that is, one in which regulation and leakage are so proportioned in its construction as not to benefit one at the expense of the other. In thickly populated or central business portions of the city, where an extensive secondary distribution is possible, and where large transformers may be connected in parallel at different points, it would be an advantage to use transformers of very small leakage current and high "all-day efficiency," as in this case the transformers share the load between them, and regulation can be sacrificed to gain diminished leakage current. However, as it is only in very large cities, and only in the most thickly populated centers of these that the secondary distribution system can be economically used, the make of transformer giving the best all round results should, in general, be selected. To further improve the regulation beyond that to be obtained by improved transformer regulation it is intended to change the primary distribution from 1,000 to 2,000 volts, thereby decreasing the copper losses on the existing circuits to one-quarter of the present losses, and reducing the feeder drops so that good service and regulation will be obtained without the use of feeder regulators or the erection of additional copper. A source of additional improvement in regulation will be the use of generators with very close regulation. The necessity of transferring the circuits from one dynamo to another makes close inherent regulation in generators an imperative feature if satisfactory service be desired.

Another factor in increasing the capacity and earning power of a plant is the use of an efficient lamp with an economic life. The best known makes of lamps on the market have a difference in efficiency of from 10 per cent. to 15 per cent., which means a difference of from 10 to 15 per cent. in the earning power of the plant, depending on the efficiency of the lamp in use. A 10 per cent. difference in output or capacity should receive consideration.

Lamps with long life are found to be inefficient; very efficient lamps are usually short lived. There is a point between these extremes which makes a lamp suitable for electric lighting station use. Using an efficient lamp increases the earning capacity of a plant and permits of using higher candle power lamps with a proportionally less increase in cost.

It has been determined that lamps which have been made by identically the same process differ in lots. It has been observed that lamps received from the same factory do not average the same candle power and efficiency for different invoices, that is, lamps received in one invoice are generally quite uniform throughout that lot, but they vary considerably from lamps received at other times. From this it will appear that to derive full benefit from using efficient lamps it is necessary to test the lamps and ascertain that they come within the limits of efficiency which have been decided to be the most economical for the local conditions. To determine what lamp is best suited for any electric lighting station, it is necessary to know the cost of producing current per lamp hour, and having established this for any special make of lamp, the following formula will permit of a comparison of different makes of lamps and the determination of the best lamp for the conditions under which they are to run. In considering the cost of production per lamp hour in connection with the lamp question, the cost of service may be divided into three parts:

A. That portion of the service per lamp hour that is practically not affected by the average efficiency and life of the lamps and such portion of the maintenance, operating and generating expenses, as is practically not increased by increasing the current consumption per lamp hour.

B. The cost per lamp hour, coal, water, interest and depreciation on the lines, dynamos, engines, etc., and such part of the expense of the service as increases proportionately to the amount of current served per lamp hour and as the maximum station output.

C. The cost of the lamp per lamp hour, and the expenses per lamp hour for replacing exhausted lamps. This is equal to the cost of one lamp, plus the cost of exchanging one exhausted lamp, divided by the average life of the lamp.

Under the first division (A) should be included the cost of

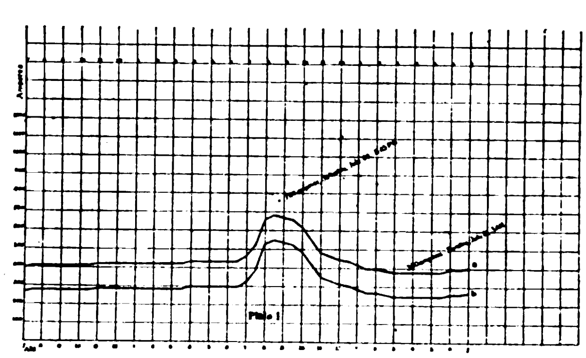

Fig. 2.—Load Diagram with Different Leakage Currents.

fuses, meters, transformers erected, and secondary connections, line construction, maintenance, etc., and such proportion of the operating and general expenses as is not increased by increasing the current consumption per lamp hour.

Under (B) should be included that portion of the cost of service per lamp hour, exclusive of lamp renewals, that increases proportionately to the current consumed per lamp hour.

These divisions of cost should be so made that the sum of A, B and C will represent the total cost of service per lamp hour. The values of A, B, and C representing the above divisions of cost having once been established for a lamp of any

given efficiency and average life for any particular lighting station, the cost of service per lamp hour for this same station with any other lamp which has a current consumption different from the current consumption of the first lamp, and having an average life of "Y" hours, would be A + XB + C. = the cost of service per lamp hour, "X" representing the proportion between the current consumption of the lamps being compared, and "C" being the cost of one of the new lamps, plus the cost of replacing one exhausted lamp, divided by "Y," the average hours of life of the new lamp.

This formula applies for comparing the cost of producing light with lamps having different costs, efficiency, and average lamp life, when they are to be burned in the same plant and under the same conditions of average lamp hours burned per lamp installed, and the same maximum number of lamps burning for a given number of lamps wired. Value (B) in this formula includes the coal consumption and the materials which practically vary proportionately to the watt hours output required for providing the light. It also includes the interest and depreciation on the plant, which must be enlarged when the lamps consume large amounts of current, because the generating and supplying capacity of the plant must be proportionate to the maximum output called for by the lamps. In many plants the interest and depreciation account will form quite a considerable portion of the factor B, and as a large value to the factor "B" makes a showing against the high consumption of current per candle power hour very bad, it would appear that any lamps installed that did not burn at the time of maximum current output from the station could be economically used of a poorer efficiency with longer life than lamps which do burn at time of maximum output, because any additional demand for current on a plant that is not a call for current at the time of maximum output, does not require an increase of plant capacity. In estimating the best efficiency per candle power hour, or per lamp hour, for these lamps that do not burn at the time of maximum output, the cost of interest and depreciation entering into the factor "B" in the formula (in fact, all the costs that increase proportionately as the size of the plant required to serve the lights wired) should be excluded from the factor "B." The result is that lamps that do not burn at the time of maximum output can be economically used of considerably lower efficiency than lamps that do burn at that time.

The outline of the reconstruction contained in this paper and the statement of the results so far obtained are for an electric lighting station serving 60,000 incandescent lamps. Another much smaller electric lighting station has had its transformer system rearranged, within the past year, upon the same plans outlined for the station serving 60,000 lamps. This smaller station had, and still has, a capacity of two 500 light dynamos, serving 2,100 lights wired. At the time of heavy load, the station was loaded beyond a safe limit. Apart from this the demand for an increase in the number of lights wired could not be met. An increase in the boiler, engine and dynamo capacity appeared, to some, the only way to meet the requirements; however, this was unnecessary, as the transformer system was rearranged, and thereby ample capacity to meet the immediate demands was furnished. Prior to this rearrangement there were seventy-nine transformers on the lines, having a leakage of about 20 amperes. The seventy-nine old were replaced by forty-two modern transformers, having a leakage of less than four amperes. By this rearrangement and the substitution of modern for the old transformers, a reduction in load was obtained of 16 amperes which permits of the station not only carrying safely, with the same station equipment, what was formerly an overload, but also permits of an increase in the earning power of the plant of approximately 1,000 16 candle-power lamps.

NIGHT-SIGNALS AT SEA.

Some experiments have recently been made in regard to a new night-signaling apparatus, the invention of a Captain Sellner, an officer in the Austrian Navy. The signaling is carried out with two lanterns, on either of which five different arrangements of red and white lights can be shown, the two together being able to show no less than thirty different combinations. Electric lights are used for the lanterns, and though separate batteries are used for the lights and for the signaling apparatus by which the lights are changed and obscured at will, eventually it is intended that one dynamo shall be so arranged as to supply all the current required. A check on signals sent by the apparatus is obtained by a device by which the message sent is automatically printed by the working of the signals. It was found that no difficulty was experienced in reading the signals at a distance of six miles and more.

MUNICIPAL ELECTRICAL ASSOCIATION OF ENGLAND.

THE first meeting of the Municipal Electrical Ass'n was held in London on June 10-12. The first session, held in the United Service Institution, was well attended, among those present being Sir Courtnay Boyle, Major Cardew, and representatives of all the large electrical manufacturing firms. The papers were read in abstract, which we give below. The president, Mr. Arthur Wright, of Brighton, took the chair and addressed the meeting as follows: Although the objects of the association are generally and very tersely stated in the constitution, I wish to amplify the wording there by stating that, in promoting the special interests of municipal electricity undertakings by bringing together, for the purpose of comparing experiences, the men responsible for their management; we hope to succeed in getting the representatives of the ratepayers to participate in our discussions, and to obtain their valuable co-operation and municipal experience in trying to solve our difficulties, so that our recorded conclusions may receive the greater consideration from the head governing bodies. The problems that have already confronted the management of municipal electrical undertakings may be divided into three distinct groups—those relating to policy, to commercial, and to technical questions.

The group of "Questions of Policy" must obviously include those relating to what should be the proper period allowed for the repayment of loans. That some decision ought soon to be arrived at is evident when we remember that in London the vestries can get permission from the County Council to repay their capital in periods exceeding forty years, whereas in many of the provincial towns twenty-five years is the period fixed by the Local Government Board. Take, again, the question of assessment of electricity works and mains. The interpretation of the law on this point is so uncertain among experts that it is actually possible, in the case of two municipal electrical undertakings in the South of England, for the relative assessments to be nearly as 10 is to 1, although the capital invested is about equal.

The decision arrived at as to what policy should be pursued in relation to the profits obtained, has a great effect on the rapid growth of municipal electricity undertakings.

Another point in connection with the general policy is whether a corporation should make all ratepayers pay a uniform profit on the cost of production of the electricity they individually consume, or charge a uniform price to everybody. I scarcely need add that the two systems cannot both be adopted. The former has the advantage of justice on its side, while the latter has that of greater simplicity.

The wisdom, or the contrary, of municipalities taking joint action in threatened patent litigation, or in view of new parliamentary regulations or restrictions, wants discussion and settlement. The questions whether municipalities should carry out the wiring of private premises in competition with local tradesmen; whether they should have powers to hire out motors, arc lamps, and fittings; the advisability of establishing municipal telephone systems, electric fire alarms, and electric fire engines; the possible benefits of combining the water and electricity works; the use of the plant in periods of light load for the production of such by-products as disinfecting fluids, acetylene, and carborundum, etc., are all interesting problems of policy which, I trust, will be ventilated and argued at our conventions.

With the second class of problems connected with our work—viz., those requiring consideration from a commercial point of view—it seems to many of us quite impossible to get this class of question satisfactorily and adequately discussed before societies, however influential and well organized, which comprise among their members men representing absolutely conflicting interests, and it appears equally futile to discuss these questions before institutions including among the members the managers of electricity supply companies, whose object in developing their business—viz., to get the biggest return on the capital expended—is so entirely different to ours in trying to supply the greatest number of ratepayers at the smallest possible cost.

Under the heading of "Commercial Problems" must come the important question of the proper organization of the electrical staff—that is to say, how to so organize a staff and separate the undertaking into separate departments as to be able to define the duties and responsibilities of each member of it, and to ensure against any discontinuity in the business in case of illness or resignation of the chief officers..

Another most interesting and still unsettled point is what should be the basis on which to calculate the cost of energy wasted in feeders, transformers, etc., for the purpose of determining the relative cost of different systems of distribution. I have not yet succeeded in meeting two men agreed as to how this should be done. Again, it has not yet been generally recognized, as some think it ought to be, that it pays a corporation

to cater in our industry for the same class of people that proves so remunerative to the railway companies—viz., those who choose to travel third class—and that it would probably be very much more advisable for corporations to run mains in their districts than only into the districts occupied by the houses of the rich and often-absent residents or the early-closing shopkeepers.

With regard to the last group of questions, those of technical interest, which to most of us are infinitely more attractive than those of commercial expediency, it is hardly necessary for me to do more than enumerate many of the most pressing problems. Foremost among these, in my opinion, must surely stand the question of what should be considered the best system of distribution of electricity to any particular town or district. That the present state of things cannot be finality is obvious when we bear in mind how numerous are the different methods at present advocated and in use for towns of comparatively the same class. In connection with this battle of the systems must be decided the proper voltage of supply to be adopted by works to be erected in the future, also whether it is advisable, and, if so, in what state of their progress, for works in actual operation to raise their voltage of supply, and the best method of effecting the change. I only wish I could see a chance of our discussing within the next year or so such specially interesting technical problems as the advisability of earthing the neutral conductor of a low-tension system of supply, the most suitable class of mains to adopt, the proper size of feeders and generating units, the advisability of adopting for commercial, if not technical, reasons one uniform periodicity for alternating current plant, the wisdom of interconnecting all the low-tension network of a town, etc.

"ELECTRICITY SUPPLY AT 220 VOLTS."—BY A. S. BARNARD.

The author dealt chiefly with the advantages and disadvantages of the use of 220 volts on the distributing mains, and thought it was probable that many engineers whose stations were at present working at 100 to 110 volts would gradually persuade their customers to take a supply of 200 to 220 volts, which would at any rate be an immense gain to the supply work. He considered that in the majority of cases the change likely to be made would be the doubling of the pressure throughout. The advantages of the changes were, briefly, as follows: (1) existing mains can supply twice as many customers, at the same time reducing the percentage of loss in the cables by one-half; (2) variations and fluctuations due to the switching on or off of motors or large groups of lamps, or carelessness in switching dynamos in or out at the station, are all reduced by at least one-half; (3) new customers can be supplied at a much greater distance from the station. After considering the effect the change would have on present systems, the author proceeded to explain how it would affect the wiring and fittings on consumers' premises. As far as present experience went, there was little, if any, increased danger of fire by adopting 220 volts. In regard to the necessity of a higher efficiency lamp, he adduced evidence to show that 220-volt lamps could be obtained which compared very favorably with the 110-volt lamp.

"ALTERNATING CURRENTS AND HIGH VOLTAGE LAMPS."—BY W. H. COUZENS.

The author's object through the paper was to bring before the notice of the association some of the cases in which high-voltage lamps would prove of service to the alternating engineer. In the first place, it would lead to the extension of the substation system of distribution to scattered residential districts to take the place of distributed transformers; and, secondly, the substitution of increased pressure in these places would be a comparatively simple matter. Alternating current engineers had been slower to take up this question, as it had not been forced so necessitously upon them. He had every reason to believe that the advantages of increased pressure and reliability of lamps would make themselves felt in the near future.

"MUNICIPAL CONTROL OF WIRING."—BY C. H. WORDINGHAM.

Mr. Wordingham gave a short abstract, in which he pointed out that much doubt existed as to what power municipal authorities had for making regulations for the control of wiring, and although it was greatly to be desired that the Board of Trade should assist municipalities he showed that there did not appear to be much prospect of this being done. The authority given by provisional orders was found not to be sufficiently definite for the purpose, and other orders must be obtained. Having mentioned the course adopted by the Glasgow Corporation, he said, although that was good, something more was wanted, and advocated the appointment of the municipal electrical engineer as a kind of consulting engineer. He also advocated a fee being charged. This fee would be small in case of a very small consumer, and, of course, larger for a larger consumer. Among advantages which would accrue from such a course he enumerated that of the security to a consumer in being able to obtain impartial and good advice, and of having his work done under proper supervision instead of the consumer being left to the interested advice of contractors. He felt this was a better alternative to the corporation carrying out the wiring themselves, which course would be far more likely to cause friction. The author proceeded to suggest the various headings under which these rules might usefully be framed, and the paper concluded with two suggested resolutions to be proposed for adoption at the convention for the carrying out of this object.

"COST OF ELECTRICITY SUPPLY."—BY ARTHUR WRIGHT.

The author pointed out that at present no very definite basis had been decided upon by which to calculate the cost of electricity supply, and illustrated the uncertainty on this question by the fact of so many different tariffs being still in existence. He discussed the usual methods of averages and that of Dr. Hopkinson, and as no one had hitherto published the results of applying the latter to actual figures, he proceeded to do so with those of the Brighton undertaking for the year 1895, using two methods, which he submitted were based on Dr. Hopkinson's method. He then discussed how each consumer's proper proportion of the standing charges should be apportioned, and gave the method adopted by the Brighton Corporation in ascertaining this. Having agreed on a basis on which to estimate the cost of supply to any one consumer, he then pointed out that it was possible to make a profit and loss account for each year showing those consumers who proved profitable and the reverse. He then recorded some important conclusions which followed from this analysis of electricity costs, among the most important being that he considered that it was the duty of a municipality to charge on a system of uniform rate of profit rather than a uniform price. He stated that the extremely low price at which electricity could be supplied on the former basis more than compensated for its comparative complication. He stated, in his opinion, that it was erroneous to suppose that the cost of supplying short-time consumers, such as offices, etc., would very much diminish as the business increased, as the cost of this class depended almost entirely on the standing charges, and not on the running costs. As an illustration of the effect of these standing charges, he pointed out that it cost two and one-half times as much to supply a unit to a consumer who used his light on the average one hour per day as it did to another who used it three hours. It was far easier, in his opinion, to reduce the average cost of producing electricity by improving the load factor than attempting to make the same reduction by economizing coal. It was also the small householder and his shopping districts which afforded a more promising field for electricity supply than the residential quarters of the rich, and he pointed out that one of the most important corollaries from this theory of the cost of electricity was that streets could be lighted by electricity cheaper than by any other form of illuminant of the same candle-power, and probably the cost per unit for supplying this class of consumer and basements would not much exceed 1½d.

"CABLE SPECIFICATION AND TESTS."—BY JOSEPH A. JECKELL.

The author said he was of opinion that it was fairer and better both for contractors and corporations if it was clearly stated in the specifications exactly what cable was required, and the tests could then be more conveniently specified. Tinned copper wire having 100 per cent. conductivity could now be obtained. The best way to get over the difficulties of difference between the conductive resistance of cables was to specify the resistance the cable has to have, and the number of strands of which it is to be composed, leaving it to the manufacturers to put in 100 or 98 per cent. of copper as they liked. If a concentric cable was required, care should be taken to specify that the copper resistance of the outer conductor should be the same as the inner. High insulation was not necessary per se, but it was necessary in the case of rubber cables to ensure good material and workmanship. The pressure test was advisable in all cables, but more especially compound ones. The bending test was advisable in specifications for compound cables. With regard to the laying of cable mains, he felt it was an advantage that the makers should lay their own, but should not do the trench work, which would be more conveniently done by the corporation. Whatever tests were specified as having to be conducted at the maker's works should be repeated as far as possible after the cables had been laid and jointed up. The insulation tests would be made after one month's electrification, but there was no reason for this generally accepted time limit. It was advisable, but awkward at times, to obtain a long time guarantee.

"ELECTRICITY WORKS RECORDS."—BY A. B. MOUNTAIN, A. M. I. E. E.

In this paper the author said he only attempted to give an idea of the chief records required. Some such records must

be kept by almost every engineer, and in certain electricity works the necessary clerical assistance was not provided, so that the engineers had not the means of getting the items of expenditure in detail which enabled them to make comparisons with other works. The forms illustrated in the paper were the general records that were absolutely required in the works. The cost-sheet showed the several items to be recorded for one month's expenditure. The time-sheet showed the time of any man, and the cost of such time and the work on which he was employed. The engine-room cost-sheet would give the details required from the engine-room, with the general stores required and the chief points which it was desirable to have a record of. There were also tables to give records of high and low tension mains and plant testing, and a daily log-book, a line-test record, and a consumer's register. There were many engineers, said Mr. Mountain, who had devoted considerable time to the matter of keeping these records and tests, and he thought it would be very desirable for the executive committee to obtain further information as to how electricity accounts should be kept so that a comparison between works might be more accurately made. He suggested that it would be better to get a committee appointed to go into the matter, and bring up again at the next convention a more complete form covering the whole of the points in connection with the subject of his paper. He moved a resolution to that effect. The resolution was agreed to.

"ON THE ORGANIZATION OF AN ELECTRICITY WORKS STAFF."—BY E. T. RUTHVEN MURRAY.

As the success of an electricity works depends in no small degree upon the staff directly engaged in running the plant, the organization of this staff requires considerable judgment on the part of those responsible for their engagement. It behoves the engineer to be particularly careful and far-seeing in engaging a staff to keep the wages item of the standing charges as low as is consistent with safety, since when the output is small this item is a heavy burden on the young station. No hard-and-fast rules can be laid down as to the number of men necessary on the staff, as this will depend upon the individual characteristics of the electricity works. Among other matters to be considered which have a direct bearing upon this are the size of the works, their designs, the system employed, whether a direct-current battery station or an alternating-current supply, and, of course, whether the supply is constant or intermittent. Unless there be a large demand throughout the night for public lighting, or an intermittent demand both by day and by night for motors, the small battery station may be able to give a constant supply with only one watch of men, whereas the alternating-current station will require three eight-hour watches. How many men are required for a watch will depend upon the size of the works; but probably it will be necessary to have at least one engineer in charge, one driver, and one fireman. Regarding assistant engineers, it seems only right and proper to employ them, as one can hardly expect either the engine-drivers or switchboard attendants to have the necessary technical training to enable them to take entire charge of the works during the absence of the chief engineer; moreover, it is obviously necessary to give some one man the general responsibility of the proper working of the station during each watch. In organizing the staff, it is most important that the engineer be allowed to choose or recommend men for appointment, and that the men know to whom they are responsible. It is the greatest mistake for the committee who have charge of the department not to allow their chief engineer a free hand in this respect, and internal troubles in electricity works have often been due to this cause.

On Friday morning, after holding a business meeting for the purpose of electing officers for the ensuing year the convention ended with a visit to Brighton, whose electric lighting is under the direction of the association's first president. After addresses of welcome by Mayor Blaker and Councillor Stafford on behalf of the corporation lighting committee a paper was read in abstract by Mr. A. H. Gibbings, on the subject of "Extensions to Outlying Districts." With the short discussion following this paper the convention was closed.

SHERWOOD, MICH.—The Village Council has granted a fifteen-year franchise for the installation of a complete electric lighting and power plant to Rheubottom & Bond, of Union City, Mich. It is expected that work will begin on the plant at an early date.

MR. S. EDGAR WHITAKER, who was in charge of Professor Elihu Thomson's exhibit at the National Electrical Exposition, has returned to Lynn. His work in demonstrating the apparatus was highly successful and gave great satisfaction to the public and everybody interested.

MISCELLANEOUS.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES.[1]—I.

BY J. A. FLEMING, M.A., D.S.C., F.R.S., M.R.I.

DURING the last four years much time has been spent by Professor Dewar and by me in the prosecution of a joint research on the principal electric and magnetic properties of metals at very low temperatures. Some reference has already been made in previous discourses by Professor Dewar to portions of this work[2], but the special object of the present lecture is to extend these descriptions, and put you in possession of the latest results in this department of the low-temperature investigations. It will be convenient to discuss the several divisions of it in the order in which they have engaged our attention.

One hundred and sixty-seven years ago, Stephen Gray, pensioner of the Charterhouse, in conjunction with his friend Granvile Wheler, stretched a packthread 300 feet long over silk supports and demonstrated that an electrification of the thread at one end spread instantly over the whole mass, but that if metal wires replaced the silk no electrification of the thread was possible. This experiment undoubtedly formed the starting point for the first definite recognition of the necessity for a classification of bodies into insulators and conductors, a distinction which Gray's brilliant contemporary, Dufay, extended and confirmed, and for which he and Desaguiliers coined these familiar terms[3]. Gray's contributions to knowledge as an epoch-making discoverer have received less notice from scientific historians than their real value deserves. It is less easy to state who first noticed that the powers of conduction and insulation were greatly affected by temperature. Cavendish in 1776, however, was perfectly familiar with the fact that warm solutions of salt conduct electricity better than cold[4], and made measurements of the relative resistances of an iron wire and a salt solution marvelously accurate when we consider that his means of measurement was the comparison of electric shocks taken through the bodies to be examined.

Not until after the invention of the battery and galvanometer was it clearly proved that differences exist between the conducting powers of metals; but by Davy, Becquerel, Ohm, Pouillet, Fechner, and others all the fundamental facts were ascertained and the classical researches of Wheatstone and later of Matthiessen gave us the accurate laws and constants of electrical conduction. By these investigations it was shown that in the case of electric conduction through metallic wires of uniform sectional area their total resistance was proportional to the length, inversely as the cross-section, and also proportional to a specific constant for each material called its resistivity. Moreover, it was found that this resistivity was considerably affected by temperature, generally being increased in metals by rise of temperature and decreased for carbon, electrolytic liquids, and many badly-conducting bodies.

Although much knowledge of the behavior of pure metals and alloys in regard to electric conduction has thus been accumulated, we considered that it would be of great scientific interest to examine with care the changes occurring in the conductivity of these bodies, or reciprocally in their resistivity, when cooled to temperatures of 200 degrees or more below the Centigrade zero by the aid of liquid oxygen and liquid air[5]. Knowing the great influence of very small quantities of impurity on this quality, our first attention was directed to obtaining samples of alloys and metals in a state of great chemical purity, in giving to wires drawn from them a suitable form, and in devising a convenient support, or holder, by which the electrical resistance of the wire might be measured when immersed in liquid oxygen or liquid air, either in quiet ebullition in an open vessel or under reduced pressure in a closed one. It will be unnecessary to dwell on difficulties surrounding the preparation of these accurately-drawn metallic wires of pure metals. Suffice it to say that our obligations to Mr. George Matthey, Mr.

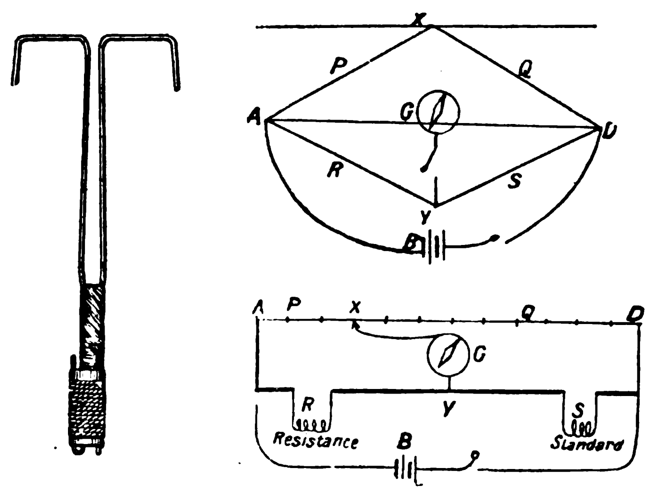
[3]See "The Intellectual Rise in Electricity," by Park Benjamin. Stephen Gray's papers on this subject communicated to the Royal Society are as follows: "Phil. Transactions," 1720, vol. 31, p. 104; 1731, vol. 37, p. 18; 1732, vol. 37, p. 285; 1735, vol. 39, p. 16; 1736, vol. 39, p. 400. See also Dufay, "Phil. Trans.," 1733, No. 431, p. 258.

[4]See "The Electrical Researches of Cavendish," edited by Clerk Maxwell, p. 234.

[5]Almost the only experimental work previously done in this subject seems to have been that of Cailletet and Bouty ("Journal de Physique," July, 1885) on the resistance of metals at —100 degrees C., using ethylene as a refrigerating agent, and a research by Wroblewski on the resistance of copper at very low temperatures ("Comptes Rendus," 1885, vol. cl., p. 161).

Edward Matthey, Mr. J. W. Swan, and other friends, were very great, with respect to this portion of the work. The final outcome of all failures was the production of a resistance coil of the following form: Two thick wires of high-conductivity copper about 3 mm. or 4 mm. thick are bent, as shown in Fig. 1, and wrapped round the lower part with a cylindrical sheath of thin vulcanized fiber laced to them by a silk thread. On this sheath, which generally had the form of an oval cylinder, a paraffined silk cord was spirally wound so as to leave a helical groove. In this groove was coiled the resistance wire of known length and section, and its ends were attached by solder to the ends of the thick copper leads. The wire was wound a little loosely in the groove so as to allow for the great contraction which takes place on cooling, and yet the wire was exposed, so as to take up instantly the temperature of the bath, whilst at the same time the mass of material to be cooled down was rendered as small as possible. The length of wire employed was generally about one or two metres, and the diameter from about one-twelfth to half a millimetre (.003 inch to .02 inch). These mean diameters were measured by the microscope micrometer at about 50 to 100 places for each metre length of the wire. Having thus prepared a great collection of resistance coils of pure metals and alloys each in the form of a wire of known length and mean diameter, the next operation was the measurement of their resistance at definite temperatures. For the sake of those not fully familiar with the details of electrical measurement, a moment's digression may be made to explain two of the principal methods in use. Becquerel's



Figs. 1, 2 and 4.

work was chiefly conducted with the differential galvanometer. In this instrument two coils of wire of exactly equal length are coiled on one bobbin, in the center of which hangs a small magnetic needle. The current from a battery divides at one point and flows around one path through the conductor under examination and through one coil of the galvanometer. The other portion of the current flows through a wire of variable length, called a rheostat, and through the other coil of the galvanometer, equal in every respect to the first coil, but circulates round the needle in an opposite direction to that of the current in the first coil. Hence, if the currents are of equal strength, the needle is not disturbed at all from its zero position. We can make these currents equal by adjusting the length of the wire of the rheostat so that its resistance is equal to the resistance of the coil being tested. By this means it is easy to verify all the ordinary laws of conduction. We can, for instance, show at once that by warming an iron wire in hot oil its resistance is increased, whereas in warming the carbon filament of an incandescent lamp its resistance is decreased.

This method is not generally so convenient as the arrangement first described by Mr. Hunter Christie to the Royal Society in 1833, redevised ten years later by Wheatstone, in 1843, and which has been always curiously misnamed the "Wheatstone's bridge," even in spite of Wheatstone's own declaration that he did not invent it*. In this arrangement (see Fig. 2) the current from a battery, B, has two paths open to it by which to complete its circuit, and we employ a galvanometer with a single coil to discover two points on these two circuits which are at equal potentials. When these two points are connected the galvanometer needle is undisturbed, and it is a simple matter to show that under these circumstances the numerical values of the electrical resistances of the segments of the two circuits are to one another in simple proportion—that is, P is to Q as R is to S. In actual work, one form which this arrangement takes is that known as the slide-wire bridge (see Figs. 3 and 4), and which is before you. In this construction the battery current flows partly through a uniform wire stretched over a scale and partly through a standard resistance, S, and the resistance, R, to be tested placed in parallel with it. We

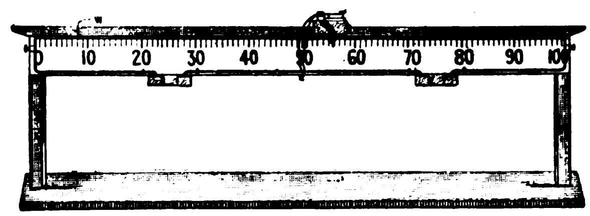


Fig. 3.

employ a galvanometer to connect the middle point between R and S with some point on the slide wire, and we can always find a point on the slide wire such that no current flows through the galvanometer. The ratio of the unknown resistance, R, is to that of the known standard resistance, S, in the ratio of the lengths of the two sections into which the contact-piece divides the slide wire. Hence, R is determined in terms of S. Another form of this appliance, in which all three arms of the bridge consist of coils of wire capable of being joined in series with each other by plugs, is most commonly used, and it was a most carefully adjusted Elliott bridge of this last pattern which we employed.

All our resistance measurements have been reduced to express them in terms of the international ohm as defined by the Board of Trade Committee and obtained by reference to standard coils carefully standardized for us at Cambridge. By this means the whole of our wires were measured at five definite temperatures—viz., at about 200 degrees C.; at the temperature of boiling water, 100 degrees C.; at the temperature of melting ice, 0 degree C.; at the temperature of solid carbonic acid melting in ether, which gives a temperature of about — 78 deg. C., and at the temperature of liquid oxygen boiling under a pressure of 760 mm., which gives a temperature at — 185 degrees C. In this last case the coils were immersed in liquid oxygen contained in suitable vacuum-jacketed vessels. In this connection I should like to express with due emphasis the opinion that none of this low-temperature research would have been possible at all without the assistance of Professor Dewar's most valuable invention, the glass vacuum-jacketed silvered vessel. For much of this work it has been necessary to employ many litres of liquid oxygen and air at a time and to be able to keep it for hours in a state of perfect quiescence and absolutely constant temperature, and in no way could this have been done without this beautiful and scientific device.

Before describing the results of these experiments it may be interesting to exhibit a few of the principal facts. The most striking of them is the very great reduction in electrical resistance or increase in conductivity experienced by all the pure metals when cooled in liquid air. Here, for instance, are two coils of iron wire. Balancing them on the bridge, we find them to be of exactly equal resistance; but if one of the coils is cooled in liquid air, its resistance is reduced to about one-tenth of its resistance at the ordinary temperature of the air. We

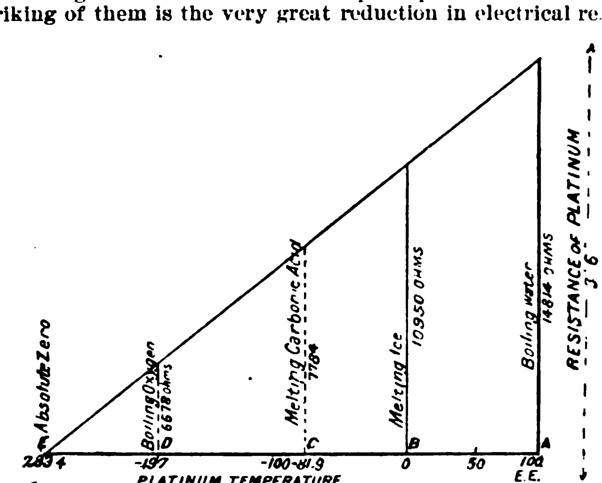

Fig. 5.

*See "Phil. Trans.," 1833: Mr. S. Hunter Christie on "The Experimental Determination of the Laws of Magneto-Electric Induction." See also Wheatstone's "Scientific Papers," p. 129, "An Account of Several New Instruments for Determining the Constants of a Voltaic Circuit" ("Phil. Trans.," vol. 133, p. 303, 1843).

may also compare the resistance of these two similar iron coils when one is placed in boiling liquid air and the other in boiling water. The resistances, instead of being in the ratio of 2 to 1, are now in the ratio of 1 to 12. Again, if we take two wires, one of pure iron and one of pure copper, of exactly equal length and equal section, we find that at ordinary temperatures (15 degrees C.) the iron wire has about six times the resistance of the copper; but if we cool down the iron wire in liquid air to 186 degrees C., still keeping the copper coil at the ordinary temperature (15 degrees C.), we now find that the iron coil has actually become a much better conductor (about 30 per cent. better) than the copper.[7] On the other hand, if we examine the behavior of this coil of German silver, which is a copper-zinc-nickel alloy, or of this platinum-silver coil, we find that the cooling through 200 degrees has but little effect upon its electrical resistance. We thus see that whilst pure metals have their electrical resistance immensely decreased by cooling to the temperature of liquid air, alloys generally do not experience anything like so great a change. A word or two must next be said on the manner in which we have represented graphically all the results of our experiments. We desired to delineate lines on a chart so as to express the change in specific resistance of all our metals and alloys in terms of temperature, and the question then arises, How was the temperature measured? You already know that an ordinary thermometer, whether mercury, alcohol, or air, would be useless to measure temperatures at which even air liquefies under ordinary pressure.

The employment of the constant-pressure hydrogen thermometer with reduced pressure would have given us temperature readings very approximately those of the absolute thermodynamic scale, but the experimental difficulties of its use would have been enormous. We preferred to use the platinum resistance thermometer and to express our temperatures in platinum degrees, as follows. Our experience has shown us that a pure, soft-annealed platinum wire may be cooled as often as necessary to the lowest attainable temperatures, and yet will always have the same resistance when measured again at other constant temperatures. Availing ourselves of this fact, we have used in all this work a low-temperature platinum thermometer made in the following way: A well-annealed platinum wire is made into a resistance coil, as already described. Its resistance is carefully measured at the temperature of boiling water (100 degrees C.) and melting ice (0 degree C.). From these measurements we construct a scale of temperature as follows: A horizontal line (see Fig. 5) is taken on which to mark off temperature, and any two points are taken on this line and divided into 100 equal parts. At these extreme points perpendiculars are set up proportional to the resistance of the platinum wire at 0 degree C. and 100 degrees C. respectively, and through the tops of these perpendiculars a sloping straight line is drawn until it cuts the axis of temperature. The graduation of the horizontal line is continued in both directions on the same scale as the sub-division of the line between the points marked 0 and 100. To measure and define any other temperature—say, for instance, the boiling point of liquid oxygen under a pressure of 760 mm.—we have simply to measure the resistance of the platinum wire in the oxygen. We then look out on the chart the ordinate which has the same numerical value as the resistance of the wire in the oxygen, and at the foot of that ordinate we find a number—viz., (—197—which is the temperature of the liquid oxygen on this platinum scale. Two questions then arise: first, Do all annealed platinum wires give, when used in this way, the same numerical values for definite and identical temperatures? The answer to this is, Nearly, but not quite. In the case of two thermometers much used by us the difference was about half a degree at —100 degrees C., the boiling point of liquid ethylene. Into this matter it is not possible here to enter more fully; suffice it to say that we have invariably reduced our temperature measurements to one standard thermometer. The second question is equally important; it is, What is the relation of the scale of temperature so defined, to the absolute thermodynamic scale, or, which is very nearly the same thing, to the scale of temperature defined by a constant-pressure hydrogen thermometer? If the air thermometer and platinum thermometer readings are made to agree at 0 degree C. and 100 degrees C., then a temperature which would be called 50 degrees on the Centigrade scale would be denoted by 50.4 (nearly) on the platinum thermometer scale, and corresponding to the —78 degrees on the Centrigrade scale, which is the temperature of carbonic acid melting in ether. The platinum temperature by our standard is —81°.9, and corresponding to —182 degrees C., which is very nearly the Centigrade temperature of liquid oxygen boiling at the normal pressure of 760 mm.; the platinum temperature by the same standard is —197 degrees. The conversion of these numbers representing low temperatures in platinum degrees into the numbers representing the corresponding absolute thermodynamic temperatures is a work we have reserved for a future research,[8] but meanwhile it may be said that there is no method of measuring low temperatures which is so easy of application and so accurate as that depending on the use of a platinum thermometer. All our work has been ultimately referred to one standard platinum thermometer, which we call P_1. A suggestion may here be made. There is no reason why the Board of Trade electrical laboratory should not possess a standard platinum thermometer defining officially platinum temperatures, or absolute, for all time, and with which other platinum thermometers could be easily and very accurately compared.

[7]The exact resistances of the coils used for the experiment were as follows: Iron at 16 degrees C. = 7.003 ohm and reduces to 0.711 ohm at —186 degrees C. Copper at 16 degrees = 1.169 ohms; reduces to 0.2033 at —186 degrees C.

[8]Callendar has shown that over a wide range of temperature, from 0 degree C. to 700 degrees C., the difference between the platinum temperature and the air thermometer temperature is a parabolic function of the absolute temperature.

AN EXPERIMENTAL STUDY OF THE ELECTRO-MOTIVE FORCES INDUCED ON BREAKING A CIRCUIT.[1]

BY F. J. A. McKITTRICK.

THE arrangement of apparatus used in the investigation is shown in Fig. 1, in which C is an electro-magnet through which a current is flowing from a battery in the branch A; B represents a galvanometer placed in series with a high resistance in parallel with C at the points F and G; L is an arc lamp.

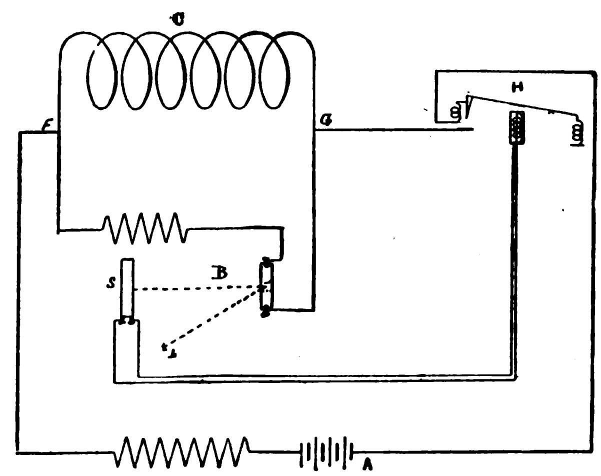

FIG. 1.

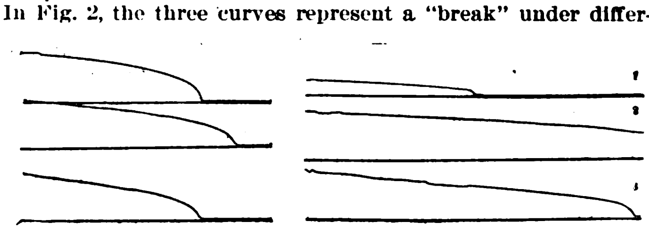
and S a slide in which a photographic plate drops; H is a form of circuit breaker placed in A and controlled by an electro-magnet operated by an auxiliary circuit. When a current is flowing in this auxiliary circuit, the terminals in the breaker are held in contact against the force of a spring and the circuit through C is complete. The plateholder, in dropping, aperates a trip which breaks this auxiliary circuit, and hence the main circuit, the effects of the break being recorded on the plate.

Since the phenomenon which we wish to study occurs when the circuit A is broken, it is well to examine what happens when a circuit through which a current is flowing is opened, and by what law the current falls to zero.

In Fig. 2, the three curves represent a "break" under different conditions. The curves are traced from left to right. The three straight lines are the three reference lines, approximately zero lines. Beginning at the left, the straight part of each curve represents the steady deflection of the needle, the distance of this deflection from the zero line being proportional to the strength of the current. The point at which the "break" begins



FIGS. 2 AND 3.

[1]Abstract of a paper read before the Amer. Inst. Elec. Engrs.

is clearly marked by a slight notch. From that point the curves fall away, approaching the reference line quite slowly at first but abruptly at the end. From the point where the "break" ends, the curves run parallel to the reference line.

Fig. 2 (1) is a "break" in which the terminals of the circuit-breaker are of copper; e. m. f. of the circuit is 170 volts, L, the self-induction, .029 henrys, and I, the current flowing before the "break," 5.2 amperes. The time taken by the spot of light to trace out any part of the curve is found by comparing the curve with the vibrations of a tuning fork of known pitch photographed on a plate dropping at the same speed. Since in all cases the plateholder fell quite freely, it can be assumed that the speed of all plates in passing the slit was the same. The duration of the spark in Fig. 2 is in this way found to be .065 second.

Fig. 2 (2) shows a "break" when the breaking terminals were of brass, all other conditions remaining as in (1). The time of duration of the spark is .075 second.

Fig. 2 (3) shows a "break" under the same conditions as (2), except that the spring of the circuit-breaker is strengthened, thus separating the terminals more quickly and hastening the destruction of the arc. The time of duration of the spark is .068 second.

Fig. 3 (2) and (3) show "breaks" with brass and copper terminals, respectively, in which the current is the same as in Fig. 2, but the spring of the circuit-breaker, weaker. The spark in (2) lasts longer than one-ninth of a second, so that its ending is not recorded in the plate. In (3) the terminals are of copper and the spark again ends more quickly than with brass terminals.

No.	*I* in field amperes.	Duration spark.	Induced e. m. f. volts.
1	20.5	.08	430
2	21.2	.07	395
3	11	.05	365
4	20	.08	355
5	32	.08	290
6	42	.14	265
7	20	.02	475
8	20	.02	505
9	32	.03	530
10	32	.02	585
11	11.5	.04	370
12	12	.06	490
13	13	.05	295
14	13	.02	340
15	29	.02	710

From the curves shown above, we gather that the arc formed by a break is exceedingly variable in character and duration, and that the e. m. f.'s induced by the break vary with the arc formed.

We note that the duration of the arc depends upon:

I. The current flowing at the instant of break.

II. The e. m. f. of the battery in the branch A. An increase of the battery e. m. f., other things being equal, always increases the duration of the arc.

III. The speed at which the terminals of the circuit-breaker are separated. Increase in the speed at which the terminals of the circuit-breaker are separated hastens the destruction of the arc.

IV. The metals of which the terminals are composed. We have seen in Figs. 2 and 3 that a break by copper terminals is of shorter duration than a break from brass. A break with zinc terminals does not seem to differ greatly in duration from a similar break with brass. (b) The character of the arc formed varies, of necessity, with any condition that affects the duration of the arc. In particular, however, zinc terminals seem to produce a very irregular arc. (c) The e. m. f.'s induced by the break, as indicated by the induced current flowing through B, vary also of necessity with any condition that affects the duration of the spark. The maximum induced e. m. f. varies with:

(1) The current flowing at the instant of break. (2) The e. m. f. of the battery. (3) The speed of breaking.

During the past winter, experiments were made with the aid of Mr. W. J. Lester to determine the e. m. f. induced in the field of a motor when the current flowing through it is broken. The motor used was a Thomson-Houston, No. 3322, Class 30 R. 500 volts. The field coils in parallel had a resistance of 2.05 ohms and a self-induction of .15 henry. The arrangement of apparatus was the same as in the diagram, described above (Fig. 1). The above table gives some of the results obtained:

MR. S. B. TOLAN has been appointed architect for a new court house to be built at Fort Wayne, Ind., for Allen County. A fine electrical plant will be required.

AUSTRALIA AS A FIELD FOR ELECTRIC SUPPLY.[1]

BY J. A. DAWSON, A. I. E. E.

It may be of some interest to your readers to hear a little on the above subject from an Australian standpoint. There are several important factors to be considered when entering into the question of electricity supply in any part of the world, the chief ones being, I think, the cost of fuel and the selling price of gas, the first having an important bearing upon cost of production of electricity, and the second upon the price per unit which can be charged to successfully compete with our old-established rival.

Now, so far at any rate as the Eastern colonies are concerned, these conditions are decidedly favorable to the electricity supply company. We have an unlimited supply of cheap fuel and the ruling price of gas is very high. Our principal coal-producing districts are Newcastle and Bulli, in New South Wales, and Gippsland in Victoria. The latter mines have only been opened up of late years, and produce a very good coal, though not equal to the Newcastle coal for steaming purposes, by about 25 to 30 per cent., yet it will probably be put on the market in the near future at such a rate as to make it cheaper for Victorian consumption than the imported coal which at present is principally used in all the Colonies, and is now supplied at the seaboard at from 12s. 6d., and inland at 18s. to 25s. and 30s. per ton, according as the distance from the seaboard increases. Then again in most of the Colonies there are supplies of good firewood sufficient for generations to come, the inland cities and towns being practically surrounded by forests, and experience shows that for steam raising purposes four tons of, say, Victorian firewood are equivalent to one ton of Newcastle coal, which is our standard. This firewood can be delivered at the works at from 3s. per ton in some districts to 5s. per ton in others, so that in the far inland towns, where coal would cost, say, 30s. per ton, firewood is substituted which actually gives us fuel equal to coal at 12s. to 18s. per ton, thus keeping the cost of production of electricity very much lower than it would otherwise be. This cuts two ways, as our gas competitor must bring his coal by rail from the seaboard at the higher rate, and must charge a high price for gas—in many places it is 10s. and 12s. 6d. per 1,000 feet—while the Board of Trade unit could be produced at a comparatively low figure, and sold at a high one, say, 1s., thus giving the electricity supply company a double advantage. In the provincial cities of Victoria gas is not less than 7s. per 1,000 feet, and best steaming coal 18s. to 20s. per ton. Electricity should be produced in these cities for, say, 3d., and sold for 7d. or 8d. per unit, and at that rate easily compete with gas and show a good margin of profit. Then, again, many of these cities and towns are important mining centers, with numbers of large payable mines abutting on the leading streets along which supply mains must pass, and these will undoubtedly become consumers both for light and power, and, what is of great importance, will give a steady day load, and thus materially assist in maintaining a good "load factor." Climatic conditions also are favorable, the hot weather experienced in the Colonies making the electric light much more welcome than gas.

A question which is sometimes asked is, Are the existing supply companies in Victoria paying? Detractors say, No. We say, Yes; they are paying, not dividends to shareholders, but a high rate of interest to the banks from which most of the companies have borrowed a large proportion of their capital—a circumstance due to some of the companies commencing operations just about the time of the great financial collapse. Their annual reports show a credit balance over working expenses of from 8 to 10 per cent. on their capital outlay, and each year these companies are extending their mains—to meet the increasing demand—and carrying out other works, all of which have to be paid for out of revenue, and this during a period of financial and business depression, when almost every other industry is languishing. With the return of prosperity, of which there are evident signs, and under the recent Electric Light and Power Act of Victoria, giving supply companies a tenure of 30 years, with option of renewal or selling to Local Authority at the expiration of that time, electricity supply companies will take their right place, and, on the whole, their outlook for the future is very bright.

MR. HENRY F. COTTLE, of Charlestown, has just been appointed chief of the department of electrical construction of Boston, by Mayor Quincy. This department has been only recently created, and as its chief, Mr. Cottle will have general supervision of all the electrical work belonging to the city.

[1] London "Electrician."

AN ELECTRICAL IGNITER FOR GAS ENGINES.

AN ingenious igniting device for gas and petroleum engines has been invented recently by Mr. Arthur A. Hamerschlag, of New York, which we illustrate diagrammatically in the accompanying engravings. The object of this device is to provide a simple and effective means for supplying electric impulses of equal intensity to two or more igniting devices simultaneously from a single source of current in order to accomplish the simultaneous explosion in two or more cylinders of a gas engine.

This can be done either by passing a current through the divided sections of a sparking coil, the igniting devices being

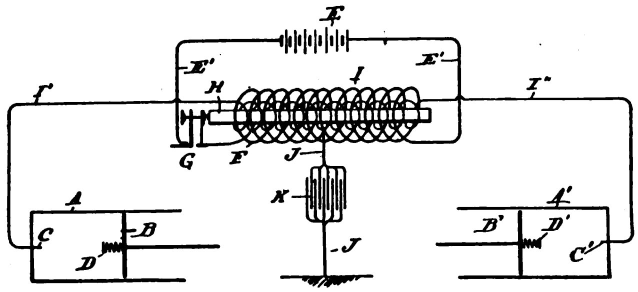


FIG. 1.

in circuit with the divided sections of the coil, by obtaining the impulses from divided sections of the secondary coil of an ordinary induction coil, or by connecting the electric igniting devices in the secondary circuit to a common return connected to the primary coil.

The essential features of the device will be seen by reference to the illustrations, Figs. 1 and 2, which are lettered correspondingly. A A' represent engine cylinders in which the pistons, B B' work. C C' are sparking points, supported in the ends of the cylinders from which they are insulated, and D D' are spring supported contacts mounted upon the pistons, the latter being electrically grounded through the engine cylinders and frames. E is a battery and E' is a circuit wire leading from the battery to the primary circuit, F, of an induction coil. I is the secondary of the induction coil, each end of which is connected to the sparking contacts, C C'. A wire, J, connects one of the central convolutions of the secondary coil with the ground, forming two circuits through the sections of the secondary coil and sparking points of the engines.

The pistons, B and B' operate simultaneously toward and from the cylinder heads. It will therefore be observed that the contacts, C D, and D' C' will simultaneously touch and close or almost touch and close the circuits through the sections of

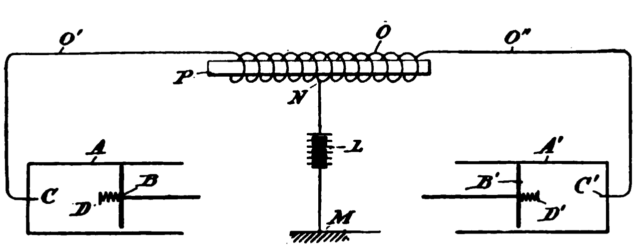

FIG. 2.

the secondary coil, I, and thereby produce sparks in the cylinders, A and A' simultaneously and of the same intensity.

A condenser, K, Fig. 1, is interposed in the ground-wire, J, connected to the center of the primary coil and forming the common return for the igniting devices in the secondary circuit.

Fig. 2 shows a circuit containing an ordinary sparking coil. In this arrangement the battery, L, is grounded at M and connects at N with a central convolution of a sparking coil, O, which is coiled around a soft iron bar, P. The opposite ends, O' and O'' of the coil connect with the contacts, C and C', respectively. It will, therefore, be observed that when the contacts, C D and D' C' engage, impulses will simultaneously pass through the divided circuit and cause sparks of equal intensity between the contact points.

PHENOMENA OF COMMUTATOR RESISTANCE.[1]

BY H. J. EDSALL AND M. C. RORTY.

PROBABLY owing to a belief that commutator losses, outside of friction, were unimportant no investigation of the question had been made until the spring of 1895, when Messrs. Cox and Buck, at Columbia College, experimented upon the effect of pressure in reducing contact resistance and determined the friction losses for different brushes.

Making the natural but unwarranted assumption that the the resistance was the same whether measured by means of one ampere of current or ten amperes, they entirely neglected the effect of varying current density.

The apparatus employed by the writers consisted simply of a commutator 5⅝ inches in diameter, made up of sixty-four hard copper segments, mounted upon a shaft having a pulley at one end to permit its being driven at any desired speed. To secure electrical connection from brush to brush a strip of sheet copper was wound around one end and carefully soldered to each bar. The results for the different pairs of metallic brushes tested were practically the same, and what variations there were in the runs made with carbon brushes may be laid rather to differences in the condition of the commutator surface than to any difference in the behavior of the brushes themselves.

Two typical series of readings were taken for metallic and carbon brushes. These observations were made upon a metallic leaf brush having a contact area of .4 square inch, and a carbon brush of the Eickemeyer type having an area of .2 square inch. The first pair had been in use on a 10 kilowatt bipolar Edison machine and the second upon a twenty-light Weston arc machine. The resistance curves are both hyperbolae, the one for the metallic brushes being equilateral. The behavior of the brushes is best shown, however, by the volt-ampere readings. It was found that the fall of potential is independent of current in the case of the metallic brushes and very nearly so for the carbon brushes. In many cases with metallic brushes the fall of potential was actually greater for very small currents than for the heavier ones. One pair gave 1.6 volts drop for four millionths of an ampere and only .7 volt drop for 50 amperes. The corresponding resistances are 400,000 ohms and .014 ohm respectively. These rather surprising results can only be explained on the assumption that the coating which forms upon the commutator surface is practically a non-conductor, and that each different current tears it apart to a different degree. This theory is supported by the behavior of the resistance when sandpaper is applied to the surface of the commutator. Under such circumstances the voltmeter reading falls practically to zero. With metallic brushes oil produces much the same effect by softening the film.

Besides testing the effect of current density upon the contact resistance runs were made to determine the effect of speed and brush pressure. These seemed to show that mere change in the velocity of rubbing had little or no effect, any increase of resistance with speed being due to increased vibration. These curves for resistance as a function of pressure agreed with those obtained by Messrs. Cox and Buck as to form, which was much like that of the curves for resistance as a function of current. In one case increasing the pressure of a metallic brush from one to six pounds per square inch caused a decrease of only 12 per cent. in the resistance. A pair of carbon brushes showed 28 per cent. decrease in resistance for an increase of pressure from ½ lb. to 5½ lbs. per square inch. It is seen from the above figures that brush pressure, within the usual working limits, is not a very important factor in determining the contact resistance.

The results of the experimental work may be summarized as follows:

1. Mere change in the velocity of rubbing has no effect upon contact resistance.
2. Within ordinary working limits increase of brush pressure causes only a slight decrease of resistance.
3. Sandpaper used occasionally upon a commutator will greatly reduce the losses through resistance.
4. Oil used with metallic brushes materially reduces the resistance, especialy for small currents. The effect is, however, temporary.
5. Both carbon and metallic brushes tend to reach a limiting condition in which the resistance varies inversely as the current.

ELECTRIC LIGHT RACE-TRACK AT CINCINNATI.

A new electric light race-track has been laid out at Rosedale, near Cincinnati. The track is a third of a mile in circumference, and has 1,000 lights, with powerful reflectors. The grand stand, fences, rails and outbuildings are all painted a glistening white, so as to intensify the lighting effects.

CONTENTS.

INDUCTANCE AS A NEGATIVE CAPACITY.

THERE is an impression in some quarters that the hoary electrical patriarch—submarine telegraphy—has been in a state of coma for years and that in its lexicon there is no such word a "progress." It is true that the general method of working cables has not changed materially during quite a number of years, but progress in many of the details has been steady and complete. Duplex working, for instance, on the longest cables is now universally successful, while automatic working is being rapidly introduced. The principal obstacle to progress has lain, of course, in the fact that the commercial capability of a given cable, more especially a long one, can only be increased by modifications of the terminal arrangements. The cable itself is constant when submerged, unless a fault develops and lowers the insulation. In some cases this increases the speed of working slightly for a time, but it is usually so troublesome that the submarine companies pray without ceasing for deliverance therefrom.

Nowadays, it is fashionable to make the cores heavier, that is, with more copper, and some remarkably successful trunk cables of this type have been laid recently. It is hardly necessary to say that the capacity of any system is the capacity of its longest section, while another point of great importance is the reserve capacity of the remaining cables in case of interruption of any in that section. The great obstacle to high speed working is, of course, the electro-static capacity, and great efforts are made to decrease this without impairing the mechanical strength or durability of the cable. As stated above, more copper is put in the core even at the expense of increasing the capacity, but this increase is wiped out by the reduced resistance and a lower time-constant is the result.

The veteran scientist, who has just celebrated his jubilee, was probably the first to draw attention to the value of inductance as a negative capacity. Since then Prof. J. J. Thomson has also written on this point, but it has received its amplest development at the hands of Mr. Oliver Heaviside.

The treatment, so far, has been mainly mathematical, and The Electrical Engineer, therefore, thinks it desirable to place before its readers, elsewhere in this issue, some experimental results bearing on this point. The experiments, while not conclusive on the value of inductance in a submerged cable, show that, in a coiled cable, the inductance effect can be made to eliminate the capacity effect. The matter is greatly complicated by the mutual induction of the coils and also by the impulsive character of the charge, as Mr. Heaviside has pointed out. The latter is of the opinion that, in this particular case, it is nearly possible to adjust the cable circuit so that it will act as a mere resistance to simple harmony currents, but his well-known "distortionless" circuit is the only one that will behave like a mere resistance to any sort of impressed voltage. Incidentally, the arrangement shown in the third illustration of Mr. Davidson's article may possible be modified to measure that wily and much-disputed quantity—the effective capacity of a metallic loop. In conclusion, we may point out, that the method adopted throughout has been used frequently in measuring inductances, more especially those of telegraph apparatus, and is another instance of the extraordinary adaptability of the Wheatstone bridge to all kinds of electrical measurements.

GENERAL STREET LIGHTING.

DURING the convention of the Street Lighting Association, held in New Haven, recently, the subject of street illumination was the foremost topic, and this was very fully discussed in all its aspects. One of the facts brought out prominently was that, although street lighting by means of either oil, gas or electricity, has been systematically practiced for a hundred years or more, we still lack a standard by means of which the efficiency of a street lighting system can be judged.

The object of general street illumination is broadly the preservation of public peace and the safety of night travelers,

but not to turn night into day. With this view of the subject it is apparent that there is as much objection to having too much light as there is to having too little, as in the former case, with more than sufficient light, so that one pedestrian may not approach another unseen, it is not only wasteful, but may be injurious in disturbing the natural hours of rest. Assuming this theory to be correct, several conclusions are at once apparent. First, considerable difference in the amount of illumination is desirable in the cases of residence districts, business districts and in the neighborhood of public places of amusement. The opinion seemed to prevail also that it would be preferable to have a uniform intensity of illumination from a large number of small light units rather than a succession of alternate light and dark spots as with lamps of very high candle power placed a considerable distance apart. The question is in this case not so much one of the absolute amount of illumination as that places in the shadows may be light enough in themselves; but to the pedestrian who passes from the glare of a high candle-power lamp into a shaded spot the contrast is so marked as to make the shadow appear for the moment like absolute darkness. While illumination of the business districts is generally easily and satisfactorily accomplished by means of arc lamps at the intersections of the streets, residence districts, especially where a large number of trees are found, are much more difficult to illuminate effectively. The city of New Haven, where the street lighting convention was held, is a good illustration in point. While the amount of light supplied by the arc lamps would be ample if no obstruction existed, yet during part of the year the foliage is so dense as to make the lights almost useless. Trees are certainly important to the beauty of cities and will not be legislated away for the benefit of the town lighting, and the problem remains to divide the light units into a larger number of small ones and place them on poles sufficiently low so that the distribution of light will be uniform under the foliage even if the illumination is in general the less intense.

THE UNDER-RUNNING TROLLEY.

THE upholding by the courts of the underrunning trolley patent has been followed by the filing of a large number of infringement suits by the electrical trust combination, and in several cases settlements have been made by railway companies sued rather than stand the expense and annoyance of a lawsuit. It was to be expected, however, that inventive genius would be soon at work to find new means of establishing electrical contact between the car and the overhead wires, and we illustrate on another page a device for which non-infringing properties are claimed. Whether or not this device comes under the Van Depoele patent is a question which the courts will probably be called upon to decide; but, be their decision what it may, we have full faith in the power of American inventive genius to devise a non-infringing overhead contact-making device, which will be practical in every respect. We have always been in favor of affording the patentee all reasonable protection in his rights and property, but when the possession of a patent is used as a club to compel the purchase of apparatus not covered by patents, then the circumvention of the patent acting in restraint of legitimate trade and competition is to be encouraged and as such welcomed.

Already we note a tendency toward the avoidance of the trolley in the adoption of the third rail on the Nantasket Beach road, and if it prove successful there the future equipment of such roads is hardly a question of doubt. On the other hand, the conduit and surface contact roads are coming to the front with rapid pace. The combine may for a time succeed, but they may, sooner than they expect, kill the goose that lays the golden eggs. We may also recall to convenient memory the history of the incandescent lamp patent and the barren victory achieved in that litigation.

It is a subject for congratulation that at least one large company has thrown down the gauntlet to the Trust and proposes to make a fair fight for business.

ELECTRICITY AS SHE IS TAUGHT.

IN one of the addresses made by Lord Kelvin during his jubilee celebration he remarked that he knew no more of electric and magnetic force or of the relation between ether, electricity, and ponderable matter, or chemical affinity, than he knew and tried to teach to his students fifty years ago, in his first session as professor. What are we to say, however, to this ignorance of the Nestor of electrical science when one of the questions which he still confesses himself unable to solve is expected to be answered by the girl graduates of the Normal College of the city of New York. Here it is: "Explain why a current of electricity is developed in a loop of a continuous conductor when it is rotated in a magnetic field on an axis transverse to the lines of magnetic force." We have not seen any of the replies given to this question, but we venture to say that it was "skipped" in the majority of cases. Nevertheless, it would be interesting to know the views of our aspiring young girl graduates on this all-important topic. We refrain from commenting further on the nature of the other questions employed in this examination and merely draw attention to the employment in three distinct cases of the term "amphere hour!" It is hard to believe that this is due to a misprint, and if such be not the case it is a matter for regret that our young women are launched upon the world with such erroneous notions of even the nomenclature of electrical science.

THE SPECTRUM OF VACUUM TUBE LIGHT.

WE print elsewhere in this issue a contribution from the pen of Dr. W. H. Birchmore, on the spectral properties of vacuum tube light which has a most important bearing on the most recent developments in that field. Scientifically, the interesting part of the experiment described by Dr. Birchmore is the possibility that heatless or nearly heatless light can be produced under conditions of choice by the precipitation of carbon from a very tenuous vapor by splitting the molecule by undulations produced electrically instead of by heat under the conditions previously discussed by him in this journal. Should the precipitation of carbon at a very high temperature and the excessively rapid cooling and re-formation of the molecule taking up the heat thus generated, prove to be the solution of the phenomena, it will be very interesting; at any rate, one more step has been taken in the direction of heatless lighting. The statement that the disturbance was magnetic in its lines of force within the closed tube is not to be taken as a demonstrated fact, but only as a probable explanation of the phenomena. Should a rigid investigation prove it true, a new means of investigation into the phenomena of light will have been reached.

ODYLE AND X-RAYS.

MANY have been the theories advanced to explain the phenomena of the Röntgen ray, but perhaps the quaintest which has thus far come under our notice is that which is put forward by a contributor on another page, who finds Von Reichenbach's "odyle" all-sufficient to account for everything that the Röntgen ray has accomplished. We print the communication as much as an illustration of the peculiar speculations which the X-ray has called into life, as to recall to memory the work of Von Reichenbach, which created quite a sensation at the time of its appearance, just fifty years ago, but which has long since been classed among those speculative works based rather on imagination than on facts.

ELECTRIC TRANSPORTATION.

THE EFFICIENCY OF COMPRESSED AIR FOR STREET CAR MOTORS.

BY GEN'L HERMAN HAUPT, PRESIDENT GENERAL COMPRESSED AIR COMPANY.

MY attention has been directed to an article under the above caption in The Electrical Engineer of June 10, 1896, by Mr. Robert Lundell, in which the writer declares his object to be "to remove confusion from the minds of the readers of Mr. Herman Haupt's book."

Mr. Lundell may be an expert electrical engineer and a profound mathematician, but he has much to learn in regard to the practical applications of compressed air, and a visit to Rome, N. Y., where the Hardie motors have been in use for eighteen months, or a conference with such compressor experts as William L. Saunders, of the Ingersoll-Sargent Drill Company, E. Hill, of the Norwalk Iron Works, or the officers of the Rand Drill Company, would have convinced him that they do, can continue to do, and will give reliable guarantees to do, that which Mr. Lundell demonstrates to his own satisfaction to be impossible by algebraic formulas, calculus, and logarithms. I will not attempt to review the figures, but will point out some of the errors and will simply state that the claims of the Hardie motor are based upon more than twenty years of experiment, tests, observations and development by educated and competent engineers and verified by a score or more of the most eminent engineering experts in this and other countries.

That 300 cubic feet of free air will run an eight ton Hardie motor one mile has been demonstrated by actual tests where the average of many runs on a poor track at usual speed was 298 cubic feet of free air per mile. The Rome motors require a little more in consequence of a change in the valve; but the tests made by Captain Fiebeger, of the U. S. engineers, by instruction from the Commissioners of the District of Columbia, gave an average of 308 feet with a motor of 8½ tons. Mr. Lundell thinks that to obtain the same results in speed, etc., "under street railway conditions the horse-power must be at least doubled," evidently assuming that increasing the speed and doubling the horse-power will double the consumption of air." This is a very common error. The consumption of air is increased by increase of the resistances to be overcome, but is very little affected by speed, within ordinary limits. The journal resistance, which is far in excess of all other resistances to a train, is given by Wellington and other writers at eight pounds per ton on a railroad car in ordinary conditions, and this resistance is very slightly increased for speeds of from 10 miles per hour to 40 or 50 miles. The theoretical horse-power in which time and distance enter as elements, is increased; but not the resistances, or the consumption of air proportionately.

To settle this question absolutely, so far as the Hardie motor is concerned, I requested Mr. Hardie to make a series of actual tests, and I have now before me tables of twenty-five tests with loads of 19,150 pounds, 24,990 pounds and 36,000 pounds, the latter with trailer. The speeds varied from three miles per hour to 22.8 miles per hour. The results were very variable, showing that the differences of speed did not affect the resistances sufficiently to be indicated with any accuracy on the ordinary pressure gauges. For example, at 3 miles per hour the readings of the gauge gave 347 cubic feet of free air per mile, at 5.7 miles 334 cubic feet, at 10.30 miles one reading gave as low as 275 cubic feet, at 13.7 miles 447 cubic feet and at 22.8 miles 445 cubic feet. With the load of 36,000 pounds and speed of 15.34 miles per hour, the consumption of air was only 334 cubic feet. These tests were made on the same track and under like conditions, and the average of the whole was 373 cubic feet.

The gauges are not sensitive enough for accurate determination; but where a charge of, say, 2,000 pounds is put in a motor reservoir of given capacity and the motor runs for a given distance with a known reserve at the end of the run, it is folly to assert that we do not know the average consumption of air per mile or to attempt to prove by intricate calculations that we cannot do that which has been done thousands of times and is being done daily. Let those who doubt take a trip to Rome and satisfy themselves. Opportunities for examination have never been refused, although some parties have used them to try to steal an idea and get up an opposition.

Mr. Lundell gives an elaborate calculation on the efficiency of air compression to demonstrate that to compress 3,600 cubic feet of free air per minute to 2,000 pounds will require 2,480 horse-power. Any of the manufacturers of first-class compressor plants will contract to perform this service at about one-half of this calculated horse-power and guarantee the result. This should be accepted as conclusive. Facts are stubborn things and facts established by the experience and observation of years cannot have their evidence impaired by any number of theoretical computations. We affirm what we know and prefer to prove assertions by practical results rather than by figures. It is said that figures cannot lie, but it is quite certain that they can mislead, of which the article under consideration is an evidence.

NEW YORK STATE CIVIL SERVICE EXAMINATION FOR ELECTRIC RAILROAD EXPERT.

We print below the questions used in the examination just held for electrical expert to the New York State Railroad Commission:

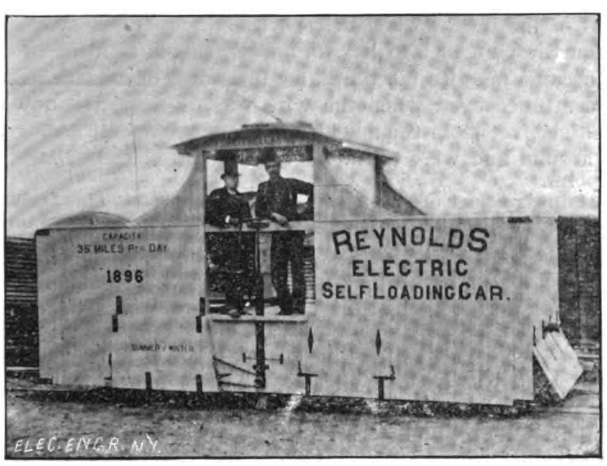
1. State your age, education and experience in the electrical business. Give details of positions held and duties performed, with time and place.
2. Give names of your present and former employers in electrical work, with addresses.
3. What type of electric generator is generally used in the electric railway power house of to-day?
4. When more than one generator is used what practice is generally followed in their operation?
5. Give sketch showing connections of two railway generators when operating on the same circuit.
6. Give list of the protective and controlling devices on a railway generator switchboard with sketch showing connections of same.
7. (a) What method would you employ in insulating generator base from foundation? (b) Why?
8. How would you quickly ascertain that the generator and switchboard operating devices were properly installed, and insulated from ground, while generator is in operation?
9. How would you ascertain if generator and switchboard operating devices are properly insulated from ground when generator is not in operation?
10. What would be good practice in supporting, locating and insulating wires from railway generators to outside circuits?
11. Explain methods employed to build up a generator when it fails to generate when running at normal speed.
12. Give full description of your method of figuring the amount of copper necessary for an even distribution of power on a trolley system with 10 per cent. loss in lines.
13. What drop in potential does good practice allow in the rail and ground return?
14. Complete the connection between the overhead supply circuit and the return circuit through the car, with list of articles employed therein.
15. What safety devices should a motor car be equipped with, electrically?
16. What safety devices should a motor car be equipped with, mechanically?
17. What is your opinion of speeds for electric cars in cities of the second and third classes?
18. What is your opinion of fenders?
19. What is a guard wire for electric street railways?
20. What is your opinion of the utility of guard wires?
21. (a). What is the cause of shocks being received from electric railway tracks? (b) What is the remedy?
22. Give length and type of car, in your opinion, best adapted for ordinary street railway practice in cities of 100,000 to 500,000 inhabitants.
23. (a) What, in your opinion, is the best method of returning the current on a horse car road which is to be equipped electrically and is laid with flat rails on stringers, if such rails have an iron plate under each joint? (b) If no plates are under joints?
24. What direct current potential would you consider dangerous to human life, and what in the case of the alternating current?
25. Explain the electrolytic disintegration of underground metallic conduits, by reason of leakages from railroad circuits. A complaint is made that a water pipe in a street upon which there is a trolley road is suffering from electrolytic corrosion. How would you determine whether the alleged corrosion was partly or wholly caused by electrolysis, and how would you determine the length of time the pipe would last under such action, and what means would you suggest for its partial or complete prevention? Should there be any communication between the rails and water or gas pipes, and if so, at what point?
26. To what would you connect the ground bus of the central station? Would you advise positive or negative terminals of dynamos to be connected to ground, and give your reasons?
27. What is meant by over compounding, and what is its function in practice?

28. Describe the chief functions of a series parallel controller for street car motors.
29. How does the fluctuating character of an electric railroad load affect the choice of engines as regards condensing and non-condensing?
30. What factors determine the speed of a motor, and what factors determine its power? Give complete details and formulas.

REYNOLDS ELECTRIC STREET SWEEPER.

An electric self-loading car has been patented by Mr. A. J. Reynolds, of Montreal, for the purpose of cleaning the streets and automatically removing the sweepings. The accompanying illustration shows the first car manufactured at Deseronto, Ontario, at Rathbun & Company's works.

The system of cleaning is as follows: About one-third of the surface of the street is swept from the curb towards the railway tracks by the ordinary horse sweepers. The refuse is then taken up by the self-loading car at any desired speed and conveyed to the desired location. The car shown is 22 feet in length, 8 feet wide and 9½ feet high, very compactly and strongly built. It is fitted with all the electrical appliances common to a regular trolley car. Contrary to general use the brakes, motors, etc., are all situated above the wheels and axles so as not to impede the full action of the brush. The operating platform on which the persons stand while directing the motion of the car and broom is 8 by 5 feet, and so placed as to prevent them from being touched by the dust thrown from the revolving brush.



Reynolds Electric Self Loading Car.

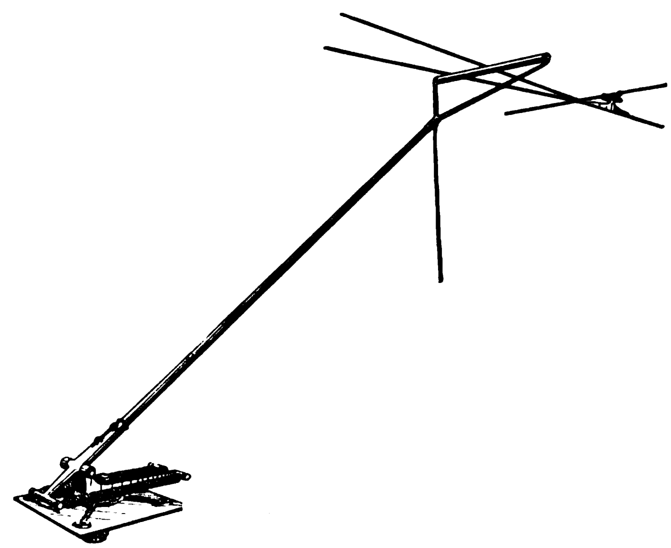
The revolving brush is placed across the center of the sweeper and is covered with steel casings which are provided with proper outlets for discharging the sweepings from the ground into the car body. The casings are also provided with rubber aprons which fit close to the pavement. The high speed of the brush forms a powerful suction, which takes up all the finely divided matter and deposits it over the brush into the body of the car, which is provided with pivoted dump floors for dropping the load instantly at any point desired. The brushes, steel casings and rubber aprons are so constructed as to work in either direction automatically. The cars are driven by a motor placed directly over the brushes on the operating platform of the car, the brush being operated from a counter-shaft by sprocket wheels and chain. The brush makes five revolutions to one revolution of the car axle, is carried on a solid heavy shaft, and is arranged so that it always fills the case which contains it. This is effected by a simple but ingenious device by means of which the casing is altered in size to suit the changes made by the wear on the brush by the pavements. The broom acts equally well running in either direction, steel deflectors being so arranged that it can be run backward without making any change in the adjustment of the machinery or even without touching it. The car can be unloaded in thirty seconds, one man doing the whole work by manipulating a lever. The car illustrated is equipped with two 30 horse-power motors, and its estimated capacity is 45 miles of street cleaning per day. It will pick up 50 carloads of sweepings without stopping. Where the street conditions will permit, the machinery may be made wide enough to cover the whole street, and it may also be made of any length desired.

The cost of operating this electric sweeper is claimed to be about $3 per mile. The side sweeping by horse machines can be done for $1.50 per mile, which makes the total cost $4.50 per mile.

THE NEW WALKER TROLLEY.

The accompanying engraving illustrates the new type of trolley base and trolley contact just brought out by the Walker Company, which, it is claimed, not only avoids existing patents, but possesses advantages not possessed by the form of trolley now in general use in the United States.

It will be noted in the first place that the trolley wheel is dispensed with and in its place there is substituted a long horizontal contact cylinder fixed at the upper end of the pole. This cylinder is mounted on ball bearings, and, therefore, requires no oiling whatever. On account of its width it will be evident that even the maximum lateral motion which the car may receive will not cause the trolley contact to leave the wire, and hence it is unnecessary to provide for any lateral adjust-



The New Walker Under-Running Trolley.

ment of the trolley base, which, as will be seen, is so arranged that the trolley pole can move in a direction only in a vertical plane, without lateral motion.

One important advantage of this trolley is that no overhead switches are required, the width of the trolley contact permitting it to ride over easily to any branch line in the overhead system. The well-known troubles with the grooved wheel at switches and curves are thus avoided, and the repairs at these points obviated.

Many European electric railways are equipped with an analogous type of underrunning contact, and from the results obtained abroad it appears quite probable that its introduction in this country on an extended scale may be looked for at an early date.

WEED KILLING BY ELECTRICITY.

A communication from Mr. J. F. Wallace, Chief Engineer of the Illinois Central Railroad, is published in "The Railroad Gazette," and contains an account of some experiments carried out by that gentleman in the direction of destroying weeds and grass by means of an application of electric current to them. The apparatus, which was used in a small way experimentally, consisted of a wire brush about ten feet long and four inches wide, suspended from a frame on the end of a flat car upon which the dynamo and necessary electrical equipment were carried. This car was hauled by a locomotive, which also supplied the steam for the electric plant.

The brush was connected to the dynamo circuit and moved slowly along the track in contact with the vegetation, the theory being that the vitality of the plants would be destroyed by passing the current through them to the ground. The apparatus traveled over the track at the rate of about four miles an hour. When the experiment was made it was found that the thick Bermuda grass was apparently not affected at the time, but on the day following the application of the current it was dried up and quite dead. Also milk weed and other vegetable matter in which there was a large percentage of moisture

would, when brought in contact with the brush, absorb the current and be killed, while the drier grass which came in contact with the brush at the same time would not be injured.

More extended experiments would, of course, have to be made in order to determine the amount of amperes, voltage, etc., required to give the most economical and efficient results; and it would be necessary for the machine to completely kill vegetation inside of the rails and for a space of three to four feet on each side, and be able to do so continuously at a rate of five or six miles per hour, in order to do satisfactory work.

The advantage of this method of destroying vegetation is in the destruction being absolute. The partial destruction accomplished during the above mentioned experiments would not, according to Mr. Wallace, be satisfactory.

RAILWAY EXTENSION IN MAINE.

Superintendent Hawken, of the Rockland, Thomaston and Camden Street Railway, has completed the new extension of the electric road up into the town of Thomaston, Me. The first car, decorated with flags and bunting, and with a band of music on board, made the first trip into the town on June 16. All of the Thomaston people are greatly pleased, as, for three years, on account of the opposition to the road of a few prominent business men, they have been obliged to walk up the steep Mill Creek hill. This piece of road is considered the best in the State; it was pushed to completion in a very few days. The ballast for this road is composed of lime rock chips and gravel. The Rockland, Thomaston and Camden Street Railway have also completed this season a new electric line from Main street, Rockland, to Tillson Wharf. One car does the work on this line, leaving the end of the line every ten minutes. It connects with all boats and will prove a great accommodation to all summer tourists.

A RAILWAY RUN BY GAS.

Zurich has an interesting electric street railway 1½ miles long. The novelty consists in that the power to generate the current is obtained from gas engines run by Dowson fuel gas. This is one of the first instances in which gas engines have been used for such work.

SOCIETY AND CLUB NOTES.

INTERNATIONAL CONGRESS OF ELECTRICIANS IN SWITZERLAND.

Utilizing the opportunity presented by the holding of the National Swiss Exhibition at Geneva, the Swiss Society of Electrical Engineers is organizing an International Electrical Congress, to be held from August 4 to 9, next.

An invitation to this Congress has already been sent to the American Institute of Electrical Engineers, New York; Elektrotechnischer Verein, Berlin; Elektrotechnischer Verein, Vienna; Institution of Electrical Engineers, London; Société Belge des Electriciens, Brussels; Société Internationale des Electriciens, Paris; Verband Deutscher Elektrotechniker.

Information relative to the Congress will be given to all who inquire at the office of the International Electrical Congress, Université, Genève.

The programme of the congress includes discussions of the following subjects: Magnetic units, photometric units, transmission and distribution of power for great distances by means of direct currents and by alternating currents, protection of high pressure overhead electric lines against atmospheric discharges, and various disturbances caused by electric traction.

This programme will be followed by an excursion which is intended to include a visit to the principal electrical installations in Switzerland.

MARRIED.

MR. LUDWIG GUTMANN was married to Miss Emma Wilkins, at Chicago, June 24.

PERSONAL.

MR. T. C. MARTIN, on June 19, delivered his Niagara lecture at the Royal Institution, London. Lord Kelvin presided and among the many distinguished auditors present were Sir Douglas Galton, Sir Frederick Bramwell, and M. Moissan.

ROENTGEN RAYS.

ARE X-RAYS ODYLIC RAYS?

BY S. F. O'REILLY.

PROFESSOR CROOKES claims to have discovered a fourth state of matter, namely, radiant matter, the three previous states being gaseous, liquid and solid. Röntgen is said to be the first to depict by electrical means a photograph on a sensitized plate, despite the intervention of a solid body. The ray which produces this is called the Röntgen or X-ray. Mr. Edison advances the theory that the Crookes tube in which the Röntgen ray is formed is simply a converter of electrical energy into Röntgen energy; but they have all forgotten one element well known, namely odyle. It emanates from all things and is probably a fourth state of matter. It has been found abundantly wherever chemical action takes place, particularly in electrically excited bodies, having, like the magnet, polarity, but without the power of attraction or repulsion. The appearance of the X-ray is not the first time that odyle has been mistaken for something else and misnamed.

Baron von Reichenbach is the author of a book published in 1846 which will throw light on the subject and will probably be of interest to X-ray promoters. On page 131 he describes an experiment. A lady placed in a dark room and holding the end of a wire twenty feet long, connected to a static machine outside the room, saw flames arise from the free end of the wire to a height of ten inches when the spark of the machine was only one-fourth of an inch in length, and when the rotation of the disc became more rapid, the flame increased to greater height and continued even when the wire was disconnected and removed six feet from the machine. These flames diffused coolness around and were not attracted, like an electric spark, to any point.

In the retrospect of the same chapter he says: "The feeblest chemical action sufficed to develop the new force abundantly, to charge other bodies with it, to excite polarity and to produce light visible in the dark."

On page 165 he gives the new discovery the name of "odyle" and claims that it emanates from all matter. That from electrolytic action he calls electrodyle or electrod; from the magnet, magnetod; from the sun, solod; from the moon, lunod, etc., the universal name being pantodyle.

He discovered that odyle has polarity, that heating a body excites + odyle and cooling — odyle, for which he uses the signs + O and —O. All kinds of fire diffuse —O.

On page 211, he says that odyle has an existence independent of magnetism or electricity. In the dark it gives a bluish or bluish-gray light from its north pole and a yellowish-red from its south pole. Odyle can be conducted by a wire, but much more slowly than electricity and faster than heat or about as fast as the movement of the hand. Bodies can be charged with it, but it takes several minutes to see the charge effects.

On page 214, he speaks of odic rays and found that they pass through solid matter, but with less facility than magnetism. The light diffused by odylically excited bodies is exceedingly feeble, and it is probably on this account not visible to every eye. A person of moderately sensitive vision might remain two hours in absolute darkness before the eye could see odyle.

Reichenbach also states that a hollow ball of metal glows when charged with odyle; a variety of shades of light are seen, the golden yellow being the most intense.

On page 378 he describes experiments made with a magnet on a vacuum tube. Light was seen by a blind man and others. All light disappeared when air was admitted and also when extreme rarefaction was produced. When the experiment lasted long the whole vacuum was filled with odylic vapor, the tube itself fluoresced and the fluorescence lasted after air was admitted. "Steel in this light became as transparent as window glass." He speaks of odylic smoke and ray; the flames are affected by the pressure of the atmosphere and under diminished pressure they increase considerably in brightness. The glow in the vacuum produces no smoke externally and appears inside up to a certain point of rarefaction beyond which it diminishes and disapears.

Now I perceive in the fluorescence of the X-ray tube just these phenomena. The X-ray glow is odylic smoke. The X-ray is odylic and to Von Reichenbach belongs the honor of being the discoverer of the ray which makes solid matter transparent. Verily, "there are more things in Heaven and earth, Horatio, than are dreamt of in our philosophy."

THE ROENTGEN RAYS AND OPTICALLY ACTIVE SUBSTANCES.

BY PERCY F. FRANKLAND.

In an article in "Nature, by Professor J. J. Thomson, it is suggested that the leakage of electricity through non-conductors under the influence of the Röntgen rays is "due to a kind of electrolysis, the molecule of the non-conductor being split up, or nearly split up, by the Röntgen rays, which act the part played by the solvent in ordinary electrolytic solutions." It has occurred to me that if such ionization really does take place, independent evidence of it should be obtainable in the case of optically active substances by a change in their rotatory power taking place when they are exposed to the X-rays, as it is well known that the ionized molecules of active compounds are possessed of very different activity from the undissociated molecules themselves. To put this point to the test, Mr. MacGregor and I have polarimetrically examined two optically active compounds, ethylic dibenzoylglycerate and methylic acetylglycerate, interposing a Crookes focus tube between the polarizing Nicol and the column of active liquid; but although the discharge was maintained in both cases for three-quarters of an hour, there was not the slightest change in the rotation observable. To facilitate the passage of the rays, we employed a thin microscope cover-glass to close the polarimeter tube at the end nearest to the Crookes tube, and that the rays were actually traversing the column of active liquid was demonstrated by obtaining a photographic effect at the other extremity of the tube, whilst the efficiency of the Crookes tube was further proved by the favorite test of the skeletal photograph of a hand, which yielded an impression of great sharpness and exhibiting a most remarkable amount of detail. It would appear, therefore, that the Röntgen rays either do not give rise to any ionization at all, or that the concentration of the ions is so small as not to be detectable by means of a sensitive polarimeter. I have previously shown, in conjunction with Mr. Pickard (Trans. Chem. Soc., 1896), that the active bodies in question exhibit what appears to be a process of ionization when dissolved in certain organic solvents, which process is accompanied by a very conspicuous change in their rotatory power, so that they appeared to be specially adapted for testing this suggested influence of the X-rays.

Incidentally we have roughly tested the relative opacity of a number of organic compounds to these rays by spreading approximately equal thicknesses of each on a number of microscope cover-glasses, which were placed on a photographic plate inclosed in a black envelope, and then exposing them all simultaneously to a Crookes tube placed a few inches above. Out of nearly forty organic compounds belonging to both the fatty and the aromatic series, the only ones exhibiting any marked opacity contained iodine, bromine, or chlorine, the iodine compounds being the most and the chlorine compounds the least opaque. Thus methyl iodide, ethyl bromide, ethylene iodide, ethylene, monobromacetic acid, tribromacetic acid, bromobenzoic acid, and trimethylenebromide were very markedly opaque, and curiously monochloracetic acid was much more distinctly opaque than either dichlor or trichlor-acetic acid.—"Nature."

A PHOTOMETER FOR ROENTGEN RAYS.

All those who have had occasion to use Crookes tubes to produce Röntgen rays will have noticed the extraordinary variations in the intensity of the radiation produced by an apparently trifling change in the vacuum and the make and break of the coil. A useful step toward some quantitative measurement of the intensity of Röntgen rays has been made by M. Meslin, who, in the current number of the "Journal de Physique," gives an account of a photometer for the rays. The principle on which this photometer depends is the matching of the brilliancy of the two halves of a circular patch of barium-platino-cyanide, one-half being rendered fluorescent by Röntgen rays, and the other rendered fluorescent by the light rays proceeding from some standard source, such as a candle or lamp. The light is passed through a colored glass, so that the fluorescence produced has the same tint as that produced by Röntgen rays. The author finds that the barium-platino-cyanide, under the influence of Röntgen rays, fluoresces with a light of such a color that the maximum brilliancy occurs for a wave-length of about 0.500 μ. The barium-platino-cyanide fluoresces most strongly when exposed to light having a wave-length of about 0.460 μ. By means of this arrangement the author has been able to verify the law that the intensity varies inversely as the square of the distance, the following numbers being obtained:

Distance of photometer.	mm.	mm.	Quotient.
From luminous source	350	410	0.853
From source of Röntgen rays.......	54	63	0.857

DARKENING OF THE CATHODE IN A CROOKES TUBE.

BY FLORIAN CAJORI AND WILLIAM STRIEBY.

A pear-shaped Crookes tube with a cathode disc in its narrow end has been used extensively by us during the past ten weeks in private experimentation and in public lectures on Röntgen rays. In common with many other experimenters, we have observed that after much usage the glass opposite the cathode disc and the glass about the anode became darkened. But we do not recall having seen any statement recorded regarding the darkening of the cathode disc. When we began using the tube the surface of the aluminum disc was uniformly bright throughout; now there is on the surface facing the broad end of the tube a dark brown ring concentric with the disc. This ring has an internal diameter of about 6 mm., and is darkest near its inner edge, the densest portion being, perhaps, 1 mm. across. Outside of this darkest portion the ring fades off gradually toward the outer edge of the disc. Taken as a whole, the internal and external diameters of the ring are about 5 mm. and 11 mm., respectively. The circular area inside of the dark ring is the brightest part of the disc. The diameter of the disc is about 17 mm.

During the discharge through the tube we now observe what we did not notice before, viz., a pencil of faint bluish light emanating from the circular area of the disc inside the dark ring. The pencil is normal to the disc. The light resembles the blue or purplish light about the anode. The cylindrical pencil is most distinct at the disc and gradually fades away and becomes invisible at a distance from it of about 2 or 3 cm. If, by reversal of the current, the disc is made the anode, then the pencil of blue light cannot be seen, but almost the entire tube is filled with the same purplish light. Sometimes this purplish light fills the tube also when the disc is used as a cathode. In such cases the discharge at the spark gap (placed in series with the tube) is fat and noisy; the tube shows very little fluorescence and the radiation of Röntgen rays is greatly diminished. —"Science."

EDUCATIONAL.

ELECTRICAL COURSE AT THE WISCONSIN UNIVERSITY.

WE are in receipt of the catalogue of the University of Wisconsin, containing a résumé of the courses of instruction for 1896. In the department of electricity, in charge of Profs. J. E. Davies and D. C. Jackson, the electrical laboratory is well supplied with exact scientific and commercial instruments. With the additional space and apparatus which is allowed through the generosity of past legislatures, the equipment has been made unusually complete in the line of continuous current, and single and multiphase alternating current generation and distribution, and commercial electrochemistry. The dynamos in the laboratory are arranged in a large special room, with a special engine of exceedingly close speed regulation. For use in testing dynamos, all necessary apparatus, including a Brackett cradle dynamometer is at hand. A photometer room is well arranged for the commercial comparisons of arc and incandescent lamps, or for scientific investigations.

ELECTRICAL ENGINEERING AT TULANE UNIVERSITY, NEW ORLEANS.

THE Tulane University is now occupying its new buildings in a suburb of New Orleans, in which everything has been carefully planned with a view to its adaptability to the uses of the higher engineering courses taught there. The buildings include the Sciences Building, the Physical Laboratory, the Chemical Laboratory, and the large group of engineering laboratories and workshops.

In electrical engineering, the equipment is very fine, there being in all about twenty dynamos for direct and alternating incandescent and arc service. The switchboards are of marble and slate, and there is a large collection of arc lamps, converters and measuring instruments. The course in electrical engineering is under the direction of Prof. Brown Ayres, dean of the University.

PLANS have been prepared by Cyrus L. W. Eidlitz, architect, for a ten-story brick store and terra cotta factory building, to be erected by the Western Electric Company, at a cost of $1,000,000, on a plot 285.9 x 142.10, at the southeast corner of Bethune and West streets. The building will be rectangular in shape, with a court in the center, opening on West street.

POWER TRANSMISSION.

A STUDY OF A THREE-PHASE MOTOR.[1]

BY C. W. VAN LAW AND H. S. SIMPSON.

THE methods of testing, power measurement, etc., here described, are applicable to machines of any size and power, and although the motor tested was a small one the results are typical of motors of this class.

The machine tested was a three horse-power Siemens & Halske motor, designed for three-phase currents at low periodicity and at a pressure of 115 volts. It was at first attempted to obtain the power required from two direct current generators which had been fitted with collector rings for three-phase working, but it was found that these generators would not answer the purpose at all.

After some delay, another direct current generator was tried as an alternator, and found to give very fair results.

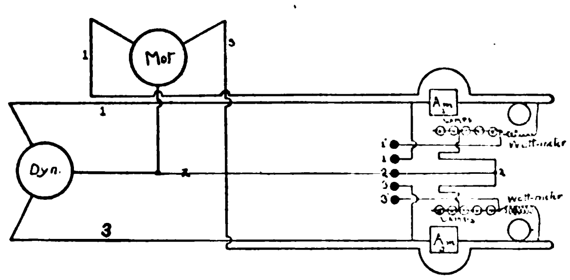


FIG. 1.

The armature was of the Gramme type, wound with large wire and few turns per coil, giving a comparatively small self-induction. To convert this machine into a three-phase alternator, the commutator was covered by an insulating sleeve of fiber, upon which were mounted three brass collector rings. These were separated by fiber rings, and were connected to three commutator segments 120 degrees apart, by set screws tapped through the fiber sleeve and into the segments. Thus, between any two rings was embraced one-third the armature coils, and three-phase current could be led off from brushes resting on the rings.

The generator was driven from a De Laval steam turbine which made 24,000 revolutions per minute. This, with 10 to 1 reduction gearing, and a bi-polar field, gave a periodicity of 40. Ordinary excitation failed entirely. On open circuit, exciting from an Edison machine, 65 volts could be obtained, but this dropped to 35 on full load. Fluctuations in the Edison voltage also caused great trouble. To avoid these difficulties the following scheme was tried. Only a part of the commutator was covered by the collecting rings, and it was determined to take direct current from the bare portion, for the fields, while taking three-phase current from the rings, thus making the machine self-exciting. This was tried, but variations in the load on the three-phase circuits so changed the "direct" voltage as to make this means unsuitable. We could get 100 volts or so for excitation when the motor was not connected, but this dropped to about 70 when load was thrown on.

This means also failing, the following was finally adopted, very satisfactory results being secured. The Edison generator was placed in series with the direct current brushes on the generator in question. This summation of potential gave 170 volts available for exciting purposes, which could be cut down to the desired amount by a rheostat and bank of lamps.

The fields were now saturated, so that fluctuations in the Edison voltage were hardly noticed. Still, the potential was much lower than was needed for the motor tests, and step-up transformers were resorted to. Only two of these could then be obtained, to transform up all three circuits. This was, nevertheless, accomplished by the following arrangement.

The two primary coils were connected in series, as were also the two secondaries. One brush of the dynamo was connected to the primary junction, and the other to the free ends. If the secondary ends be used as the three terminals of the system, three-phase current may be taken off just as from the machine, but raised in potential by the ratio of the transformer employed. Conard and Ehret transformers were used, and it was found possible, owing to their excellent regulation, to hold the motor's voltage at any point desired by slight variation in the exciting current.

[1]Abstract of Thesis, Cornell University.

The efficiency runs were first undertaken; the motor being tested at various loads up to 50 per cent. above its rated power, and at voltages from half its normal potential to somewhat above the figure for which it was designed. For these runs the following scheme of connections and arrangement of apparatus was adopted.

Three wires led from dynamo to motor, the two outside wires running to the instrument table and then back, while the third ran direct from one machine to the other; a light potential wire only being carried to the instrument table.

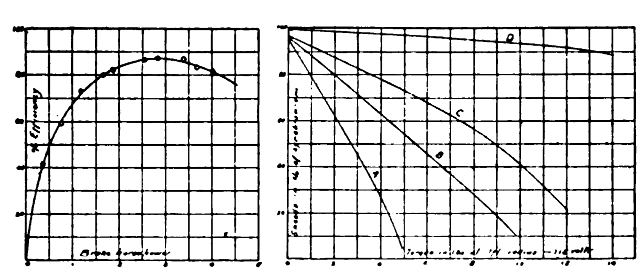
Wires 1 and 3, Fig. 1, led through two ammeters, AA, of the Westinghouse "Station" type, and thence through the current coils of two Thomson recording wattmeters to the motor. The potential coils for these meters were connected between potential wire 2, and wires 1 and 3 as shown. Both meters were designated for fifty volts only, and to protect their potential coils at the higher voltages used, strings of lamps were connected in these two circuits as indicated in the diagram. Potential wire 2 could not then be connected at such a point as to give about 50 volts across the coils of the instruments. A small switchboard was so arranged that by placing voltmeter terminals in the appropriate clips, voltages could be read across any leg of the circuit (1-2, 1-3 and 2-3) or across the potential coils (1-1' and 3-3') very quickly and easily. This switchboard is shown in points 1'-1-2-3-3' on the diagram.

Load was applied to the motor by means of a special Prony brake, having water circulation to keep it cool. The load was increased by approximately equal increments from zero to a point where the safe current capacity of the machine was reached. At each load were taken the voltmeter readings referred to above, the wattmeter speeds—time in seconds of a given number of revolutions—ammeter readings in branches 1 and 3, brake load, and simultaneous speeds of dynamo and motor. From these data, and the instrument calibrations, the efficiency, etc., at the various points could easily be obtained.

During these runs one interesting fact was noticed. It may be proven that when the angle of lag in the individual circuits is greater than 60 degrees one meter will run backward, and its readings must be subtracted from those of the other wattmeter. At 60 degrees this meter stops entirely, while as the angle becomes less than 60 degrees it starts again in a positive direction, running faster and faster as its load is increased. This was observed during the tests: One meter at light loads running backward quite rapidly. As the load was increased it slowed up, stopped and started in a positive direction, its speed now increased with the load as the other meter had done all along.

At each of the voltages at which efficiency runs were made (65, 80, 95, 110, 115 and 120) a set of torque data was also obtained. Non-inductive resistance was introduced into each of the armature circuits, and the brake load increased as before, up to the machine's capacity. At each brake load, simultaneous speeds of dynamo and motor were taken, and the results were expressed in speeds in per cent. of synchronism, and torque at one foot radius. Three different resistances were used at each voltage, of approximately 10, 5 and 2½ ohms in each circuit, and these, with the data from the efficiency runs, when the armature was short-circuited, gave four curves for each voltage.

In Fig. 2 is shown the efficiency curve taken at 115 volts, and typical for all the higher voltages. The showing made by



FIGS. 2 AND 3.—STUDY OF 3-PHASE MOTOR.

the motor is remarkably good in many respects. In the case of most small motors, the efficiency at anything but full load is very low; and the efficiency rising at once to a fairly high value, a maximum well within the capacity of the motor, and a curve nearly flat through a wide range of load, about its rated horse-power. Further, as seen from curve "D" of the torque curves taken at this same voltage, Fig. 3, the slip increases but slightly from zero to full load; being only 10 per cent. at 50 per cent. overload. The machine can be run at much above its rated capacity, right along, without danger, and is most

satisfactory in every way. The efficiency curves taken at other voltages possess much the same characteristics, that at 110 being the highest; reaching a maximum at 88 per cent., and being above 85 per cent. for quite a range of load. The efficiency at 65 volts—half the normal voltage—is still fairly high, reaching a maximum of 76 per cent., and being above 70 per cent. from less than a half horse-power up. The power, however, is much less at these lower voltages, reaching a maximum of only about 1.3 horse-power for 65 volts.

The torque curves, for 115 volts in Fig. 3 are of considerable interest as well. Curves A, B, C and D are taken with 10, 5, 2½ and 0 ohms, respectively, external resistance, approximately, in each armature circuit, for all runs. Curves "D" show only a slight slip from zero to full load, for the higher voltages, but this rapidly increases as the lower voltages are used, and at 65 volts "D" drops 10 per cent., at less than half load. The other curves are chiefly interesting as showing what starting torque might be expected with the various resistances used. By producing the curves to intersect the 0 speed line, the starting torque is evidently obtained, and is for the higher voltages, amply high for the motor to start under full load, with 2½ ohms in each circuit. A certain resistance may be found for each voltage, which will give maximum starting torque; if the resistance be either increased or diminished from this value the torque will fall off rapidly. If the armature be short circuited, as it is when running at speed, the starting torque produced is very slight; and the machine will burn up before it can be gotten to start under load. Resistance must first be cut into the armature circuits till the machine starts, and then gradually cut out as the motor speeds up, the armature being fully short circuited.

SCOTT'S SYSTEM OF POWER TRANSMISSION.

A SYSTEM of power transmission has recently been patented by Mr. Gordon J. Scott, of Philadelphia, by means of which a single-phase alternating current is broken up so as to produce a rotary magnetic field in a motor connected to the system. The single-phase alternating current is led, by means of this invention, through any desired number of circuits consecutively, and without commutation.

Fig. 1 shows the arrangement of the apparatus and circuits in this method of distribution. A represents a single-phase alternating current motor; B, an induction director, and C, the motor. The induction director, B, which is the principal feature of the system, is shown diagrammatically in Fig. 1, and in detail in Figs. 2 and 3.

The single-phase circuit A is connected to the induction director and the latter is connected with the motor by the motor circuits, b, b′, b². In this illustration b, b′, b² are field circuits,

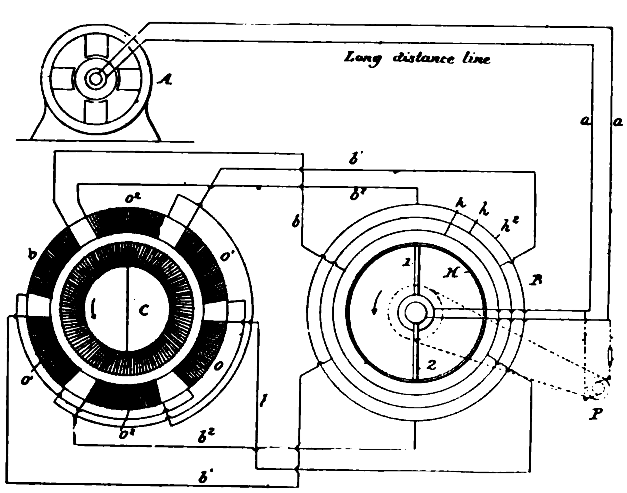


Fig. 1.—Scott's System of Alternate Current Power Transmission.

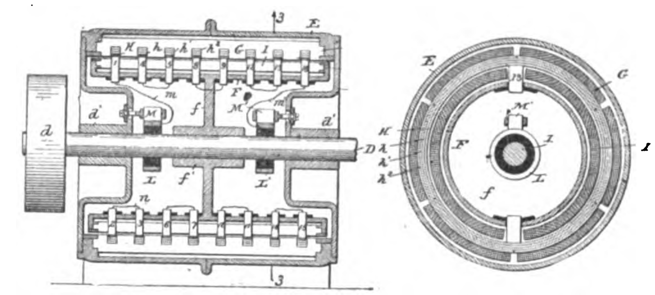
but it will be evident that they may be either field or armature circuits.

Within the frame E is a revolving cylinder, F. Surrounding the cylinder is fixed the circular laminated core, G, composed of plates which are supported in the ends of the drum. In the inner faces of the plates G are notches in which are embedded a series of copper coils or rings, the inner rings H being continuous, or closed, while the outer rings h h′ h² are continuous when solid, and made in two sections when composed of coils of wire.

On the periphery of the cylinder F is a circular series of iron plates, forming a core, I, which is arranged close to the stationary core, G, of the drum. At diametrically opposite sides of the cylinder are longitudinal rows of brushes, which are arranged opposite to, and constantly in, direct contact with, the closed or primary rings H. These rows of brushes are indicated by the numbers 1 4 5, and 2 3 6, etc., respectively, the reference figures upon the brushes indicating the order in which the current passes through them. Upon the shaft D are insulated rings, L and L′, and in contact



Figs. 2 and 3.

with these rings are stationary brushes, M M′, to which are connected the terminals of the alternating circuit a.

The internal circuits of the induction director are as follows: The current entering through the brush M passes to ring L and thence through wire m to the brush 1, where it divides and passes in opposite directions around the ring H to the brush 2, (see Fig. 2), thence through wire n to the brush 3, and then around second ring H in opposite directions to brush 4. Similarly the brushes in each of the rows are connected in pairs, and the current passes in opposite directions around each pair of adjacent rings until it reaches the last brush, which, in the illustration, is numbered 16. In other words, the rings H are connected in series. From brush 16 the current passes to the ring L′ and back to the line through brush M′.

It will be seen that the direction of the currents being opposite in adjacent rings H will set up alternate north and south poles throughout the laminated cores G. The movable core I is arranged close to the stationary core G in order to complete the magnetic circuits around the rings. The sets of secondary rings h h′ h², respectively, may be connected together in series or in multiple, and the motor circuits are connected to the terminals of the sets.

For turning the shaft of the induction director several methods are possible. An independent motor, P, is adopted for this in the illustration, Fig. 1.

The operation of the induction director above described is as follows: The current passing in opposite directions through the rings H will set up strong induced currents in the secondary rings. The points of greatest difference of potential in the secondary rings will always be opposite the brushes, and the points of least difference of potential will be at right angles to the brushes, while diametrically opposite points in other parts of the rings will have a difference of potential varying with their proximity to the line of the brushes. It will thus be understood that with the brushes and connections, as shown in Fig. 1 the coils o² in the motor circuit b² will be strongly energized, while the coils o and o′ in the circuits b and b′ will be less active, all of the coils tending to set up poles of opposite polarity at points midway between the coils o² The rotation of the brushes, it will be readily seen, will rotate the points of maximum and minimum potential in the secondary rings, and the motor circuits will be energized in rotation and a rotary field be set up in the motor. It will, therefore, be seen that in order to regulate the speed and direction of the revolving part of the motor it is simply necessary to regulate the speed and direction of the induction director, as the motor will run synchronously with it.

The currents set up in the motor circuits gradually rise from zero to a maximum and then gradually fall, and may be aptly called the waves of current and electromotive force. This wave action of the induction director is a feature which distinguishes it from machines having similar functions, and in which the current is shifted from one circuit to another by means of commutators, switches, or other make-and-break devices.

BERLIN, GERMANY.—Messrs. Siemens & Halske, of Berlin, have recently secured a contract for an electric drilling plant for the State salt mines at Hallein. The plant will comprise a high-pressure turbine coupled direct to a continuous-current dynamo and two boring machines.

Telephony and Telegraphy.

INDUCTANCE AS A NEGATIVE CAPACITY IN SUBMARINE CABLES.

BY A. DAVIDSON.

THE following experiments, to exhibit the value of inductance as a negative capacity, were made on a length of submarine cable of modern type, armored with steel wires and coiled in an iron tank. This piece of cable gave a circuit possessing inductance, capacity and resistance. By a suitable arrangement, either capacity or inductance could be made to predominate. It is hoped that the experiments will be of interest, on account of the commercial value of a "distortionless" cable.

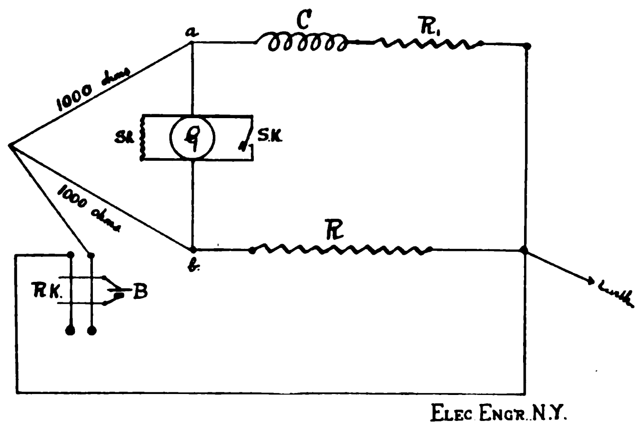


FIG. 1.—R.K., REVERSING KEY; B., BATTERY (20 CELLS LECL.); G., GALVANOMETER, 30,000 OHMS. THOMSON; Sh., GALVANOMETER SHUNT, $\frac{1}{1000}$TH THROUGHOUT EXPERIMENTS; S.K., SHORT-CIRCUITING KEY; R., RESISTANCE BOX; C., 54 N. MILES CABLE. C.R. = 157 OHMS. CAP. = 18.9 MFS.; R., ADJUSTABLE NON-INDUCTIVE RESISTANCE.

The arrangement used is shown in Fig. 1. The cable was inserted in one arm of a Wheatstone bridge, together with an adjustable resistance, R_1. It was then balanced for steady C_1R_1 with $R_1 = 0$. The galvanometer short-circuit key was then left open and the swing, on depressing the battery key, observed. R_1 was then increased, a steady balance again taken and the new movement noted. Table 1 gives the value obtained.

When inductance prevails in the cable circuit the potential at a lags behind that at b. The result is a swing on the galvanometer. Owing to the great inductance of the coiled cable quite

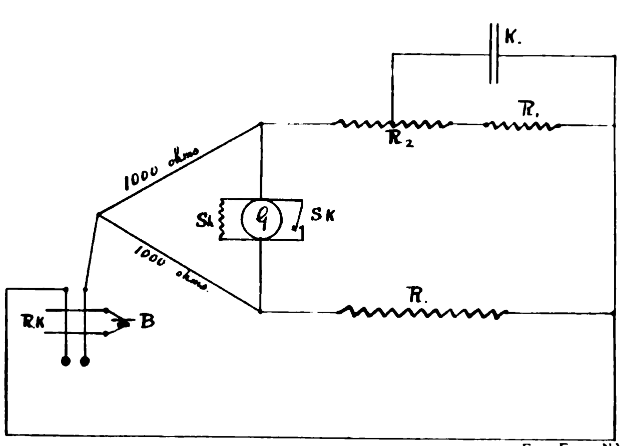

FIG. 2.—R_2, NON-INDUCTIVE RESISTANCE EQUAL TO C.R. OF CABLE; K., 20 MFS. CONNECTED TO THE MIDDLE OF R_2. The other parts are the same as in Fig. 1.

an appreciable time elapses before the potential at a equals the potential at b, and the spot drifts back very sluggishly to zero. When capacity prevails, the potential at a leads the potential at b, giving a swing in the opposite direction to that observed when inductance prevails. This swing is quite sharp. At certain times, (R_1 = fom 700 to 1,300 ohms), it could be observed riding over the inductance swing; first, a sharp swing to the right, followed by a slower swing to the left, then a drift to zero. Both swings are given in Table 1. This overlapping was the principal difficulty met with in taking these observations. It was, of course, essential to use an

"earth," as shown in Fig. 1, in order to bring the full capacity into play. When "earth" is not used the capacity effect did not become apparent, even when R_1 was very large.

To separate the inductance from the capacity effect the "earth" connection was thrown off and a series of readings taken. These are entered under "Inductance Swing" in Table 2. Experiment showed that with R_1 = 50,000 ohms, the capacity between the legs of the cable loop was not in evidence. These readings may, therefore, be taken as due to inductance.

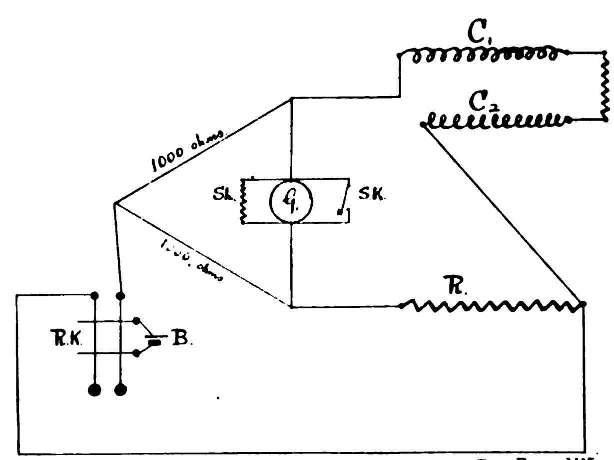

FIG. 3.—C_1 = 65 N. MILES OF CABLE. C.R. = 600 OHMS; CAP. = 22 MFS.; C_2 = 54 N. MILES OF CABLE. C.R. = 140 OHMS; CAP. = 18.9 MFS.; R_1 = ADJUSTABLE NON-INDUCTIVE RESISTANCE. Other parts as in Fig. 1.

An artificial circuit was then made up, as shown in Fig. 2, with resistance and capacity only, to represent the cable. The capacity was lumped at the center of the circuit for convenience, but the error due to this is probably slight. The readings

with this arrangement are tabulated in Table 2, under "Capacity Swing." Comparison with Table 1 shows that with R_1 = about 1,300 ohms, the inductance and capacity swings are approximately equal, but opposite in both experiments.

To bring the capacity between the legs of a metallic loop into evidence, the arrangement shown in Fig. 3 was used. Two lengths of cable were used and R_1 inserted between them. Unfortunately, the lengths were of different types, so that the loop was not a symmetrical one electrically. Still the results, shown in Table 3, are interesting, as displaying a method which may possibly be useful in determining the effective capacity of a metallic loop, an important quantity in telephone engineering.

These experiments can only claim to be of a qualitative value. As such, they show that inductance does tend to nullify a distributed capacity, though not completely, owing to the enormous difference between the electromagnetic and the electrostatic time constants of the circuit. As an old truth in a novel form, I think they are worthy of publication.

NEW MOVES IN THE TELEPHONE FIELD.

THE POSTAL-TELEGRAPH-CABLE COMPANY has recently arranged to extend its business into Southern territory, where at present it has no lines whatever. A new company called the Postal Telegraph-Cable Company of Texas has been organized and arrangements have been entered into with the parent company in New York for the transaction of this business. The fact that the directorate of this Texas company contains the names of a number of men who are heavily interested in the Erie Telephone Company, one of the largest of the subsidiary Bell telephone companies, gives rise to the suggestion that the Postal company is about to enter the telephone field, a step that might greatly annoy its great rival, the Western Union Company. It is further reported from Texas that the Postal will use the wires of the Erie Telephone Company to cover Arkansas and Texas. This, however, is denied by officers of the company.

President A. B. Chandler, of the Postal company, said recently:

"This company is not in the telephone line. It seeks only commercial telegraph business. In order to reach the Southwest it was deemed advisable to form the separate Texas company, principally from among men interested in the Postal company. There is no alliance with the Erie Telephone Company, and we have made no arrangements to use its wires. I can see that the fact of Erie men being in the Texas company would naturally give rise to reports of an alliance, but such is not the case. The telephone men went into the corporation simply as an investment. It is a common thing for men of wealth to be interested in several companies. The Postal company is not going into the telephone business. We are not restricted or bound by telephone agreements of any kind."

In regard to the telephone situation in New York, there is still much reticence concerning the new $16,000,000 New York Telephone Company, which takes the place of the Metropolitan Telephone and Telegraph Company. The officials of these companies have not yet published any statement regarding it. This company will still be subsidiary to the American Bell Telephone Company, which is the parent corporation of most of the operating companies throughout the country. It is generally believed now that the New York company was formed for the purpose of combining more compactly existing companies in the East, and the secrecy is due to delay in perfecting details.

It is probable that the Philadelphia and Pennsylvania telephone business will be affected by this new company, as $9,000,000 of its capital is available for the purchase, lease or control of companies outside of New York. Many companies in Pennsylvania operate under licenses from the Bell company, and most of them have been controlled by local capital, but it is now said that the leading spirits of the Western Union and some of the stockholders of the American Bell Telephone Company have been quietly buying stocks until the most important of the local companies are prepared to go into the deal. The new company is believed to be behind a large number of new local telephone companies lately organized in various places, which have been brought into life for the purpose of forcing into the deal the Bell companies that are adverse to either selling or leasing.

THE NEW YORK TELEPHONE CO.

The above company have issued notices to their subscribers that they have assumed the business of the Metropolitan Telephone and Telegraph Company.

Regarding a new method of overtime charge on Long-Distance messages, the following notice has been issued:

On and after July 1 the charge for overtime, beyond the initial period of five minutes, will be made by the minute, at the rate of one-fifth of a single message for each additional minute. We shall discontinue the practice of notifying the subscriber at the end of each five minutes how much time has elapsed. To suburban points, including Monmouth County and Lakewood, N. J., there will be no change from present method of charging excess time, i. e., for five minutes, or fraction thereof, one message; from five to ten minutes, two messages, etc.

NEWS AND NOTES.

THE ELECTRIC FURNACE.

Professor Dewar, in a lecture at the Royal Institution, in discussing the posibilities of synthetical chemistry which have been disclosed by the electric furnace, stated that from the carbides prepared in the electric furnace we can get benzine, and, therefore, all the aniline dyes, and even crude petroleum. Acetylene gas, another product of the electric furnace, combines directly with nitrogen in the presence of an electric discharge and gives prussic acid, and from this we can readily get cyanides. In fact, there is no end to the sphere of usefulness of the electric furnace.

ELECTRICAL SEPARATION OF TELLURIUM FROM COPPER RESIDUES.

A method for the separation of tellurium from copper residues is described by Mr. Cabell Whitehead in the "Journal" of the American Chemical Society. In the electrical refining of copper the washings from the gold residues contain the tellurium as tellurous oxide or sulphate. The tellurium may be obtained from these either by precipitation with copper or by passing sulphurous anhydride through the solution. It may be finally purified by distillation in hydrogen. When a solution of sodium tellurite is added to a solution of an ammonium salt, a white precipitate of tellurous anhydride is thrown down, which becomes granular on boiling. A small amount of tellurium or of some metal which can be precipitated by sulphurous anhydride remains in solution; this soluble portion is still under investigation. Potassium ferrocyanide does not react with tellurium chloride at once, but after a few hours prussian blue is formed. When tellurium is heated with aluminum the two combine with explosive violence, forming a chocolate colored compound difficultly fusible, which has the composition of $Al_2 Te_3$. It is hard and brittle, and can readily be ground to powder; when exposed to moist air it is decomposed and hydrogen telluride is slowly evolved; when thrown into water it is rapidly decomposed. Tellurium is readily deposited by an electric current either from an acid or alkaline solution. It has been found possible to separate tellurium from copper by adding an excess of sodium hydroxide and about 3 grammes of potassium cyanide for each gramme of copper present, and passing an electric current through the solution, when the tellurium is thrown down as a black, nonadherent precipitate, which can readily be filtered off; the solution can then be slightly acidified with sulphuric acid, and the copper estimated in the usual way by electrolysis.

A HIGH-PRESSURE CURRENT AND FIRE STREAMS.

An experiment to ascertain whether a high-pressure alternating current can be sent from a conductor to earth by means of a jet of water from a hose of a fire engine, and also whether the current can be transmitted to the fireman under such circumstances, was made a short time ago by Professor Slaby, of Berlin. The overhead conductors of a 10,000 volt power transmission line were used for the experiment. A voltmeter was connected between the metal mouthpiece of the water hose and the earth. On turning the water on to the live conductors no flow of current to earth was noticeable.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JUNE 30, 1896.

Alarms and Signals:—

ELECTRIC SIGNAL. C. H. Sherwood, Utica, N. Y., 562,929. Filed Oct. 21, 1895.
Consists of bell located at street crossing and means for closing and breaking circuit by passing trains.

AUTOMATIC ALARM FOR POSTAL CHUTES. T. F. Hagerty, Woburn, Mass., 563,033. Filed Jan. 21, 1896.
An electric contact within the chute adapted to be operated by falling letters.

FIRE ALARM. J. R. McCoy, Marshalltown, Ia., 563,203. Filed July 10, 1895.
The combination with alarm mechanism and leads under tension connected with the alarm mechanism, of fusible couplings arranged at intervals in the leads.

Batteries, Galvanic:—

GALVANIC BATTERY. E. S. Boynton, Brooklyn, N. Y., 563,127. Filed Feb. 21, 1895.
The elements while independently removable have one common electrolyte.

Conductors, Conduits, and Insulators:—

CONDUIT FOR ELECTRICAL CONDUCTORS. J. F. Cummings, Detroit, Mich., 562,806. Filed March 4, 1895.
Consists in an outer metallic pipe and an inner lining of wood or similar material, made in sections arranged in tubular form, and forced into the outer pipe, which acts to hold the lining in shape.

MEANS FOR PROTECTING UNDERGROUND ELECTRICAL CONDUCTORS. F. Davis and R. E. B. Crompton, London, England, 562,808. Filed April 11, 1893.
Cellular cases divided longitudinally into polygonal passages.

Distribution:—

SYSTEM OF ELECTRICAL DISTRIBUTION. G. J. Scott, Philadelphia, Pa., 562,924. Filed Jan. 3, 1896.
See page 43.

Dynamos and Motors:—

DYNAMO ELECTRIC MACHINE. N. W. Storer, Wilkinsburg, Pa., 562,864. Filed Oct. 2, 1895.
The extreme edges of the field magnet pole pieces are provided with slots extending transversely to the armature axis.

DYNAMO ELECTRIC MACHINE. C. C. and H. B. Warren, Chicago, Ill., 562,868. Filed Jan. 31, 1896.
Comprises a field core in the form of a hollow ring, armature coils disposed upon said core with a magnetizing coil secured within the interior of said ring, and a shelf projecting from the interior wall of said hollow ring, adapted to support said magnetizing coil.

Electro-Metallurgy:—

APPARATUS FOR CIRCULATING LIQUIDS IN TANKS. O. Szontagh and A. F. Schneider, Perth Amboy, N. Y., 563,093. Filed March 12, 1896.
Adapted for use in tanks for the electrolytic deposition of copper and other metals.

PROCESS OF EXTRACTING COPPER FROM ORES. J. Douglas, New York, 563,144. Filed Jan. 8, 1896.
Consists in suspending solid cuprous chloride in an electrolyte, inserting the cathode into the said solid cuprous chloride, and the anode into the electrolyte, and passing a current therethrough.

PROCESS OF EXTRACTING COPPER FROM ORES. J. Douglas, New York, 563,143. Filed April 11, 1895.
Consists in moistening solid cuprous chloride with water, inserting both electrodes of an electric circuit in the said solid cuprous chloride, and then passing an electric current therethrough.

Lamps and Appurtenances:—

HANGER FOR LAMPS. Erastus F. Hershaw, Abingdon, Ill., 563,232.
Comprises a pulley, and counterweight, the lamp being secured to the end of the wire.

Miscellaneous:—

ELECTRIC GAS LIGHTING APPARATUS. F. O. Plummer, Worcester, Mass., 562,850. Filed Aug. 16, 1895.
Adapted for incandescent gas burners.

ELECTRIC HAND LIGHTING GAS BURNER. G. J. Galbraith, Boston, Mass., 562,891. Filed April 18, 1896.
Details of construction.

THERMOSTAT. C. B. Rogers, Stevenson, Md., 562,917. Filed April 1, 1896.
Details of construction.

ELECTRIC HAND LIGHTING GAS BURNER. H. C. Thomson, Boston, Mass., 562,937. Filed April 18, 1896.
Consists in devices for operating the movable electrode simultaneously with the gas valve.

ELECTRODE FOR GALVANIC BELTS. E. S. Collicott, London, England, 563,016. Filed May 18, 1896.
Embodies two or more reticulated plates of aluminum or other metal which does not injuriously affect the skin, the said plates being connected by wires to the two poles of a pocket electric battery.

ELECTRIC HEATER. W. S. Hadaway, Jr., New York, 563,032. Filed Feb. 27, 1896.
The combination of a heat-radiating surface, and an electrical conductor in the form of a graduated helix disposed in spiral form, upon said radiating surface, but insulated therefrom.

AMALGAMATOR. F. B. Austin, Tempe, A. T., 563,119. Filed June 4, 1895.
The combination with a sluice having an opening therein, of a pan arranged in said opening and having inwardly extending and horizontal flanges at its sides, a cover plate resting on said flanges, the plate being insulated from the pan, spikes respectively projecting from the plate and pan, and means for electrically charging said plate and pan.

DOUBLE ACTING THERMOSTAT. H. Cortland, Toledo, O., 563,138. Filed June 3, 1895.
Comprises a frame, a convex flexible diaphragm secured therein, conducting fingers secured to the frame and insulated therefrom and operated by the diaphragm, the opposite ends of the fingers extending over the opposite side of the frame, and a contact screw secured directly in the frame beneath the ends of the fingers.

ELECTRIC PROGRAM-CLOCK. Dora Ogden, Columbus, Ind., 563,052. Filed Oct. 12, 1895.
Details of construction.

Railways and Appliances:—

ELECTRIC RAILWAY. H. Brandenburg, Chicago, Ill., 562,796. Filed March 11, 1895.
A shallow conduit adapted to rest upon the cross-ties of any railroad, having portable covers of angle irons, forming a continuous slot on the top, and conveying the electric conductors therein.

ELECTRIC RAILWAY. B. Ford, Johnstown, Pa., 562,890. Filed Aug. 30, 1896.
A sectional conduit system employing a battery on the car for operating the circuit controlling devices.

ELECTRIC RAILWAY. W. E. Hanshue, Kalamazoo, Mich., 562,894. Filed Feb. 27, 1894.
Comprises a double tubular casing with an opening at the top; suitable insulating lining for said casing; and copper bars supported on said insulation to transmit the electric current to the motor in the car and return it from the car.

TROLLEY WHEEL. I. B. Metzger, Canton, O., 562,904. Filed June 20, 1894.
A hollow wheel in which is placed an oil reservoir and means for feeding oil to the wheel spindle.

AUTOMATIC SPEED CONTROLLER FOR ELECTRIC CARS. H. A. Seymour, Washington, D. C., 562,925. Filed May 10, 1896.
The combination with an electric motor and its casing, of a speed governor and set of resistances mounted in or upon said motor casing, and brake mechanism having its brake magnet in circuit with said resistances.

TROLLEY. C. E. Powell, Bryn Mawr, Pa., 562,972. Filed Sept. 19, 1895.
Comprises a frame attached to the top of the car and carrying a trolley wheel, said frame being hinged to the top of the car.

ELECTRIC RAILWAY. J. Tatham, Philadelphia, Pa., 563,094. Filed Sept. 1, 1891.
Comprises a slotted conduit, a conductor therein, an insulating lining within the conduit and insulating blocks for supporting the conductor therein, said blocks having inclined approaches for lifting the current collector.

ELECTRIC RAILWAY TROLLEY SYSTEM. W. C. Keithly, San Francisco, Cal., 563,244. Filed Oct. 22, 1895.
Underground trolley.

Switches, Cut-Outs etc.:—

CUT-OUT FOR ELECTRIC CIRCUITS. G. W. Scovil and E. F. Gooding, Elgin, Ill., 562,980. Filed Aug. 27, 1895.
Details of construction.

Telegraphs:—

TELEGRAPH ALPHABET. S. V. Essick, Yonkers, N. Y., 563,148. Filed Sept. 16, 1895.
The characters are distinguished by the distance between two indicating points.

TELEGRAPHY. S. V. Essick, Yonkers, N. Y., 563,149. Filed Sept. 27, 1895.
Consists in means for causing impulses successively alternating in polarity in the line, each alternation of which represents a complete letter, combined with a receiver controlled by such successive impulses and adapted to record a letter for each alternate impulse.

Telephones:—

TELEPHONE ATTACHMENT. Will W. Dale, Fostoria, O., 562,807. Filed July 10, 1895.
Coin controlled apparatus.

SIGNALING APPARATUS FOR TELEPHONE LINES. F. R. McBerty, Downer's Grove, Ill., 562,906. Filed Oct. 29, 1895.
Provides a subsidiary path controlled by the current to the substation, for permitting the normal signal exciting current to flow.

ELECTRIC SIGNALING APPARATUS. M. Du Perow, Washington, D. C., 563,025. Filed Aug. 3, 1895.
Consists in the use of an electric motor, actuated by the local battery of a telephone and automatically set in motion by the switch hook, for operating the electric generator.

APPARATUS FOR TELEPHONE SWITCHBOARDS. C. E. Scribner, Chicago, Ill., 563,073. Filed June 12, 1895.
A system of signals adapted to indicate continuously the condition of each telephone line.

TELEPHONE SYSTEM. J. G. Smith, New York, 563,084. Filed Aug. 6, 1894.
Details of an individual call system.

TELEPHONE SWITCHBOARD SYSTEM. C. E. Scribner, Chicago, Ill., 563,245. Filed Nov. 4, 1895.
Consists in the combination, with the telephone line, of a relay controlling the connection of the line with the central source of current, and means for exciting the relay during the use of the line in conversation.

ARCTIC THUNDERSTORMS.

At the last meeting of the Royal Meteorological Society for the present session, Mr. H. Harries read a paper on "Arctic Hail and Thunderstorms," in which he showed that the commonly accepted opinion that hail and thunderstorms are almost, if not quite, unknown in the Arctic regions is incorrect. He had examined 100 logs of vessels which have visited the Arctic regions, and found that out of that number no fewer than 73 showed that hail was experienced at some time or other. Thunderstorms were not so frequent as hail, but they have been observed in seven months out of the twelve, the month of greatest frequency being August. Mr. Harries is of opinion that the breeding place of thunderstorms in these high latitudes is in the neighborhood of Barent's Sea.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

CHRISTY FIRE CLAY COMPANY.

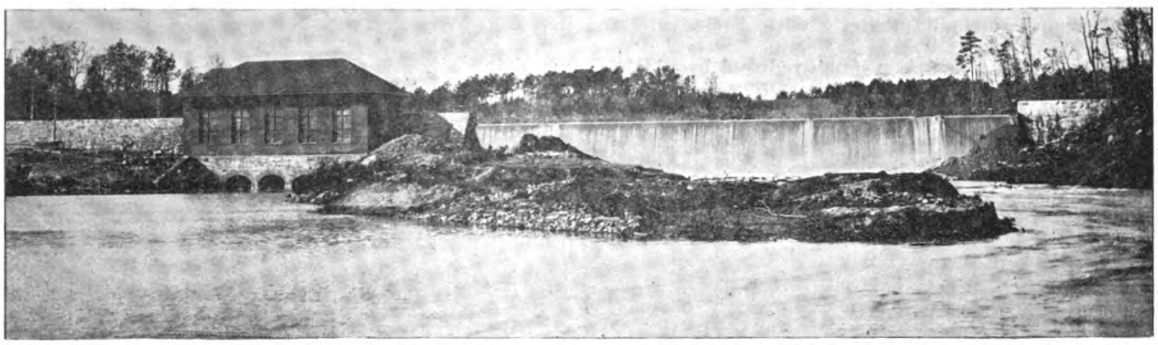
We are in receipt of a souvenir paper weight from the Christy Fire Clay Company, corner of Fourth and Olive streets, Chicago. The paper weight is a sample of one of the products of this company and its material will resist the action of high temperatures up to 3,800 degrees F., as determined by tests made on Seger cones by Prof. H. O. Hoffman, of the Massachusetts Institute of Technology, Boston, Mass.

The importance of suitable material for fire clay is now fully realized in numerous lines of manufacture and the preparation and manufacture of high grade refractory material for glass works, smelters, iron and steel founders, steam plants, etc., requires exhaustive and continuous theoretical and practical investigation.

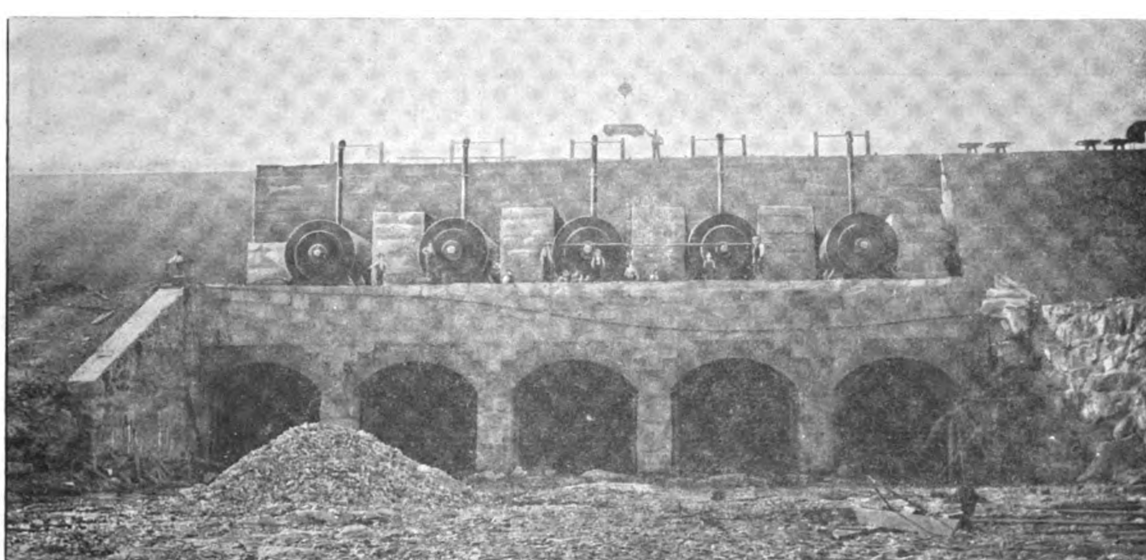
The company makes a specialty of manufacturing tank furnace blocks and pot furnace stone, fire clays raw, burnt and ground for all purposes.

THE PELZER (S. C.) MFG. CO.'S POWER PLANT.

The accompanying engravings illustrate the power plant recently installed for the Pelzer Manufacturing Company, Pelzer, S.C. One engraving shows the dam and power house, the other view showing five pairs of 39-inch horizontal Victor turbines in position, each pair of which is coupled direct to a 1,000 horse-power generator and regulated by a Giessler electro-mechanical governor. The power thus generated is transmitted electrically to the cotton mills of the corporation about three and one-half miles distant. This is putting 5,000 horse-power into a very narrow space and the arrangement permits locating the factories at a most eligible site. The dam and power house were built by W. A. Chapman & Co., Providence, R. I. The electrical machinery was furnished by the General Electric Company, of New York, and the turbines, feeders, power connections and electro-mechanical governors, together with all the plans for the entire development were furnishd by the Stilwell-Bierce & Smith-Valle Company, Dayton, O.



POWER HOUSE AND DAM, PELZER MFG. CO., PELZER, S. C.



VIEW OF TURBINES, PELZER, S. C., ELECTRIC POWER TRANSMISSION PLANT.

ENLARGEMENT OF THE PITTSBURG REDUCTION CO.'S PLANT AT NIAGARA.

In the enlargement of the electric plant of the Pittsburg Reduction Company, at Niagara Falls, the General Electric Company are placing rotary converters, which are the largest machines of their kind ever built. They will be five in number, each designed to deliver 600 kilowatts in direct current at a voltage of 160. They have sixteen poles and are operated at a speed of 188 revolutions per minute. Their commutators are of very large size, 3,750 amperes being delivered from each with carbon brushes.

The General Electric Company have adopted a novel method of construction in these machines by which the commutator is very effectively kept cool by ventilation. Air is drawn through the commutator spider, and, after passing over an extended surface inside the commutator, it passes out between the laminations of the armature and around the leads from the windings to the commutator.

In connection with each of the machines two 300 kilowatt transformers are used. The rotary converters are operated in pairs, each pair supplying one of the Pittsburg Reduction Company's circuits. So far two of these pairs, also one spare machine, have been installed, and there is still room for another pair in the apartment assigned to them. When the full equipment has been installed, the capacity of the electrical plant will be 4,500 horse-power, not counting in this the spare 750 horse-power unit. In the electrical plant of the Pittsburg Reduction

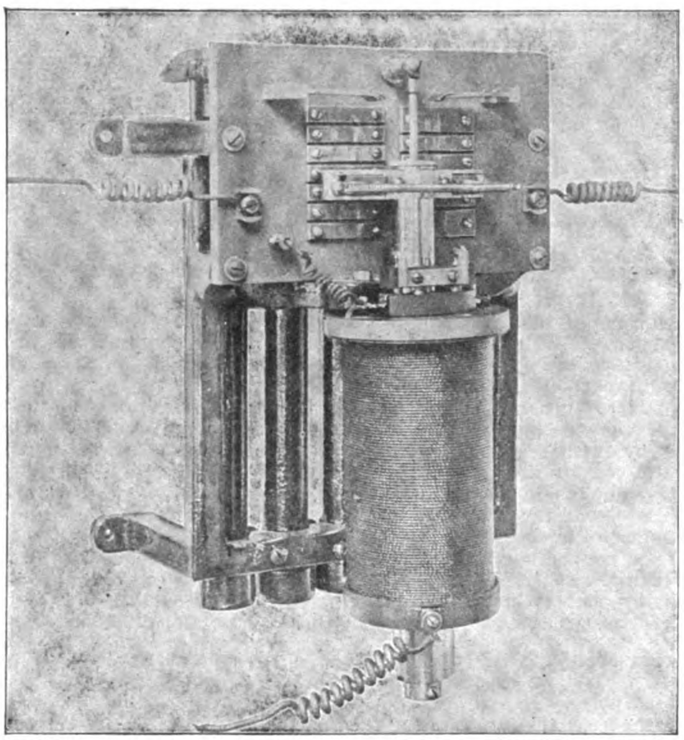
Company, the transformers are built on iron floor plates over a trench having brick retaining walls. In this trench air pressure is maintained by a small blower, and the air from the trench passes upward through the transformers and in its passage carries off the heat generated in them. All the conductors used, except the heavy current bus-bars, are placed below the floor, many being in the trench below the transformers.

The new plant of this company, now being erected on the property of the Niagara Falls Hydraulic Power and Canal Company, will be in operation before long.

A NEW SOLENOID AUTOMATIC MOTOR STARTER.

THE accompanying illustration shows the latest development of this form of automatic motor starter, brought out by the Automatic Switch Company of Baltimore, Md., which combines the remodeled working parts of their well known "Whittingham solenoid starter" with their tubular fireproof resistance.

The size of the apparatus has been much reduced by placing the dash pot and plunger inside of the solenoid, and the direction of movement allows the use of compression, instead of suction control.



THE SOLENOID AUTOMATIC MOTOR SWITCH.

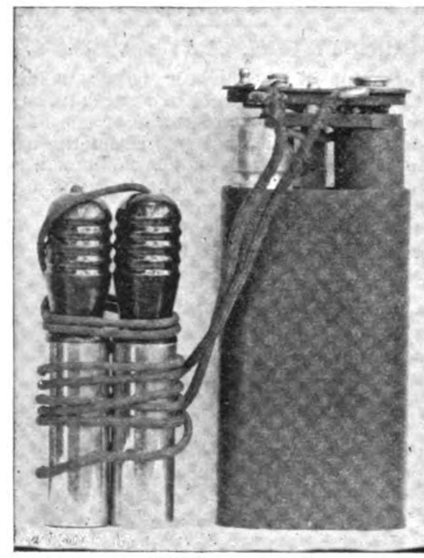
Renewable carbon brushes engage heavy copper contacts while carrying the starting current, and a substantial metallic circuit is closed when all the resistance is cut out.

This apparatus is particularly adapted for service wherever it is desired to start a motor automatically from a distance, such as elevator, pumping, and similar installations.

A POCKET FARADIC BATTERY.

THE CAPO-FARAD BATTERY AND APPLIANCE WORKS, of 27 Thames street, New York City, are putting upon the market a very efficient and compact pocket Faradic battery, which we illustrate herewith. The use of Faradic currents in certain cases of nervous and other affections is now a recognized necessity and has resulted in developing a large variety of apparatus for this purpose. It is necessary in such cases to employ a battery capable of yielding considerable current, and if good results are desired it must also be free from polarization.

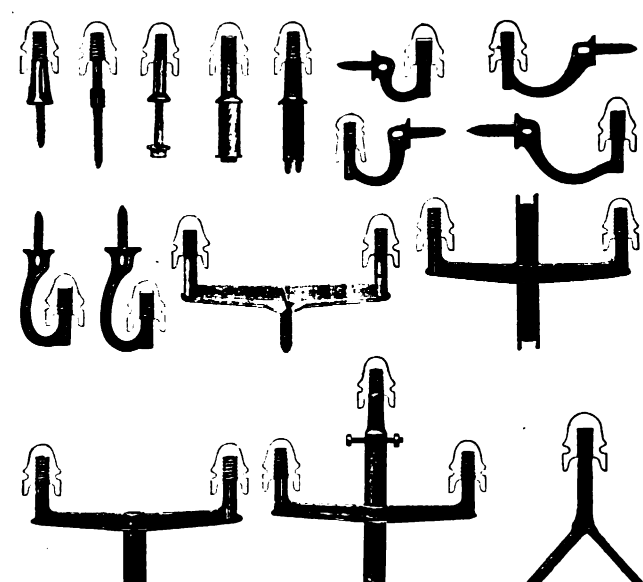
The apparatus consists of a single cell of the well-known Capo-Farad battery in conjunction with a Faradic coil of approximately the same length, both being inclosed in a vulcanite case. A switch is provided and the strength of the current is perfectly controlled by means of a sliding tube which forms a closed secondary around the iron core. The apparatus measures 2 by 3¾ by 1 inch, weighs 6 ounces and may be readily carried in the vest-pocket.



THE CAPO-FARAD MEDICAL BATTERY.

L. S. BEARDSLEY'S SPECIALTIES.

WE illustrate herewith a number of the line fixtures and other metal devices manufactured by L. S. Beardsley, of Naugatuck, Conn. Among these will be seen screw pins and bolt pins of various designs, window and cornice hooks of different patterns designed for use with different thicknesses of glass; break-arms to use either under or over cross-arms; and branch-arms to be inserted either from the top or bottom of the cross-arms. The general design and arrangements of these articles will be readily seen by reference to the accompanying illustrations.



BEARDSLEY'S MALLEABLE IRON PINS AND BRACKETS.

THE CARBON ELECTRIC GENERATOR COMPANY has been formed at Portland, Me., with a capital stock of $5,000,000, $800 paid in. The officers are W. H. Forbes, president, and W. C. Forbes, treasurer, both of Milton, Mass.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

Vol. XXII. JULY 15, 1896. No. 428

Electric Lighting.

THE ELECTRIC LIGHTING OF THE METROPOLITAN LIFE INSURANCE COMPANY'S BUILDING, NEW YORK.

It is not so very long ago that a private plant of a few hundred lights was considered a large installation and well worthy of extended notice in the technical press; but at the present time such installations have barely a paragraph devoted to them, overshadowed as they are by those in the large modern skyscrapers with thousands of lamps. A striking example of this kind, not only on account of the magnitude of the installation, but also on account of the methods employed in carrying out the work, is the electric lighting plant in the new Metropolitan Life Insurance Company's Building, facing Madison Square, New York, where its white marble front makes it the most prominent architectural feature of the Square.

ENGINES AND DYNAMOS.

Beginning with the heart of the plant, the engine and dynamo room, which part of the equipment is located on the Twenty-third street side of the building, running out under the sidewalk to the curb line, it may be premised that the new plant which we are about to describe is an extension of the one originally installed, which was found to be inadequate when the new eleven story annex on Twenty-fourth street was erected. We find as a remnant of the original plant two Corliss engines, driving by means of belts two 100 kilowatt 110 volt dynamos, revolving at 270 revolutions per minute, shown in our engraving Fig. 1; and in addition to these machines there are two 100 kilowatt generators, direct coupled to Armington & Sims engines, running at 230 revolutions per minute. One of these units is shown in Fig. 2.

All of these machines are compound wound, with iron clad ventilated armatures. They all have six poles, and are provided with carbon brushes, all of which can be raised simultaneously by means of a single lever. In order to avoid the resistance due to loose contacts, all the brushes are in direct connection with the brushholder by means of flexible copper strips. In order to provide for thorough ventilation, the armature core is built up in sections of one inch of core and 1-16 of an inch of air space alternately. The air is drawn in at the sides between the commutator segments, and thrown out by centrifugal action at the periphery, thus keeping up a continual circulation. The result is that the machines can carry an overload of 40 per cent. for one hour, and the regulation is such that no movement of the brushes is required between zero and full load. The belt-driven machines have outboard bearings on the pulley side, so that the bearing is relieved of all strain.

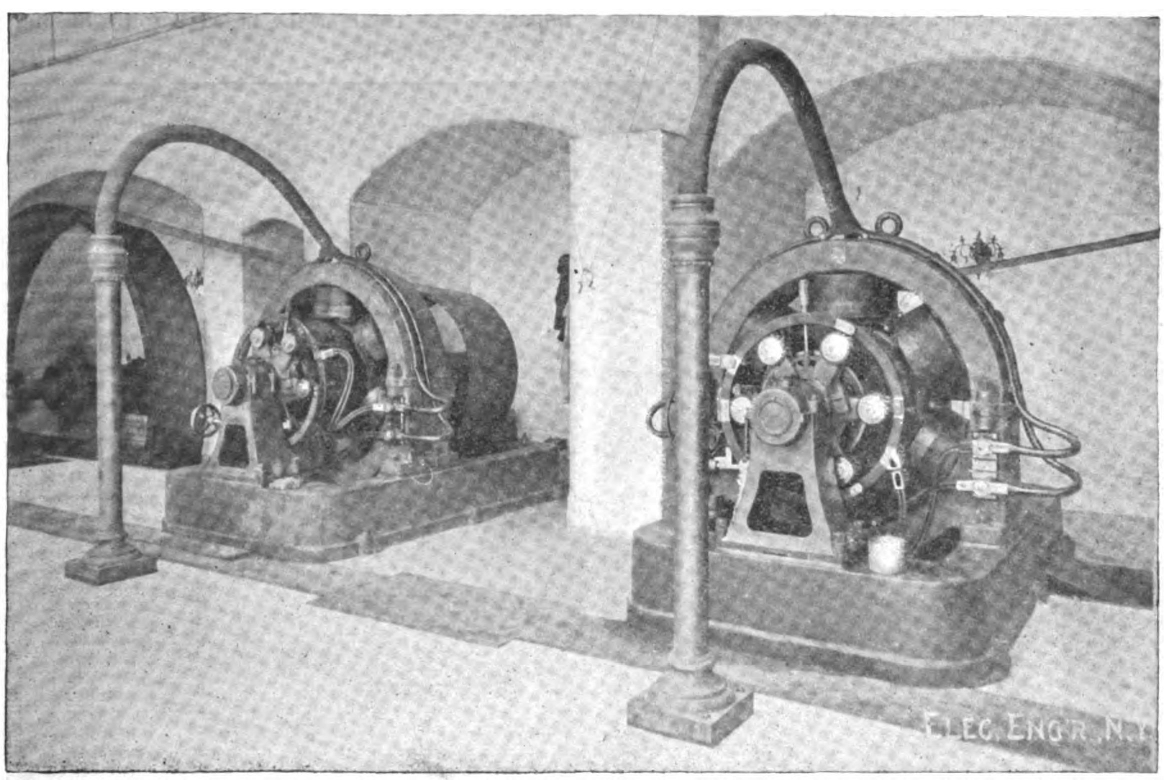


Fig. 1.—View in Dynamo Room, Metropolitan Life Insurance Building, New York.

The Corliss engines mentioned above which formed part of the original plant, drove a pair of high speed bi-polar dynamos through counter shafting, but as it was found that these machines could be used for running during light loads, they have been retained in another part of the plant, and the Corliss engines utilized for direct driving, and space considerably economized by the discarding of the counter shafting.

THE SWITCHBOARD.

The switchboard controlling the entire plant is illustrated in engraving Fig. 3, which gives but a faint idea of its beauty; the board embodies every device recognized as the latest and best of its kind for switchboard work. It is arranged for six

dynamos, four being the 100 kilowatt machines in the main engine room, above described, and two 50 kilowatt bi-polar machines, which were replaced in part by the new plant.

The current is led from the machines through heavy cables, which arch gracefully into the top of and pass down ornamental

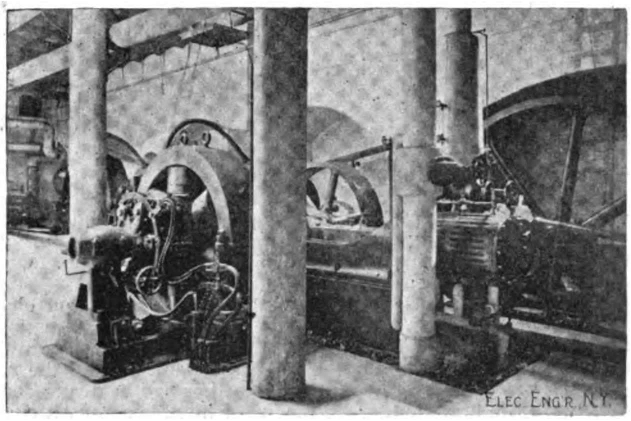

FIG. 2.—DIRECT CONNECTED UNIT, METROPOLITAN LIFE INSURANCE BUILDING.

pillars into the floor; here they enter into iron armored conduit, laid in brick-lined trenches which run to the back of the switchboard. The outlets are shown in Fig. 4, which gives a rear view of the central dynamo section of the switchboard.

As will be seen in Fig. 3, this section of the switchboard is equipped at the bottom with a row of six Harrington circuit breakers, one for each machine. Above these are the handles

meter, etc. Two ammeters are taken off the same shunt of the main bus-bar, one of these ammeters being placed on the switchboard, and the other in the boiler room to indicate the

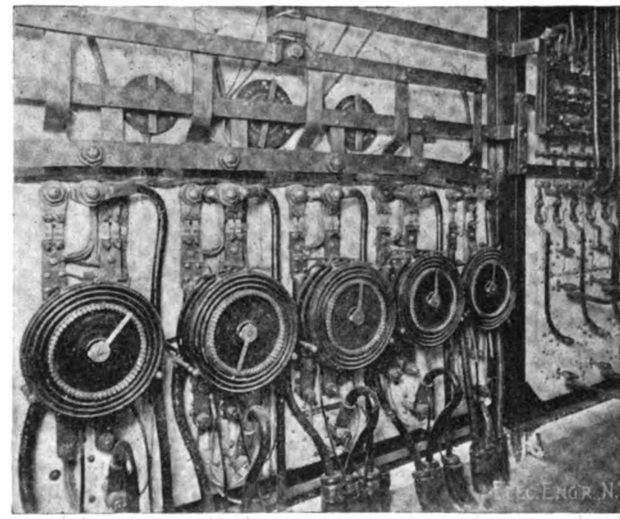

FIG. 4.—VIEW OF BACK OF SWITCHBOARD.

load to the firemen, so that they may be able to regulate the supply of steam according to the demand.

In order to reduce the number of ammeters required ammeter shunts are placed on all feeders, and a switch so arranged on the front of the board that by turning a handle

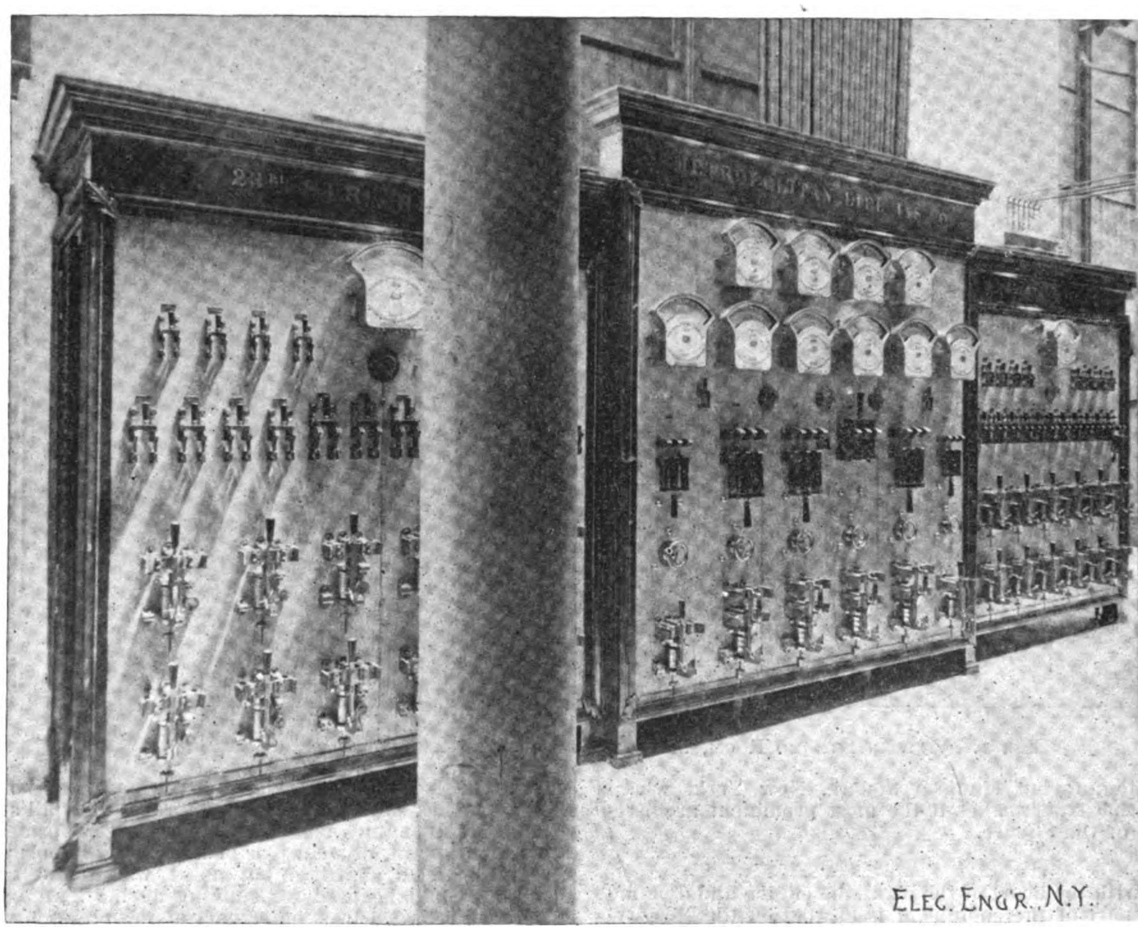

FIG. 3.—VIEW OF SWITCHBOARD, METROPOLITAN LIFE INSURANCE BUILDING, NEW YORK.

the ammeter is successively placed in circuit with each Fig. 4. Above these again are the main multiple-contact jaw switches, and then a row of Weston ampere meters. The board is also equipped with a differential galvanometer for throwing the machines in multiple, ground detector, and volt-

the ammeter is successively placed in circuit with each feeder. Great care has been taken in the construction of the switchboard, and especially with the joints. As shown in the upper right hand corner in Fig. 4, double bus-bars are employed on the back of the board for one-half the distance, and

double contact joints are employed. The feeder panels shown on either side of the central dynamo panel in Fig. 3 control, respectively, the Twenty-third street building and the newly added eleven story wing, controlling in all 4,340 lights.

Both these panels are also provided with Harrington circuit breakers, and in addition thereto fuses placed at the back of the board. This also holds true of the dynamo leads.

The switchboard is surrounded by a bronze frame, with solid bronze doors at each end, and the board stands out four feet from the wall, thus giving plenty of room for access. The cut-

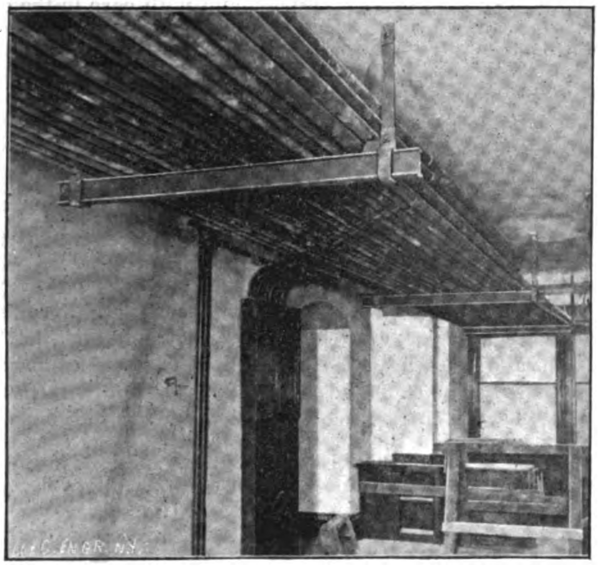

FIG. 5.—RUNWAY OF INTERIOR CONDUIT TUBING.

out panels are of marbleized slate, and the mountings in polished brass.

DISTRIBUTION.

From the switchboard the cables, of the Grimshaw type, rise in fifty-six interior iron conduits, of the Interior Couduit Company's type, suspended in the basement from the ceiling after the manner shown in Fig. 5. This runway of iron interior conduits is necessarily subjected to a number of curves before reaching the cable shaft, which is especially provided for that purpose, and this piece of conduit work is one of the finest which has yet come under our notice, doing infinite credit to those in whose charge it was placed. The extent of this work may be gathered from the statement that twenty-seven miles of duct, thirteen miles of feeders and thirteen miles of tap circuits are distributed in the building.

One feeder is provided for each floor, so that each floor can

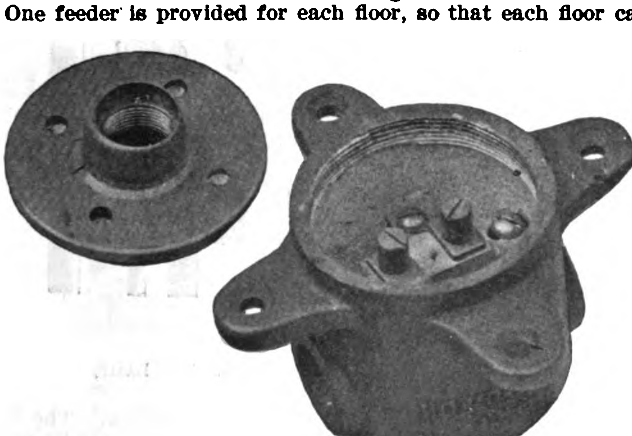

FIG. 6.—FLOOR OUTLET BOX.

be separately controlled, and in order to permit of easy manipulation iron gratings are provided at every floor level in the cable shaft. At the end of each feeder pipe a junction box is placed in the shaft, and the feeder then led through the wall of the shaft into the cut-out box. These cut-out boxes are designed so that the switches and cut-outs are placed together in the same cabinet enclosure, so that access to either can only be had by the person authorized to handle one or both. From each of these switches and cut-out boxes there are run four sets of submains on each floor. These again go to four locations, and from each of these points four submains are run, making eight centers of distribution on each floor.

The work of the Metropolitan Life Insurance Company requires the services of several hundred clerks and typewriters, and in order to avoid drop lights a special system of floor wiring was adopted by which the circuits are brought up directly beside the desk of each clerk. In order to accomplish this, floor outlet boxes, one of which is illustrated in Fig. 6, were designed, the construction of which is shown in the cross-section, Fig. 7. As will be seen, it consists of a cast iron pot, enameled on the inside, into the sides of which lead iron pipes carrying the conductors. Suspended in the center of the pot is an insulator, upon which are mounted the terminals, to which the conductors are connected. Four wings are cast at the side of the pot which are screwed into the rough floor, and the pot is closed by a brass cover, made watertight by a rubber gasket, the flat part of the cover coming flush with the finished floor. From the center of the cover rises a short threaded pipe section, into which is secured interior conduit pipe, finished at the top with a hard rubber cap, which screws soft rubber washers in contact with the top of the conduit

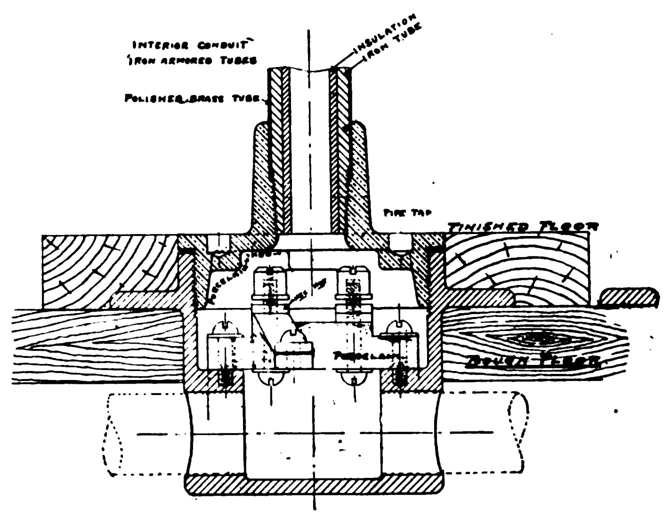

FIG. 7.—FLOOR OUTLET BOX.—SECTION.

pipe, thus sealing it hermetically. This gives a complete waterproof construction, and has proved a very efficient device. There are 544 of these floor outlet boxes, which were manufactured by Jos. DeRycke, furnishing 1,319 outlets. The magnitude of this part of the work will be realized when we state that are 4,000 lights for desk wiring, and 2,000 fixtures.

On the second floor of the building, which contains all the company's filing cases, 275 ceiling boxes are employed, each controlled by a Cutter flush switch, grouped in suitable panel boards. These iron ceiling boxes are covered by a 4½ inch block of hard wood screwed directly to the iron box. No cords whatever are employed.

The outlet boxes on the various floors consist of two slate boxes, one placed within the other, so that every possible precaution against fire has been taken at this point.

In this necessarily brief description of a plant containing many details we can give but a faint idea of the care and oversight with which the work has been carried out, and the result has been that the plant may well be considered one of the finest in the city. The entire work was carried out by the Western Electric Company, according to the specifications of the consulting electrical engineer, Mr. C. O. Mailloux.

PUBLIC ARC LIGHTING ON MOTOR GENERATOR AND CONVERTER SYSTEMS.

HIGH tension continuous supply systems possess one desirable feature. It is that arc lamps may be run in series across the primary mains, and all the advantages that are claimed to result from the adoption of rectifiers in alternate current stations are at once gained. The one set of plant can be run for the incandescent and arc lighting during the early hours of the morning, and no additional apparatus of any kind is required either in the station or at the lamps.

The engineers on alternating systems are divided in opinion as to the best manner of securing like benefits with their type

of plant. It has been proposed to run continuous current arc lighters from synchronous alternating motors, but the efficiency of this combination seems to be rather low and we are not aware that it has been adopted anywhere on a large scale.

In principle it is nothing else than another adaptation of the motor-converters used in the outlying portion of the Dublin tramway lines, and this will be fresh in the minds of our readers from the illustrations and description that recently appeared in our columns. As the arrangement was specially designed for power transmission, three-phase currents were adopted, but there is no reason why ordinary single-phase supply should not be utilized where, for the present at least, lighting forms the principal work of the supply concern. Instead, therefore, of running 500 volt dynamos, arc lighters might be so driven and the efficiency of the continuous current arc, together with the advantage of running only one unit of generating plant for the greater part of the night would result. Indeed, the whole object of Messrs. Hesketh and Gibbing's paper, read at the meeting of the Municipal Electrical Association last week, is to prove that the alternating motor-continuous-current-generator combination is a feasible and satisfactory method of tackling such branches of electrical work as require currents, popularly described as being of a different kind to that provided for the incandescent supply of a district.

A second method of meeting the conditions considered by some to be requisite for successful arc lighting is to install rectifiers. We have dealt with this phase of the question so fully in a recent article in these columns that it is unnecessary to say much more on the same topic, except to point out that rectifiers are running machinery and take quite as much attention as an arc lighter or motor-converter, while they do not hold in synchronism as steadily or strongly as would an alternating motor. Considering that a large number of alternating stations persistently run in parallel, and find no difficulty in so doing, it is evident that there need be little anxiety on the score of reliability with a synchronous motor.

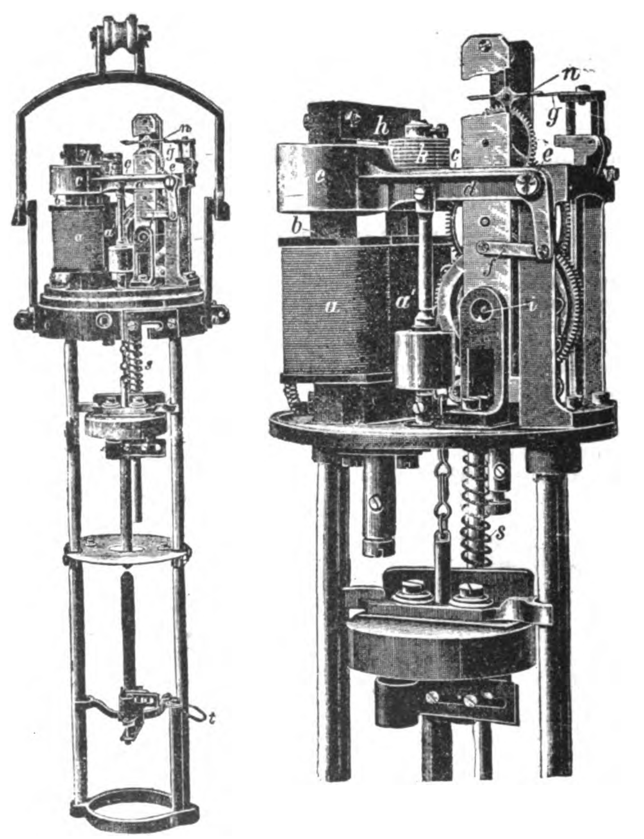
Although the alternate current arc is not itself so efficient a light-giver as the continuous, the exigencies of public supply have led to arc lighting by alternating lamps run off separate transformers, and the simplicity of this system has a great deal to recommend it. The effect and general illuminating qualities of a 600 watt alternating arc are quite as good as those obtained from a 500 watt continuous lamp, and what is lost in the arc, due to its intrinsic lower efficiency, is compensated for by the absence of losses elsewhere. Those who have seen the lighting of Hastings with Brush lamps, of Newport and Ayr with Lewis lamps, and the Crompton-Pochin lamps at Yarmouth, will appreciate the force of the argument. Of course, some engineers have thought it worth while to put in separate plant for arc lighting, and the Siemens constant current machine at Derby, the Siemens constant potential machines at Hampstead, and the Johnson & Phillips arc lighters at St. Pancras, are due to the strong opinions held by the designers of these stations.

Where high tension continuous currents are employed, the problem is one of details only. Thus, at Oxford, an experiment in public lighting was commenced two years ago, when the Corporation authorized the local company to erect and supply some arc lamps for street lighting, and, as the results were in every way satisfactory, the electric lighting is being extended on lines suggested by Mr. J. Hardie McLean. The number of lamps first tried was 16, and this number has now been doubled. The lamps are run 20 in series across the high tension 1,000 volt primary mains, being supplied direct from the station omnibus bars. The remaining 12 are connected two in series across the 100 volt low tension distributors. Twenty-four arcs are extinguished at midnight, and, when this occurs, a couple of 16 candle-power incandescents, carried by supplementary brackets on the column, are switched on. The other arcs, eight in number, are kept lighted during the hours of darkness. Mr. McLean has devised an automatic switch to extinguish the all-night arcs and incandescents at daybreak. This consists of a switch of the tumbler type operated by an electro-magnet, which is itself under the control of a clock. The switch is fixed above the electro-magnet, and the armature of the latter has a small connecting rod fastened to it and connected with the switch. In the upper end of this rod is a long slotted hole through which a steel pin fixed in the end of the switch lever passes. The clocks are wound daily by the lamp trimmers, and left set at the time when the lamps are to be switched off. When one of the clocks makes contact, its armature is pulled down by the magnet and a spring then comes into action separating the contacts, and the pin in the lever working in the slotted hole gives a quick break. As the magnet-circuit is broken at the same time, sparking in the contacts of the clock is obviated.

At Portsmouth, where the arcs and incandescents are also in use, the change-over from arcs to incandescents is effected by a polarized switch, brought into action by reversing the rectified current. As it is becoming general to run arc lamps off the low tension mains in large cities, a clock-switch that can be relied upon will prove a very useful appliance, and be an improvement on the bicycle switchman who is employed in the absence of a suitable automatic device. It appears that in America the tendency is to press up the number of lamps in series beyond even the present figure of 100; in this country there is evidence of greater success attending the running of lamps in parallel and utilizing the distributing mains for both private supply and public lighting. Alternating arcs are now being largely used by shopkeepers, and with care in the choice of carbons and proper adjustment, combined with the trend towards lower frequencies, there seems to be no reason why a similar course should not be adopted with them.—London "Electrical Review."

KOERTING & MATHIESEN'S ALTERNATE CURRENT SHUNT ARC LAMP.

INSTEAD of employing the usual attraction of a magnet in its armature for striking and regulating the arc, the inventors of the lamp illustrated in the accompanying engravings make use of the inductive repulsion of the rings placed in front of the poles of an alternate current magnet. For this purpose there is employed a horseshoe electro-magnet, having a core, b, and coils, a a', the ends of the core rising above the induction rings, c c'. These rings are cast in one with the lever d, and when no current is on the lamp the weight of the rings presses them upon the tops of the spools; but as soon as the magnet is energized the secondary current induced in the rings causes a repulsion in the direction of their axis depending



ALTERNATING CURRENT SHUNT ARC LAMP.

upon the current passing in the shunt winding. The bent lever, d, is thus turned on its pivot, e, and transmits its movement by means of the rod, f, to the wheel train, pivoted at i. The latter swings outwardly until the fan wheel, n, is released from the tappet, g, so that the carbons, which up to that point were separated, are forced together by the weight of the upper carbon holder. As soon as they touch each other the magnet is momentarily deprived of current and the rings drop by their weight, so that the wheel train swings back, thus causing the fan wheel to be stopped and the arc to be formed.

The subsequent regulation of the arc is evident. With the maximum potential, the induction rings are raised so high that the fan wheel is momentarily released from the tappet, g, thus

allowing the carbons to approach each other for a small distance, when the escapement is stopped.

In order to increase the inductive repulsion, the magnet core, b, is provided with a magnetic short circuiting bridge, h. This bridge would not be necessary if the magnetic lines passing through the rings were absorbed in their entirety, which condition is not attainable; the object of the bridge is to allow the leaking magnetic lines to get into action on the other side. The weight of the induction rings alone constitutes the greater part of the force opposing the inductive repulsion, but is supplemented by the weight of the discs, k, by the addition or removal of which the potential taken by the lamp is regulated. The lever, d, is made of aluminum, since this metal has the most favorable relation between specific gravity and specific conductance. The magnet with inductive repulsion with regard to its electrical properties is claimed to have an advantage over magnets with armature attraction, in that the position of the armature is without influence on the co-efficient of self-induction of the shunt coils, and hence the lamp potential remains unaffected by the position of the armature. From the mechanical standpoint another advantage is gained by the absence of a regulating spring, since alternating current lamps are continually subjected to vibrations which gradually cause the weakening of the spring. The lamp can be used equally well for single parallel work, as for grouping in series.

POWER TRANSMISSION.

THE LANGDON-DAVIES ALTERNATE CURRENT MOTOR.

SOME important improvements have been introduced into the design of self-starting, single-phase, alternating current motors by Mr. Langdon-Davies, who has succeeded in making marked advances in the direction of starting torque and efficiency in this class of machines.

The machine we are about to describe, which is being introduced by the Alternate-Current Electro-Motor Syndicate, Limited, London, has an efficiency, according to Prof. S. P. Thompson's report, of 91 per cent. at its maximum power, and also at half-power, whilst between these limits it rises to the high figure of 95 per cent. Further, even at one-third load its efficiency is 75 per cent. These figures are the more remarkable in that the motor tested was of but .85 horse-power, and it has long been recognized that in general small motors are much less efficient than large ones. Further, Prof. Thompson states that the motor will start under an absolute dead load, equivalent to about a quarter of its maximum torque, while further experiments have shown that in practice this figure may be doubled, or, if a slight sacrifice of efficiency is made, the starting torque can be still further increased.

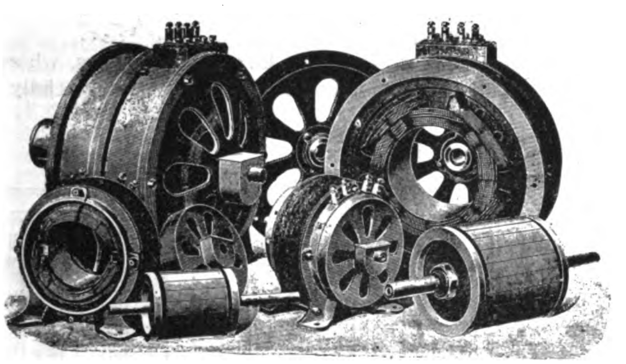


FIG. 1.—THE LANGDON-DAVIES ALTERNATING MOTOR.

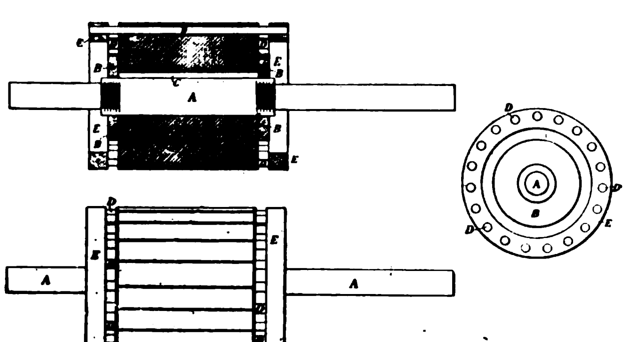
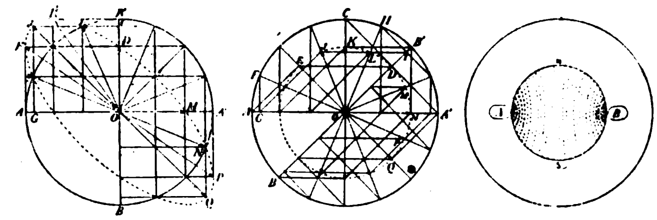
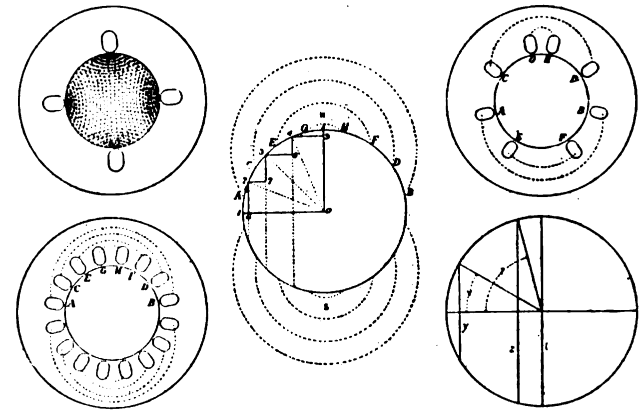


FIGS. 2, 3 AND 4.

The motor itself is shown in Fig. 1, which represents two different sizes of the motor, both complete and in their separate portions. Two of the armatures are shown lying beside their respective field magnets, while in Figs. 2 to 4 the construction of these armatures is shown in more detail. Each armature consists of a set of discs, Fig. 4, mounted securely on a spindle, A, between stout pressure plates, B, and insulated from each other in the usual way. Near their edges a number of circular holes are bored, through which pass stout copper rods, D, thoroughly insulated from the metal around them. These rods terminate at each end in stout copper rings, E. Opposite each rod, D, the armature is slotted longitudinally, as shown in Fig. 3, with a view to reducing Foucault currents.



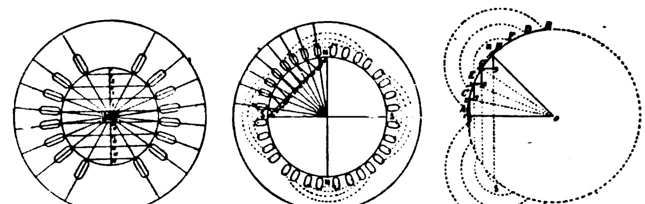
FIGS. 5, 6 AND 7.



FIGS. 8, 9, 10, 11 AND 12.

The field winding is explained in detail in Figs. 7 to 18, which represent the field magnet discs with their perforations. Through these holes are passed two entirely distinct coils of wire, arranged in such a way that when a current is passed through one coil it tends to produce poles in the ring in one direction; while if a current passes through the other coil it tends to produce poles at a direction making a definite angle with the previous one. The discs are clamped together inside a gun-metal casing, provided with flanges, by means of which the motor can be secured to any suitable foundation. Perforated covers are bolted on each end of the casing, and are fitted at their centers with bearings for the armature spindle.

It is not practicable to split a single-phase alternating current into two branches with a phase difference of 90 degrees, although it is easily possible to accomplish a phase difference of 45 degrees. If such a split current be supplied with two sets of coils wound at right angles to each other the resultant rotating field will not be uniform, as is shown in Fig. 5. Here A A′ and B B′ are the two axes of the coils, and the lines OF, OE, OJ, etc., show the magnitude of the resultant field at intervals of 1-16 of a period. Examining the ellipse which

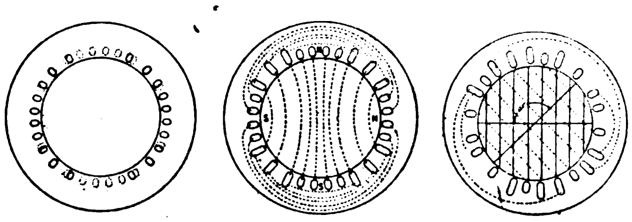


FIGS. 13, 14 AND 15.

bounds the line representing the intensity of the resultant field, it is seen that the strength varies, and that the angular advance is not uniform.

In Fig. 6 is shown the improved method of arranging the coils in the Langdon-Davies motor. The two axes of the field windings are inclined to each other at an angle of 180 degrees —45 degrees, that is, the supplement of the phase angle between the component fields (taken as before at 45 degrees). Following out the construction it will be seen that the curve joining the lines OE, OJ, OK, etc., is a circle. The resultant magnetic field is therefore of constant magnitude, and moreover it has a constant angular advance.

It has been found impossible to distribute the magnetic field in an alternate current motor as usually constructed with a



FIGS. 16, 17 AND 18.

squirrel-cage armature and small air-gap. This is shown in Fig. 7, which represents the test made with iron filings. It is evident from this that with a single coil of wire wound across a diameter there will be a constant magneto-motive force acting in the central space and the reluctance will be least at the edges and greatest at the center. It follows that the magnetic field will be densest at the edges near the winding holes in the core. Again, when two such fields are combined as in Fig. 8, the resultant field can never be uniform for any position of the coils.

In the improved motor the windings are distributed so as to compensate for the varying reluctances of the central space. For example, in Fig. 9, which shows the method of winding for a two-pole machine, a portion only of the winding is threaded through the holes A B, while another portion is threaded through C D, another through E F, etc. The several windings vary the magnetomotive force in proportion to the reluctance. The dotted lines show the directions taken by the windings in passing from hole to hole.

The number of the sections into which the winding is divided varies in accordance with the size of the motor. Three divisions are sufficient for the smallest class of two-pole motors, four or more sections for larger two-pole motors. The split current with a phase difference of 45 degrees between the two branches is obtained in the smaller motors by placing a non-inductive resistance in series with one of them and making the ampere-turns in each the same.

The coils are proportioned as follows: In Fig. 10 the points A, B, C, D, E, F, G, H correspond to equally spaced holes. The intervals between these points are bi-sected at 1, 2, 3, etc. From the neutral point 1 and from point 5 radii are drawn, meeting at 0. From 2, 3, and 4 perpendiculars are dropped on 0 1, and the horizontals 2 7, 3 8, and 4 9 are also drawn. Then the lengths 2, 6 — 3, 7 — 4, 8, and 5, 9 are proportional, respectively, to the numbers of turns of wire which should pass

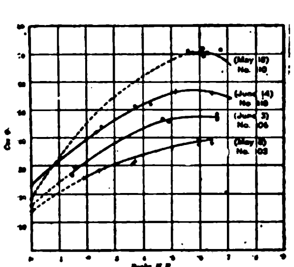


FIG. 19.

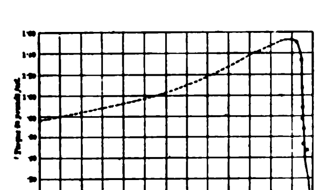

FIG. 20.

through the holes A B, C D, E F, and G H, respectively. The rule given has been deduced from the fact that the reluctance of the two paths represented in Fig. 12 by the lines y and z varies approximately as the sines of the angles Y and Z.

When the total number of turns to be wound on is but small, sufficient accuracy cannot be obtained with equally spaced holes, and it is then necessary to wind an equal number of holes in each section and to vary the distances between the holes as shown in Fig. 13. The vertical diameter is divided into twice as many parts as there are coils to be wound, as shown by 1, 2, 3, 4, etc. Then at each evenly numbered part, horizontals are drawn to meet the polar surface of the field magnets shown, and the holes for the windings are located on radii through the points thus obtained. Where a four-pole field is to be used, the method employed is shown in Fig. 15. As before, the windings in each coil must be proportional to the lines 2, 6—3, 7—4, 8, and 5, 9. If equal numbers of turns are desired through each set of holes, the latter may, as in the two-pole machine, be unequally spaced, as in Fig. 14. Here the line S N is divided into twice the number of parts required, and the holes located on the radii through the intersections of perpendiculars to the line S N at the even numbers, with the polar surface. In all these cases a single winding only has been dealt with, the requisite rotary field being obtained by superimposing two of these sets of windings, as already described. The same holes, or some of them, may be used to accommodate both sets of windings. Thus in Fig. 16 the full lines show the holes set out for one set of windings, and the dotted lines for another set. In practice the overlapping holes are adjusted so as to coincide, as in Fig. 17. Fig. 18 shows the arrangement of holes for the two sets of coils when the lag is 45 degrees, whereas Fig. 17 was designed for a difference of phase in the two sets of coils equal to 90 degrees.

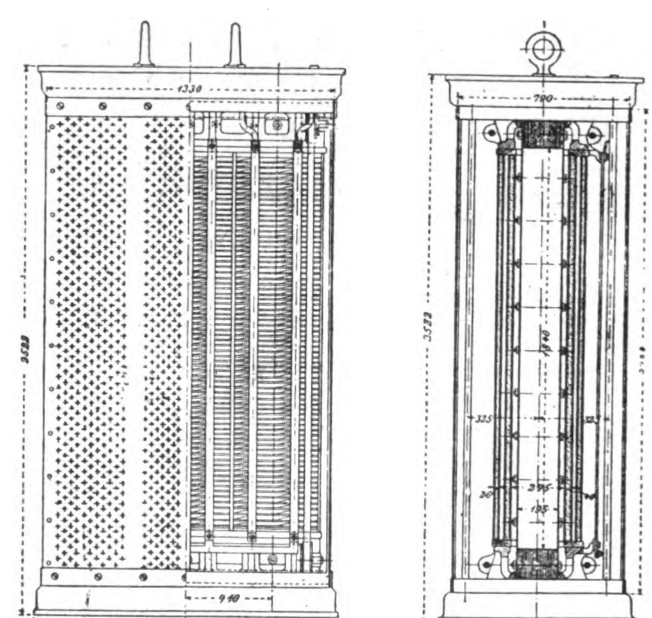
Figs. 19 and 20 show curves which were plotted from Prof. Thompson's test of a ¾ horse-power motor. It shows a good starting torque, although not so much as can be obtained with direct current machines. The power factor, Fig. 19, is considerably affected by very small details in the construction, as, for example, the width of the slots in the armature and field, width of the air gap, the number of bars in the armature and the number of sections per pole in the field winding.

TESTS ON LARGE POLYPHASE TRANSFORMERS.[1]

BY DESIRE KORDA.

NO general rule can be given for the dimensions of transformers. Cooling surface, efficiency, drop and no load currents, as well as cost, are all points which must not be lost sight of in designing and which involve at the same time some contradictory conditions.

This is the more important in large transformers, where the judicious choice of form and dimensions is made especially difficult on account of the limited cooling surface which is obtainable. There are indeed transformers which cannot stand their originally intended full load, in spite of high efficiency, partly on account of the large drop with induced load. Usually it is, on account of the insufficient cooling surface, partly preferable to use several small transformers in place of one



FIGS. 1 AND 2.—160 KILOWATT ROTARY CURRENT TRANSFORMER.

[1] "Elektrot Ztschr."

large unit. This is, besides, more advantageous, above certain sizes, on account of the idle currents, inasmuch as the transformers may be put into circuit according to demand. Nevertheless, the lack of room or first cost often causes one to decide on transformers of above 100 kilowatts, and, indeed, more frequently so, as one would think, judging by the few publications on the action of such transformers in literature on the subject.

It, therefore, seems to me to be not uninteresting to give a few experimental results, which I have made on two transformers of 160 kilowatts, which were intended for an inductive load of 185 kilowatts and which was carried out by the Fives Lille Society for a large hydraulic polyphase current installation.

Figs. 1, 2 and 3 show the construction of these transformers. They consist of three vertical sections in one plane, closed above and below by cross yokes. This form is preferred on account of the easy construction and assembling. The ratio of transformation is 1 : 100 with principal voltages of 72 and 7,200, respectively, and corresponding to a phase potential approximately of 41.5 and 4,150 volts, respectively. The periodicity is 50 per second.

The coils are wound one within the other, the high-voltage ones being within. Both are a radial distance of 15 mm. apart, separated by two paper cylinders and an air gap of 10 mm. Cooling is increased in consequence of the air draught, especially since the cooling surface is practically doubled. Finally it can be stated as an advantage that the tube thus formed can be used to hold a rope in lifting out the low-voltage coil when the transformers are being taken apart.

The winding consists of 66 parallel wound spools of twelve convolutions each. The ends of these spools are soldered to copper lasts, of which three are connected by one copper strip, which in that way form the neutral point of this star winding. The other three strips are used for the conduction of the current. The spools consist of rectangular wire of 20 square mm. cross section.

The resistance of the low-voltage winding is .000143 ohm, that of the high-voltage winding 1.5 ohms. The total weight of the copper is 1,460 kg. With a cross section of the iron of 332 square centimetres the maximum magnetic induction is 4,700 C. G. S., the total weight if iron is 2,070 kg.

The iron losses were measured by means of the wattmeter, with no load and the following values were found: While the no-load current in the outer sections in the low-voltage winding amounted to 60 amperes and in the winding of the middle section only 50 amperes, the wattmeter which was inserted into each of the three-phase windings read but 1,133 watts in the outer and 1,415 watts in the middle sections.

These differences can be explained thus: For the middle section the magnetic circuits are symmetrically situated and shorter than for the two outer ones, consequently the leakage is smaller than in the latter. Thus on the one hand the no-load currents become smaller, while on the other the iron losses become greater for the middle sections, for almost all lines of force go through the iron, causing hysteresis and Foucault currents, while the dispersed lines of the outer sections in the air have no such corresponding losses. In a similarly constructed transformer of 120 kilowatts I could determine the identical relations. While in the outer sections the idle currents were 37 amperes and the iron losses 708 watts, the corresponding figures for the inner sections are 28 amperes and 836 watts.

From the observed values we find for the 160 kilowatt transformer as watt currents, with no load:

$$1133 \cdot 41.5 = 27.5 \text{ amperes}$$

and

$$1415 : 41.5 = \quad 34 \quad \text{"}$$

and therefore as magnetizing currents for the outer sections

$$\sqrt{60^2 - 27.^2} = 53.5 \text{ amperes},$$

and for the minor ones

$$\sqrt{50^2 - 34^2} = 36.5 \text{ amperes},$$

corresponding to a lag with no load of cos. $\phi = .45$ and .705, respectively.

Judging by the above, symmetrically arranged magnets, such as the triangular (Oerlikon), or star arrangement (Siemens), would be preferable to three sections lying in one plane. But by putting on the load these differences become negligible.

According to the above values the total loss in the iron = 3,681 watts. On the other hand, the copper losses in work equivalent to 160 kilowatts, to which correspond 1,280 amperes in each of the low-voltage spools is 1,500 watts, from which we get an efficiency of 97 per cent. The outer surface has without the air gap 85,000 square centimetres between the spools, corresponding to a cooling surface of 17 square centimetres per watt lost. Through the air gap this cooling surface is at least doubled.

To determine the drop on account of magnetic leakage Kapp's method was used. The high-voltage spools were short circuited and the potential determined which had to be supplied to the low-voltage spools to cause the normal current in the short circuited spools. In the first measurements 8 to 10 per cent. drop of the normal potential was found with 1,500 amperes. The cause of this was discovered later when it was found that a large part of this loss was caused by C^2R losses, inasmuch as the copper connections heated up.

With a load of 12.5 amperes in the short circuited spool, to which corresponded 1,280 amperes in the primary winding, four volts difference of potential was found between any two phases and the differences for the three sections were quite negligible. The above currents correspond to a load of 160 kilowatts. On the other hand, with 185 kilowatts, that is, with 14.5 amperes in the short circuited and 1,500 amperes in the primary coil the

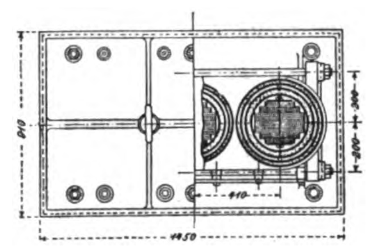


FIG. 3.

recorded voltage was 4.5 volts. In the first case there was therefore necessary 5½ per cent., in the second 6 per cent. of the normal voltage (72 volts) for the production of normal current strength.

Since every winding shows .5 volt drop, we find from Kapp's diagram that the drop of potential with an induced load of cos. $\phi = .85$, is but 1½ to 2 per cent. In feeding incandescent lamps the drop would be still smaller. In supplying motors, especially large ones, with an efficiency of not less than 70 per cent., these transformers do good service and in a combined service of motors and lamps the fluctuations are still permissible.

ELECTRIC TRANSMISSION ON THE PACIFIC COAST.

THE incorporation of the Pacific Transmission Company, of San Francisco, marks the beginning of an interesting project for the electrical transmission of power from the mouth of California coal mines. The company will be controlled by the San Francisco and San Joaquin Valley Coal Company, whose mines are at Corral Hollow in Alameda County, and is one of several important undertakings connected with that corporation. The new company will have a capital of $3,000,000, and will be empowered to build and operate steam and electric plants at the coal mines in Corral Hollow and Alameda County for the purpose of generating electrical power and furnishing the same by transmission over wires to Oakland by way of Livermore, Haywards, San Leandro and other towns en route, and also to San José and to Stockton. It is intended to ultimately extend the service to San Francisco. The cheapest item connected with the generation of the electrical power will be the fuel, which will consist of the waste and refuse screenings, dust, etc., from the coal produced at the extensive Corral Hollow mines. The supply of this kind of fuel will be almost inexhaustible, and as it is extracted from the mines with the merchantable coal, it is all paid for by the latter. As the coal company will control the transmission company there will be no charge for this fuel. The plant at the mines will generate at the start 6,400 horse-power, of which about 5,000 horse-power will be supplied to San José and to Oakland, though the towns en route, and afterward Stockton will be taken in, and if necessary the supply can be increased so as to extend the service even to San Francisco and other more distant points. The company expects to furnish this power to Oakland, San José, Stockton and intervening places at $60 per horse-power per year. The present cost ranges from $60 to $80, according to conditions.

HARD CARBON.

M. Moissan is reported, according to "Nature," to have discovered a substance harder than the diamond, in the form of a compound of carbon and boron, produced by heating boracic acid and carbon in an electric furnace at a temperature of 5,000 degrees. This compound is black and not unlike graphite in appearance. It will cut diamonds without difficulty, and it can be produced in pieces of any required size.

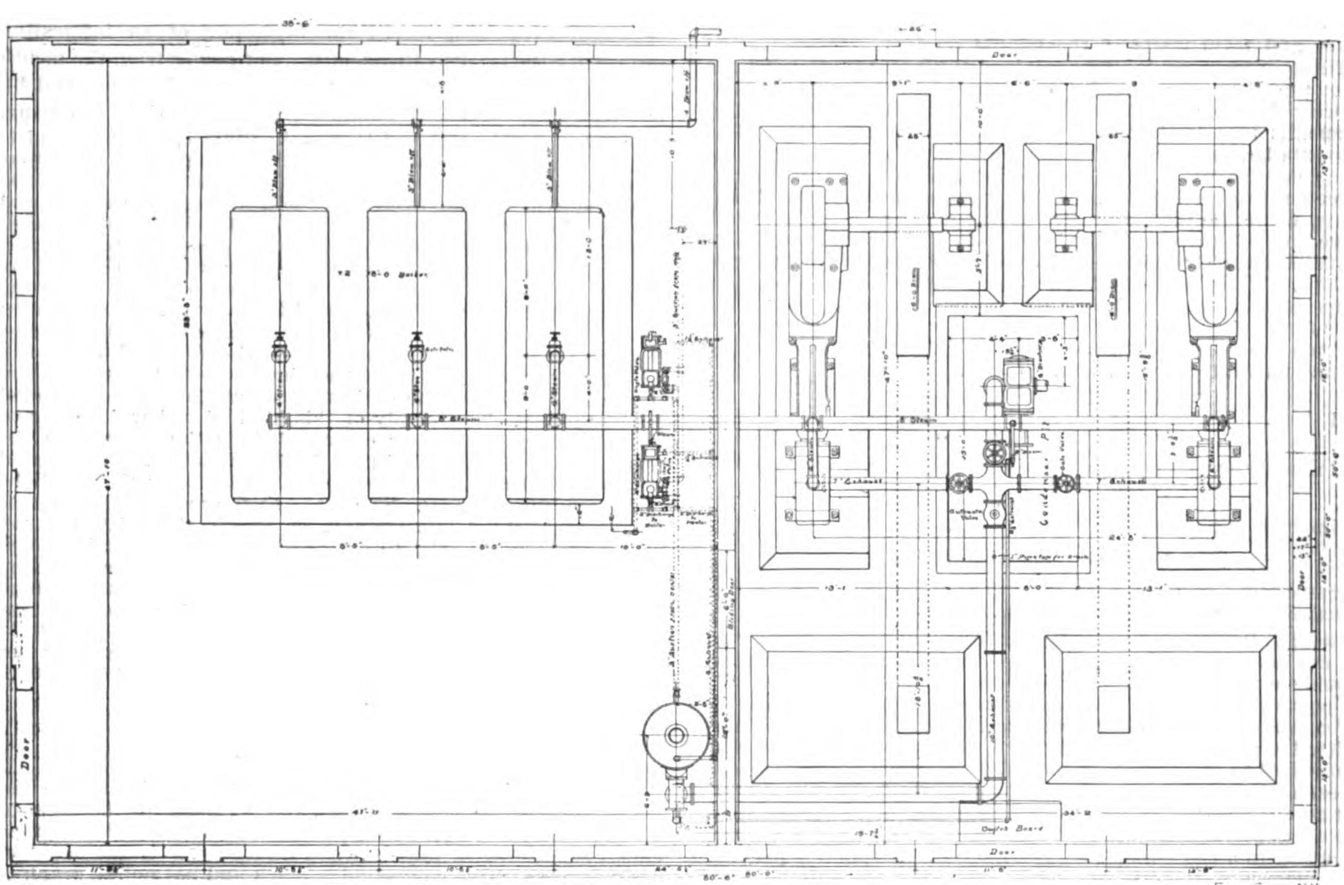

Fig. 2.—Power House of the Dayton Traction Co.—Plan View.

Electric Transportation.

THE DAYTON TRACTION COMPANY.

ON July 1 the electric railway connecting Dayton with Miamisburg, O., was opened for traffic and the results already achieved have more than realized the expectations of its projectors.

LINE AND TRACK CONSTRUCTION.

In connecting the two cities by means of an electric railway the Traction Company has followed steam railroad practice closely. The roadbed is solid, having heavy rails laid thereon, the cars commodious and strongly built.

The line is practically a direct one, although there are various angles; still the curves are so easy, of such large radius and the tangents so long that they are not objectionable. The road with turnouts and double track is 12½ miles in length, with a standard gauge of 4 feet 8½ inches. The roadbed is graded to proper elevation and is furnished with a most complete system of stone, brick and pipe culverts to successfully carry off all drains, giving absolute protection to the roadbed, and a 68-foot steel single-span bridge has been erected over the Miami Canal at Carrolton.

The rails are 60-lb. section; six-hole, double angle joints are used, provided with ¾-inch bolts, nut locks and washers. Two thousand five hundred ties, 6 x 6 x 7, are laid per mile and the roadbed thoroughly tamped and packed with gravel and stone under and between the ties.

The overhead electrical line from the city of Dayton to Miamisburg is standard bracket construction, heavy wrought iron brackets secured to wooden poles being used. In the city of Dayton and Miamisburg cross suspension construction is employed, iron poles being used. All line material is of the General Electric make and the feeders are carried along the entire length of the line with feeding-in points every 1,000 feet The system has ample protection from lightning and the greatest care has been exercised in having the trolley wire in perfect alignment with the center of the track to enable the running of the cars at the highest rate of speed possible.

THE CAR BARNS AND POWER STATION.

The car barn and power station have been erected at a point midway between the two termini and so situated as to enable the bringing in of coal at one side; and it is in close proximity to water of excellent quality and sufficient quantity for steam making and condensing.

These buildings are constructed entirely of brick and steel. Steel columns and trusses carry the roof, and the walls are built of brick encasing the columns so as to conceal the iron work, thereby adding greatly to the ornamentation and appearance of the buildings. The roofs of both power house and car barn are built of corrugated iron and that of tne power house is lined with hard wood, making the same moisture proof.

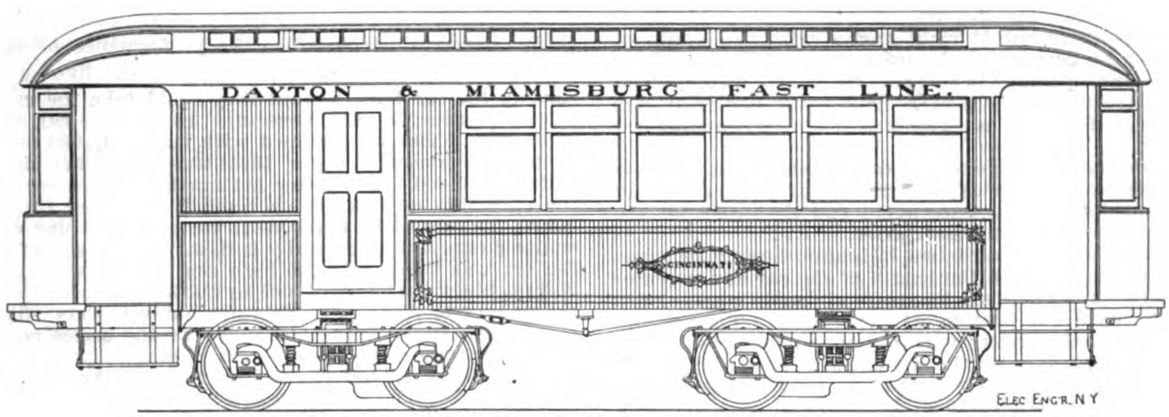

FIG. 3.—COMBINATION CAR, DAYTON TRACTION CO.

The car barn, shown in plan and section in Figs. 1 and 2, is also fireproof, and its dimensions are 75 feet in width by 105 feet in length. The car barn contains every convenience for repairs and handling of cars. Two pits, each 65 feet in length have been built of brick. The repair shop has been built at one side of the car barn and upon the opposite side are two offices, one for the general superintendent and the other for motormen and conductors.

The power station is 80 feet by 50 feet, and the interior is divided by means of a fireproof wall, the building being practically fireproof.

The steam plant is most efficient and economical. This is due to the ideal location of the plant. The boilers consist of a battery of three boilers, each 18 feet long, 72 inches in diameter and containing 72 4-inch tubes. The boilers are made of the best quality flange steel, triple riveted, and made to carry a working pressure of 125 lbs. per square inch.

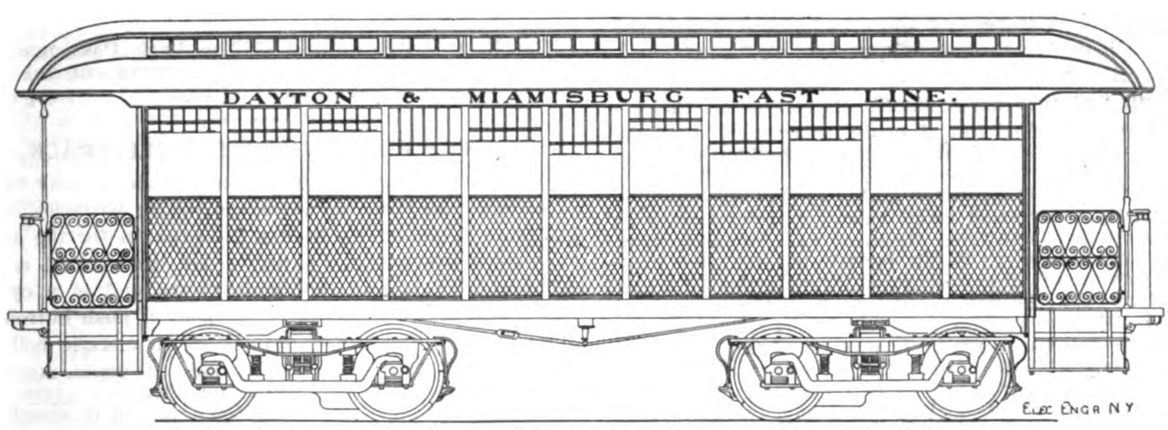

FIG. 4.—TRAILER, DAYTON TRACTION CO.

The smokestack to furnish draft for these boilers is made of steel, 60 inches in diameter and carried 102 feet above the grate service of the boilers. The stack is made of small sections of steel riveted together, and has an ornamental top and ladder.

To drive the two generators two 18 x 42-inch Hamilton-Corliss condensing engines have been installed, erected upon foundations built of brick seven feet in depth. Two General Electric 200 kilowatt multipolar generators furnish the necessary current for the operation of the road, each dynamo and engine being sufficient to operate the road in its entirety, so that the

plant consists of two duplicate units, thus guaranteeing the greatest regularity of service.

The switchboard consists of three separate panels; a panel for each of the generators and another for the feeders, switches and controlling devices. The switchboard is built entirely of slate and steel.

THE ROLLING STOCK.

The motor cars are of modern design and similar in appearance to standard steam railroad cars, built by the Barney & Smith Company. They are 35 feet long, vestibuled at both ends, 8 feet wide, and mounted upon double trucks, having all wheels 33 inches in diameter. They are straight sided with steam car roofs. The interior finish is of extra quality and of hard wood. The windows are large and double, and special arm rests have been provided.

The seats are arranged at right angles with the length of the cars, having a center aisle between them. They are fitted with springs and upholstered in cane. There are two rows of double seats, seating in all 36 passengers. The center aisle is 18 inches wide. Each car is lighted with ten 16 candle-power lamps.

The combination baggage and express car, shown in Fig. 3, is similar in appearance to the car described above, but consists of two compartments, one for passengers and the other for the carrying of baggage and express matter.

The trail cars, Fig. 4, are 34 feet in length, having seats arranged at right angles with the length of the car and a center aisle between them. There are two rows of double seats, eleven on each side, each car seating 44 passengers. Trailers are lighted by means of couplers with ten 16 candle-power lamps and in the same manner as the motor cars. The sides of the trailers are provided with wire guards to prevent accidents.

The motor cars are equipped with two 50 horse-power General Electric motors each (100 horse-power per car), with controllers on both platforms.

All work has been done by and under the direct supervision of Messrs. Stern & Silverman, Philadelphia, Pa. The officers of the company are Hon. Judge Dennis Dwyer, president; O. B. Brown, treasurer; O. M. Gottschall, secretary, all of Dayton, O.

THE EFFICIENCY OF COMPRESSED AIR FOR STREET CAR MOTORS.

BY R. LUNDELL.

GENERAL HAUPT'S reply to my article under the above heading in The Electrical Engineer of July 8, gives me the impression that he has either merely glanced over the article, or that he has completely failed to understand it. See line 32, etc., where General Haupt says: "Mr. Lundell thinks that to obtain the same results in speed, etc., under street railway conditions the horse-power must be at least doubled, evidently assuming that increasing the speed and doubling the horse-power will double the consumption of air," etc.

If General Haupt will take time to read my paper over slowly he will find that his elaborate statements in this respect are entirely uncalled for. I made no assumption in the matter of how much more air it will take to double the horse-power.

In regard to my opinion that "under street railway conditions the horse-power must be at least doubled," I wish to say that this opinion is founded on an actual test made upon a trolley car running on the Coney Island and Brooklyn Railroad. One section of this road runs through the city and another section runs through a level part of the country to Coney Island. The track of the latter section is similar to that of an ordinary small steam road. It was found that the average city speed could be maintained on the T-rails with about half the consumption of current. This fact made me believe that the air motors ought to have twice as much power when used on city roads. But my article was strictly confined to the matter of efficiency or the ratio of out-put to in-put and the above is immaterial.

On line 73, etc., General Haupt says: "Mr. Lundell gives an elaborate calculation on the efficiency of air compression to demonstrate that to compress 3,600 cubic feet of free air per minute to 2,000 pounds will require 2,480 horse-power," etc. General Haupt comes near being right when he states that any maker of first-class air compressors would guarantee to compres 3,600 cubic feet per minute with about one-half of 2,480 horse-power. This agrees quite well with the figures I finally used in my article.

General Haupt evidently does not see that the figure 2,480 is for adiabatic compression and that it is not used at all. It merely indicates the worst condition. If I had used this figure the efficiency of storage alone would only have been 27 per cent., and the total plant efficiency $.27 \times .70 \times .75 = 14$ per cent. According to the figure 1,133 horse-power, which is for isothermal compression, the efficiency of storage would be 44 per cent. Even this figure was not used, as it would have been too favorable. But the figure 40 per cent. efficiency, which was used, is so very near the best condition of 44 per cent. efficiency that it cannot be considered unfair.

AQUATIC PERFORMANCE OF STREET CAR MOTORS

The qualities of an electric motor are best shown in the ability of the device to withstand the extraordinary conditions to which it may be exposed. On March 1, 1896, a very heavy freshet flooded the streets of Derby, Conn., and Superintendent B. W. Foster thus describes the performance of one of his cars: In order to bring our employés, who live on the East side, to the car barn so that they could take the cars out on scheduled time, it was necessary to run the car across the causeway. This car, equipped with two G. E. 800 motors, had to proceed through water that was 22 inches deep for a distance of 600 feet. After getting them over we continued the operation of this car on regular scheduled time for two hours, making eight trips, until we could get one of our old summer cars to be drawn by horses. At the end of each trip the car was taken into the barn and carefully examined, the bottom plugs being taken out to allow the water that was in the motors to drain off. This amount was very slight. The power was used on the last notch of the series connections. The wave caused by the motion of the car was sufficient to come up under the bumper and wash across the front platform, so that during one-half of each round trip the resistance boxes were practically submerged.

THE COLUMBIA AND MARYLAND ELECTRIC RAILWAY.

Contracts have been awarded by the Columbia and Maryland Electric Ry. Co. for the overhead work on the city portion of its line, extending from Howard and Saratoga streets to Calverton road and Edmondson avenue, to Thomas C. Basshor for the poles, and to the Maryland Manufacturing and Construction Company for the other material. A contract for thirty-two 100 horse-power motors and twenty 30 horse-power motors has been awarded to the Westinghouse Electric Company. The larger motors will be used on the through cars between Baltimore and Washington, and the smaller ones will propel the cars running between Baltimore and Ellicott City. The contract for building the power-house at Paint Branch, Hyattsville, has been awarded to Henry Smith & Son, of Baltimore, for $81,500. The power-house will be a brick structure, 205 feet long and 130 feet wide. The plans were prepared by Henry Brauns, architect.

The East Baltimore and Clifton Park Passenger Railway Company have been incorporated to carry out the proposed extensions of the Suburban Company.

THE PUSH BUTTON BICYCLE TRACK.

An electrician says he has found a quicker way of making a fortune than running wires and selling batteries, and judging from appearances, he has good reason for the statement, says the Pittsburg "Dispatch." He has erected a platform 100 feet long and 10 feet wide at the end of a cycle path. Down this platform is ranged a series of push buttons, which are connected through a battery to an electric bell and an annunciator. The rider, having paid 10 cents, starts at one end and tries, in riding down the line, to depress as many of the buttons as possible. When a button is struck the bell rings, and the annunciator registers the particular button. The rider who is successful in guiding his wheel tire over all the push buttons wins 50 cents. This new diversion has created an extraordinary furore. The lucky inventor has organized a company which will sell the platforms outright, and give territorial protection to purchasers during the life of the patent. As a drawing card for owners of seaside and country pleasure resorts the new diversion would seem to be unique.

LIEUT. MANNING K. EYRE has been appointed manager of the General Electric Company's lamp works at Harrison, N. J. The appointment was in the nature of a promotion in recognition of Lieutenant Eyre's excellent work in the executive management of the lamp works.

ELECTRIC RAILWAY IN VERSAILLES, FRANCE.

Versailles, France, is to have an electric street railway and within two months the old horse cars will give way to the new system. The street railway will be run from the light and power station.

The steam generating plant will consist of four semi-tubular boilers supplying steam to four horizontal single cylinder engines aggregating 350 horse-power for the light and power service in the city and two steam engines aggregating 240 horse-power for the street railway. The electric generating plant will consist of two General Electric monocyclic machines aggregating 250 kilowatts and two direct coupled railway generators aggregating 200 kilowatts. The rolling stock will be 15 cars, each equipped with G. E. 800 motors and controllers.

The installation will be carried out for the Société Versaillaise de Tramways et de Distribution d'Enérgie Electrique by the French Thomson-Houston Company, of Paris.

ROENTGEN RAYS.

EXPERIMENTS ON ROENTGEN RAYS.

MR. T. C. PORTER, of Eton College, has written to "Nature" describing some curious results of experiments on Röntgen rays. He states that after examining the fluorescent and photographic action of the rays (X_2) emitted on strongly heating a "focus tube," and finding them different to the rays which have been hitherto noticed (X_1), in that the relative transparency of flesh, bone, aluminum and glass differs for the two kinds of rays, it seemed desirable to try the effect of cooling the tube. Solid carbon dioxide and ether, and then solid carbon dioxide alone were employed, with the result that in both cases the fluorescence of screen and tube very rapidly died out and the current apparently failed to pass through the latter; as the tube gradually grew warm again, the fluorescence in it returned, not gradually, but very suddenly, at a temperature not very far below that of the room, the glass lighting up brilliantly, and the shadows of the bones showing on the screen with increasing distinctness, the emission of X_1 rays reaching a maximum at about 12 degrees C. (a rough guess). On further heating X_2 rays begin to be evolved, judging from the increasing opacity of the flesh, whilst at the same time the fluorescence excited on the screen grows rather brighter. As the condition for the maximum of X_1 rays probably varies to a certain extent with the different forms of tube, and even different specimens of the same kind of tube, with the degree of exhaustion, etc., it seems to follow from these experiments that in some cases warming the tube slightly might be useful in photographing the bones, while in others moderate cooling would be better; and from the accounts of various operators such would seem to be the case, though the particular method of heating or cooling is an important factor in the result. Solid carbon dioxide seemed very opaque to the rays when its low density is considered, but the effect may have been partly due to the frost condensed upon it from the air.

The X_2 rays seem to discharge a charged plate whether positively or negatively charged, but of this he could not at present feel quite sure. Aluminum seems so far opaque to them that it is doubtful whether, when a screen is used, any of the rays get through, and when a screen is not used, one cannot feel certain that the effect observed is due to the X_2 rays either wholly or partly. After heating the tube and turning on the current, the whole tube is filled with a whitish, lavender-colored light, which comes to a focus on the glass behind the cathode, above or below it; and while in this state and giving little or no fluorescence on the screen, the tube does not charge an unscreened insulated plate, but it does rather rapidly drain it of a previously communicated charge, either positive or negative. As the tube cools the lavender light retreats more and more from the cathode till at last it reaches the upper edge of the rectangular anode, when the positive charge, mentioned before, begins to be given to an uncharged insulated plate, but very slowly; as soon as the center of the anode is bare of the lavender discharge, the potential of the unscreened plate very rapidly rises, and by the time the whole anode is clear of the lavender light the normal positive charge is re-established on the insulated plate. When the lavender glow retires from the cathode, it leaves behind it a space full of almost invisible light, which excites whitish green fluorescence on the glass of the bulb, and it is during this time that most of the rays are X_2, as is shown by the fluorescence screen, and photographs of a hand.

CATHODE RAYS AND X-RAYS.

PROF. SILVANUS P. THOMPSON describes some experiments on X-rays in a letter to the London "Electrician" as follows: Some experiments I am making on the connection between cathode rays and X-rays have just given me a result which it seems desirable to publish without delay for the benefit of other workers. Having designed a tube with the now usual oblique anti-cathode or "reflector" of platinum to receive the impact of the cathode discharge and generate X-rays, and an interiorly projecting wire of aluminum in the path of the latter rays, I have found that, with a sufficiently high exhaustion, there were produced simultaneously two shadows—an X-ray shadow on a luminescent screen outside the bulb, and a cathode ray (or Crookesian) shadow on the glass wall of the bulb. Both shadows were thrown as from the "reflector" as origin; but while the cathode ray shadow was capable of being deflected both magnetically and electrostatically, the X-ray shadow was not so deflected, even though the wire object within the tube was itself electrified either + or —. A slight shifting of the X-ray shadow was traced to a small change in the apparent origin of the X-rays, as the cathode discharge fell more on one spot or another of the platinum "reflector." At no state of exhaustion did the "reflector" convert all the cathode rays into X-rays.

FLUORESCENCE VISIBLE AND INVISIBLE.[1]

THERE has been some discussion in the Société Française de Physique on the subject of the nature of fluorescence, and particularly that produced by the Röntgen radiations. The subject is one which has at present only a purely scientific interest, and it is therefore left to those who are willing and able to spend time on the researches necessary to complete the theory of light and enable a rational account to be given of the new phenomena. But in view of the possibility of a fluorescent lamp being the ultimate result of the vacuum tube experiments now being made in the United States and elsewhere, the whole subject may any day become one of great practical importance. It has been known for some time that uranium salts and metallic uranium itself under the action of ordinary light emit radiations which are invisible to the eye, but can be reflected and refracted to a certain extent, while so far as concerns their action on a photographic plate and their power of passing through substances which are opaque to ordinary light, they resemble the Röntgen radiations. Most of the work in this direction has been done by Mr. Becquerel, but other investigators have obtained somewhat similar results with other substances, though the effect is not nearly so enduring as with uranium salts. Now, in general, in the process of fluorescence the radiations given off are of greater length than those received by the fluorescing substance, and Stokes' law, as it is called, is the expression of the theoretical reason why on the whole it should be so. But if the hypothesis is correct that the Röntgen rays and the uranium radiations belong to the region beyond the ultra-violet, we have apparently a direct contradiction of this, and what looks like a case in which the wave-length is shortened, which, of course, is just what is wanted to be done in order to utilize the energy wasted in producing invisible "heat" waves in almost every known form of artificial illumination. But at the Société it was pointed out by Mr. Guillaume that if a sufficiently complicated structure was assumed it was not theoretically necessary that there should be a degradation of all the wave-lengths, provided that the average length was lowered. It was therefore not impossible that a part of the emitted rays might have a shorter wave-length than the primitive radiation, provided that there was at the same time a sufficient amount of radiations of greatly increased wave-length. The subject is one of great difficulty both from a theoretical and an experimental point of view. Indeed, owing to the non-homogeneous character of the radiations, and the impossibility of sifting them out, so to say, no two observers seem to get exactly the same results. But it seems at least probable that the theoretical difficulties which have been believed to block the way to an efficient fluorescence lamp do not really exist.

ROENTGEN RAYS ON A NILE EXPEDITION.

So thoroughly practical are Röntgen rays considered by the Medical Department of the English War Office that two sets of Röntgen ray apparatus, it is reported, have been sent up the Nile to be used by the army surgeons in locating bullets and in determining the extent of bone fractures.

VOL. XXII. NEW YORK, JULY 15, 1896. No. 428.

CONTENTS.

THE NEW YORK FIRE DEPARTMENT WIRING RULES.

During the month of June various meetings were held at Fire Department Headquarters in New York by the representatives of the various illuminating companies and the insurance interests in this city as well as the Contractors' Association and others, for the purpose of discussing with the representative of the Fire Department, Chief Inspector Henderson, the recent amendments to the Department Rules, and other proposed amendments. As this is the first time that these various interests have been invited to an open discussion of existing and proposed rules, relating to electrical equipment in this municipality, the proceedings have more than ordinary interest. That this movement on the part of the Fire Commissioners through their chief has resulted in a great amount of good, is true, without doubt. In looking over the rules as thus far amended, and which are now in operation, we note that they are radically different in a great many cases from the present New York Board rules, but they do not differ very much from the National Board rules, which have been adopted by all the underwriters, with the exception of the New York Board, under date of January, 1896.

It is now possible, under the new rules, to make installations of light and power plants in a thoroughly consistent manner, and various methods of construction are permitted in the way of running conductors from generators to switchboards, whereas, under the present New York Board rules, if they are lived up to, there is but one way in which conductors may be run from generator, etc., and that is, they "must be in plain sight, readily accessible, and wholly on non-combustible insulators." As far as this rule is concerned, it is notorious that the number of instances of its observance that can be cited, are so few that they are not worth mentioning. We are pleased to see, therefore, that the Fire Department has so quickly recognized the inconsistent attitude of the New York Board, and has made such broad changes as to permit of a great many classes of construction, all of which are as safe as can be asked for.

The old rule relating to the location and installation of motors, has been very intelligently revised, and the "8-inch" clause has been entirely stricken from the rule. Motors may now be directly mounted, and connected to various classes of work as may be desired, without being hampered with prohibitive and impossible requirements. If no changes in the rules had been made, other than this, the electrical interests in this district have certainly reason to be thankful that the Fire Department has so quickly shown its appreciation of the true condition of affairs as they have existed for years. Chief Henderson thus shows that he is fully alive to the necessity of removing the various hardships that have been placed in the way of progress, and it is plainly evident also, that it is the intention of the Fire Department, through its commissioners and officials, to endeavor to aid in all proper ways the illuminating companies and others engaged in the business.

Probably the most important rules that were up for discussion, were those in relation to the placing of "complete conduit installations." From the printed amended rules, that we have before us, we note, with considerable interest, that an interior conduit to be approved by the Fire Department "must have an approved insulating lining that will not soften when exposed to a temperature of 140 degrees Fahrenheit, and must be so placed that neither the lining of the conduit nor the insulation of the conductors will be injured by heat from steam or hot water pipes, or otherwise." We are also informed that the following conduits are permissible, namely: "Plain conduits equal to iron pipe of standard gauge may be used for conductors having lead or other approved armor." There is no ambiguity in this ruling of the Fire Department, and it would seem to us that it must meet the approval of all concerned, especially the insurance interests, inasmuch as the raising of the temperature limit to 140 degrees Fahrenheit, will certainly lead to the placing upon the market of a higher grade of conduit than

is now in use; and, if it is desired to use plain iron pipe, then those who care to can do so, by using lead-armored conductors, the same as have been used for subway work. This last ruling, if complied with, is certainly perfectly safe, from an insurance standpoint, although a rather expensive method of construction, and we doubt whether any one will employ it, as it is a well-known fact that it would be practically impossible to pull lead-armored conductors or cables through conduits, where more than two elbows are employed, without injury to the lead armor and possibly to the insulation itself.

We know that the National Board of Fire Underwriters is giving the question of conduit construction very careful consideration, and we see no possible hardship to arise or reason why all concerned should not wait until the meeting of the National Board experts before demanding such radical changes in any rules, that will permit the general adoption of plain iron conduit work. There is one thing certain to follow, it seems to us, namely, that if plain iron pipe work is ever permitted the wiremen and electrical contractors may say good-by to this class of construction work, as steam and gas fitters can place it in position far cheaper, and with far superior results, than any other class of men.

We also note that the embargo on series incandescent work for decorative purposes has been removed. All this class of work is now provided for under the new rules. The use of magnetic cut-out devices is recommended, but is not mandatory. The department, however, suggests that their use be extended as far as possible in connection with all equipments and that the subject be taken up at some future time.

After reading the new Department rules it seems to us that the electrical industries of New York and the insurance authorities as well have no cause to complain, but, on the contrary, should congratulate themselves that at last they have secured mutual recognition of their rights. If all concerned will now but continue to aid the Department, a standard set of rules, which will be properly and fairly interpreted and enforced upon all alike by those having legal authority, will be obtained, and the much-longed-for and desired end will have been reached.

OUR SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

HOWEVER much a technical journal may strive to keep its readers informed of the state of the art and science to which it is devoted, the volume of matter and the number of sources are so great that no single publication can hope to embrace it all within its own columns. The Electrical Engineer has in the past sought to obviate this difficulty by printing abstracts where lack of space prevented the complete publication of many important papers, but even by this short-cut method the limits of our space at times prevented reference to interesting articles. In order that our readers may therefore be kept thoroughly au courant with all the principal departments of electrical science and art, we have begun this week the publication of a "Synopsis of Current Electrical Literature," which we propose to publish regularly every week. The aim of this synopsis is to give the headings, name of author and the most salient feature brought out, or principal line of argument pursued, in the publication referred to. In order to facilitate the work of students and investigators who may be able to obtain some one journal more easily than another, all, or nearly all, publications will be quoted which publish the same article. Past experience in similar work has shown it to be advisable to employ as many sub-divisions or headings as possible, and as the work progresses others beside those in present use will be added. Since it is found difficult to determine under which heading to place a given article some cross references may be necessary, but these will be limited as much as possible. In making the synopsis one of the regular features of The Electrical Engineer we hope to make this journal still more valuable to its readers, and we believe that the Synopsis in connection with our Data Sheets will make The Electrical Engineer indispensable to every one interested in electrical work whatever the nature of that work may be. We may add that the Synopsis will be under the able editorship of Mr. Max Osterberg, whose previous work in this field has met with such marked success.

MUNICIPAL OWNERSHIP.

IN a recent issue we commented editorially at some length on the paper read by Mr. A. R. Foote, before the Street Lighting Convention at New Haven, and in which the fallacies of that cult were pretty well shown up. Since that publication we have received quite a number of requests for Mr. Foote's complete paper, and in compliance therewith publish this week a very extended abstract of it. This exhibition of interest on the part of our readers is strong evidence of the lively interest which this question still arouses in many quarters. We believe, however, that its intelligent discussion by competent authorities—backed by the results and experience in the cities that have tried the experiments, and whose accounts have been properly analyzed—has already begun to work a reaction, and we know of more than one contemplated city plant that has been abandoned. No stronger proof as to the inadvisability of municipalities engaging in public lighting could be cited than the cases of those cities that have tried the experiment and found it a failure, to their sorrow. We have always believed, and still believe, that a private corporation can furnish electric lighting cheaper than any municipality can perform the same service, for reasons which must be apparent to every one acquainted with the present status of American municipal politics. But when municipalities in addition to street lighting undertake to provide private consumers they introduce a feature contrary to every principle of equity, in that all are taxed to maintain a plant in order that a limited few may be served with a certain commodity at cost. The time has not yet come, unfortunately, when the electric light will displace gas, oil and candle-light in our cities, and until that time arrives every private consumer connected to a city plant will be served at the expense of his non-electricity-consuming neighbor. In these days of populistic sentiments one would imagine that this argument would suffice to determine the question in the minds of most reasoning voters, but much will have to be done yet to bring about the desired result.

SINGLE-PHASE ALTERNATING MOTORS.

TO produce a monophase alternating current motor which would be as easily adaptable to all kinds of work as is the shunt wound direct current motor has been a standing problem among electricians ever since alternating current central stations have been established, and to the lack of such a motor are due the invention and development of polyphase systems of distributions. We illustrate elsewhere in this issue a monophase alternating current machine recently designed by Mr. Langdon-Davies, of London, which appears, according to the report of Professor Silvanus P. Thompson, to be a decided advance over any previous machine of this type. The qualifications of a motor of any kind should include high efficiency, mechanical strength, large starting torque, constant speed regulation, large power factor and moderate starting current. In all these respects the Langdon-Davies motor seems to fulfill the conditions of an excellent machine, except in regard to the power factor, which, however, is capable of improvement. The production of a monophase alternating current motor of only three-fourths horse-power capacity, which can start under full load and which has an efficiency of from 90 to 95 per cent., according to the load, certainly, marks a very decided advance in the design of this class of motors.

THE PRICE OF RUBBER.

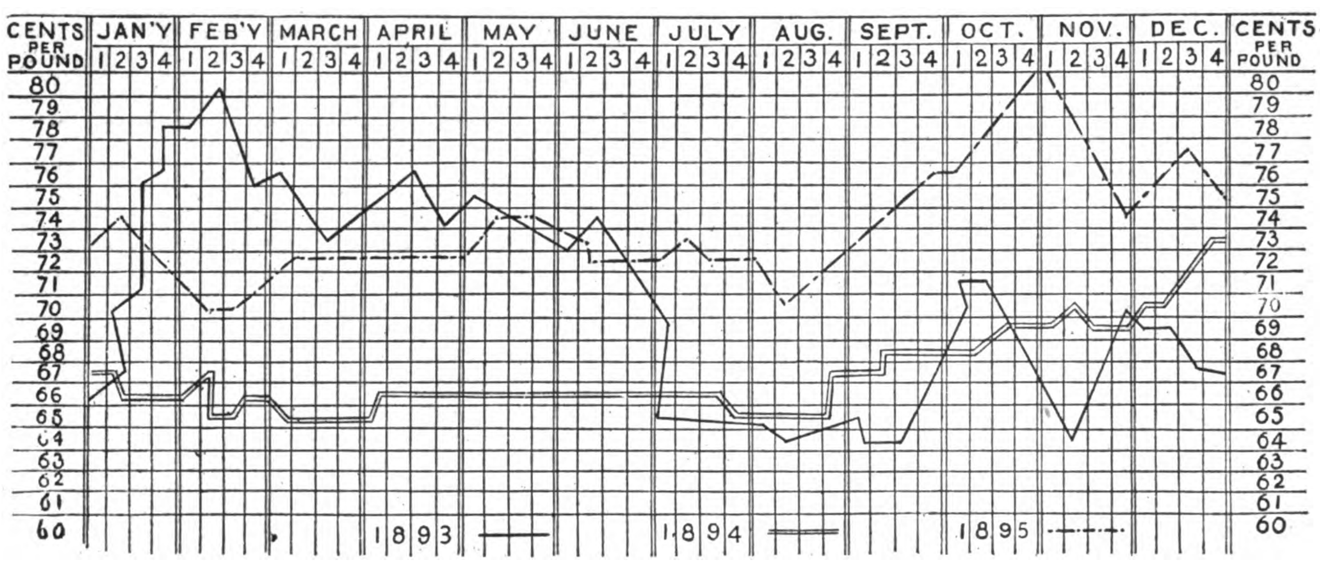
RUBBER enters so largely as a material in the electrical arts that its price must of necessity have its influence on the cost of apparatus and installations. Of late years we have heard much of the increasing scarcity of the rubber supply, and of the prospects of large increase in the price of rubber. Like many other statements of the same nature they have probably emanated from ill-informed sources. We have, therefore, thought it well to place before our readers an exact statement of the situation as regards the rubber market at the present time. As Mr. Hill shows on another page, there is little to be feared that the price of rubber will be increased materially in the future. On the contrary, the great demand made not only by the electrical arts, but numerous others within the last ten years or so, has stimulated enormously the production of rubber in the various parts of the world, and led to the opening of new fields of supply.

MISCELLANEOUS.

THE STATE OF THE INDIA RUBBER SUPPLY.

BY HAWTHORNE HILL.

WHILE the prevailing high prices of India rubber are for the moment of interest to the electrical industries, they need not cause alarm in this or any other line of manufacture. Especially should they not be regarded as indicating the beginning of the end of the supply of India rubber, as some writers have been too ready to infer. India rubber, like other commodities, always has been subject to fluctuations in the market, and the prices now asked and paid for it are to be attributed to the operation of the simple law of supply and demand, under which there may be a marked decline before the end of the year. After rubber had reached 97 cents in 1890 (for fine old Pará), it soon declined to 64; in 1891 it got up to 99 cents and fell again to 62, and so one might go on indefinitely. Doubtless the highest prices for rubber to be recorded in 1896 were paid for some small lots during June and July —90 cents per pound—and these figures were predicted weeks, if not months, in advance by experienced observers of the market. In an annexed diagram, illustrating the course of the crude rubber market during three years past, it will be seen that, although 1893 and 1895 showed frequent and marked fluctuations, prices were steady and at a low level during most of 1894. It is quite possible for similar conditions to exist in 1897, after the fluctuations of the present year, though it is to be hoped that they will not result from any such stagnation as our industries suffered two years ago.



QUOTATIONS FOR ISLAND SPOT FINE PARA.
(Copyright, 1896, by the Gould Commercial Co., New York).

But it is not so much with fluctuations in prices that this article has to deal as with the extent of the sources of supply of India rubber, the known limits of which are constantly widening. It was the work of an intelligent man for Dr. John Forbes Royle, for instance, fifty years ago in England, to urge the importance of discovering or creating new sources of India rubber, against the time of the exhaustion of those known in his day. But then the extent of the rubber forests of South America was only faintly suspected, the presence of rubber in Africa was wholly unknown, and the commercial value of the rubber of Assam had not been demonstrated. Nowadays, a single voyage of exploration in remote Bolivia may bring to light a river before unknown even to the geographers of that country, lined with more rubber trees than were known in Royle's time to exist in the whole world. The fear of the exhaustion of rubber, however, did not die with Royle, some of whose phrases have served alarmist writers to this day. The British Government, following its marked success in transplanting the Chinchona trees from Peru to India, spent no small sum in trying to introduce the Pará rubber trees into the same country. But while the attempt has established the possibility of producing India rubber under cultivation, the practical sense of the age has prevented the development of rubber plantations, while new native supplies are annually being brought to light, quite as capitalists would be disinclined to invest in the creation of artificial coal fields.

The India rubber used in insulation work is of the grade known commercially as "Pará fine," named from the port at the mouth of the Amazon, which serves as a gateway to a watershed four times as extensive as the entire valley of the Nile. The Amazon stretches for 2,000 miles across Brazil, navigable for the whole distance by ocean steamers, and at short intervals receiving the waters of immense streams, each in turn navigable for hundreds of miles, and all lined with forests unbroken by man except where the undergrowth has been cleared away to open paths among the tall rubber trees. Beyond Brazil lies Peru, which also includes a lengthy section of the Amazon, and likewise extensive navigable affluents, with here and there the settlement of an enterprising rubber collector, with his force of native workers.

One of the Amazonian affluents, received in Brazilian territory—the river Madeira—forms the only water outlet for the Republic of Bolivia, with a larger area than any European State save Russia. Into the Madeira flow streams which form a great system of waterways, draining every corner of Bolivia, and these rivers, too, are lined with rubber trees. It was not until 1880 that the first shipment of rubber from Bolivia was made, but during the last fiscal year 1,600,000 pounds of the finest rubber in the world, and commanding the highest prices, were floated down her rivers, into the Amazon, and out upon the Atlantic at Pará. This rate of progress will not seem insignificant when it is remembered that, owing to dangerous cataracts in the Madeira, scattered along a distance of 230 miles, a cargo of Bolivian rubber is sometimes three months on the way to the seaboard, at a cost for transportation of 25 cents a pound. But even this remote rubber country is about to be made more accessible, with the aid of a concession for the ultimate building of a railway around the cataracts, in compliance with which a road for the transportation of rubber by cattle is already being opened.

The increase in the export of India rubber from Pará—including the total output from the Amazon basin—is thus shown by custom house records:

Year.	Pounds.
In 1840	938,058
In 1850	1,975,974
In 1860	5,627,226
In 1870	10,528,000
In 1880	18,889,000
In 1890	36,300,000
In 1895	46,363,000

Nowhere in rubber circles is this great increase regarded as indicating the extinction of the forests. In February last there was opened for traffic a submarine cable up the Amazon from Pará, covering a distance of 1,300 miles, including branches, built by the Siemenses and laid by their cable-ship "Faraday." Almost the whole basis of its expected revenues is the India rubber industry. Last month, at the annual meeting in Lon-

don of a company operating on the Amazon, it was reported that during the year nine steamboats had been added to their equipment, making the number now in their service over thirty. Their principal business is the conveying of India rubber down-stream and merchandise up-stream for exchange with the natives for their rubber. The State legislature at Pará adjourned lately after approving of fiscal estimates for the ensuing year, including expected receipts of export duties of 10,100,000 milreis,[1] mostly on India rubber—larger than the estimate for any preceding year. Likewise are the rubber export duties the principal reliance of Amazonas, the State adjoining Pará, while the exploitation of rubber is the hope of Bolivia and of Peru, particularly since the falling-off of the guano production of the latter country. These facts may have but slight bearing upon the electrical industry, but they should counteract any impression that India rubber is becoming scarce.

In every section that has been named the India rubber trees are more carefully sought than at any time in the past, by a greater number of rubber gatherers. Every year the zeal of explorers takes them into streams before unknown,[2] generally with the result that new rubber districts are found. Finally, merchants are constantly on the lookout for new opportunities for trading goods for India rubber, and so successfully that additional steamers are needed every year for their accommodation. All through the Amazon country an annual increase in the rubber output is looked for as confidently as the return of the seasons, and not the smallest basis of their hopes is the fact that the rubber trees are no longer ruthlessly destroyed, but the "paths" through the forests have attained a fixed commercial value, the same trees being tapped year after year.

It is true, that the consumption of India rubber has grown hand in hand with the production. Now and then, indeed, it has temporarily advanced more rapidly. But an increased demand is apt to be reflected in time in a greater number of rubber gatherers at work. Just now stocks of Para rubber are exceptionally low, although the production for the crop season ending June 30, 1896, was the largest on record. The authorized figures show:

	1893—94.	1894—95.	1895—96.
Receipts at Para, in tons	19,660	19,470	20,975
World's supply, June 30	3,250	2,260	1,835

Reference has been made thus far only to Para rubber, since this is the quality used for insulation work. But the increasing production, in various quarters of the globe, of inferior sorts available for other purposes, has been of great benefit to the industries requiring fine rubber, in serving to keep down the price of the latter. The rubber belt across tropical Africa is hardly less extensive than the great Amazon basin, and the progress of its rubber development has been scarcely less rapid. Thus Gold Coast Colony and Lagos, which shipped no India rubber fifteen years ago, had a combined output in 1895 exceeding 9,000,000 pounds. Nearly half as much more comes from Angola, which began to produce rubber only a few years ago. The important and growing production of rubber in Madagascar was the indirect cause of the recent French war with the Hovas. The wealth of rubber in the Congo Free State has been a prime incentive to the building of a railway around the falls in the Congo river. The first section of the road, 113 miles in extent, is now in operation, and Belgian concessionaires are playing for first place in the rubber trade on the Upper Congo when the completion of the road shall have overcome the present obstacles to navigation.

There has been no falling off in the production of India rubber in Central America, in the upper portions of South America, in East Africa, in Assam and Burmah, or in the East Indies. It may be that the limit has been reached in the production of gutta-percha, though the resources of Borneo have as yet been imperfectly explored. At any rate, outside the field of transoceanic cable laying, gutta-percha is less important for insulation work than India rubber, the first of the two materials to be used. Not only does the increasing production of the coarser rubbers tend to check advances in the price of finer sorts, but the astonishing development of reclaiming rubber from old shoes and the like serves a similar end. At least 25,000,000 pounds of reclaimed rubber are used annually by American manufactureres alone. These figures apply to genuine caoutchouc, and not to so-called "rubber substitutes," none of which has resulted satisfactorily in the United States.

As for the cultivation of India rubber, there is no reason why the trees should not grow as vigorously from seeds planted by man as from seeds scattered by the winds, or why the cultivated trees should not yield caoutchouc as freely as the native; in fact, experiments made in planting rubber in many lands would justify us in feeling independent in case the existing forests should become wholly exhausted before we have learned how to send electrical messages over sea without the aid of wires.

[1] One milreis = 54.6 cents at par of exchange.

[2] The major part of South America is today as much a *terra incognita*, and as little developed, as was the section of our own United States west of the Mississippi River fifty years ago.

THE TRANSFORMATION OF THE ENERGY OF CARBON INTO OTHER AVAILABLE FORMS.[1]

BY C. J. REED.

THE most serious defect in the galvanic battery, as a mechanism for transforming energy, lies in the fact that it can operate only by destroying its own mechanical integrity, to replace which is much more expensive than the mere materials of which it is built up. The ideal cell should consist of two indestructible, or reasonably permanent, conducting solids, in contact with a liquid electrolyte. The electrolyte should consist of two solutions, separated by a porous partition, through which one of the solutions flows. Each of the two solutions should contain a chemical reagent capable of combining with the other, on contact of the solutions, in an exothermic reaction. The transforming substance should be precipitated in its original state to be used over an indefinite number of times, and arrangements should be such that the exhausted electrolyte may continuously flow out of the cell and regenerated material flow in.

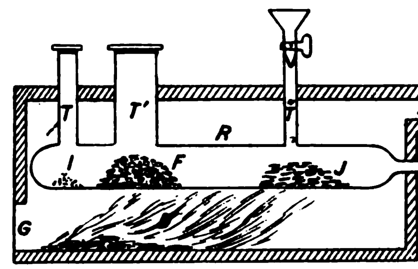


FIG. 1.

To illustrate this cyclic method of thermo-chemical transformation, we shall take as our transformer the two substances, sulphur and water; as fuel, carbon, and as oxidizing agent, atmospheric oxygen.

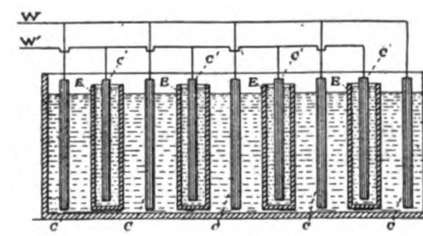

FIG. 2.

The first step in the process is the combustion of sulphur in the air, with production of sulphur dioxide, SO_2, and the evolution of 71,000 units of heat, as represented in the equation: $S + O_2 = SO_2 + 71{,}000$. The SO_2 formed by this reaction is passed through water, which absorbs it and forms the oxidizing electrolytic solution. Some sulphuric acid may be added to increase the conductivity.

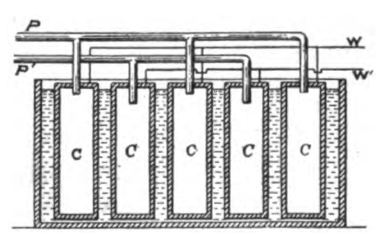

FIG. 3.

The heat developed by the combustion of the sulphur is applied to a retort, R, shown in Fig. 1. Carbon is admitted to this retort at F, through the tube, T'; sulphur is admitted at I through the tube, T; and water is allowed to drop upon a pile of broken stones at J. The sulphur is burned at D with air supplied through the opening, G. The SO_2 passes out at S.

[1] Abstract of paper read before the Franklin Institute, May 26, 1896.

The heat from the sulphur burning at D heats the carbon, F, to a dull-red heat. The sulphur, I, is vaporized, and, passing over the heated carbon, forms carbon disulphide. The carbon contains 97,000 and the S_2 142,000 units of molecular potential referred to oxygen and the CS_2 formed contains 258,000. The reaction, therefore, absorbs 19,000 external heat units.

The CS_2 next comes in contact with the steam and hot bricks at J, where double decomposition occurs with absorption of 14,000 external heat units and the formation of H_2S and CO_2, which pass out at A. We have now expended the total energy of 310,000 units, of which 270,000 have been transferred into H_2S and 38,000 lost in the furnace heating.

The next operation is to bring the SO_2 and H_2S together so that the electrical energy will be evolved and the transforming substances, sulphur and water will be regenerated.

An apparatus in which this final reaction may take place is shown in Figs. 2 and 3. In Fig. 2 the carbon electrodes, C, are in contact with one solution, either the SO_2 or the H_2S, while the carbon electrodes, C', are in contact with the other solution. The two solutions are separated by the porous cups, E. The solution within the cups should be at a higher level than that outside.

The SO_2 and H_2S may be delivered in the gaseous state under pressure to the apparatus shown in Fig. 3. One gas is delivered through the tubes, P, to the interior of the hollow carbon electrodes, C, and the other through the tubes, P', to the hollow carbon electrodes, C', both being immersed in dilute sulphuric acid. The electric circuit is completed by the wires, W and W'. The pressure should be sufficient to force the gases through the pores of the carbon electrodes into the electrolyte in which they dissolve. The regenerated sulphur is precipitated as a white powder, and may be separated by filtration or settling.

The three atoms of sulphur regenerated are exactly equal to the three atoms used, and hence they may be eliminated, leaving, as the net transaction, one atom of carbon expended and 59,000 units transformed into electrical energy, or a maximum efficiency,

$$E = \frac{59,000}{97,000} = 61 \text{ per cent.}$$

The actual attainment of 61 per cent. efficiency would require, however, that the final or galvanic step in the process should take place without loss. While this is a theoretical possibility, it cannot be expected in practice. The theoretical electromotive force of the cell would be

$$\frac{59,000}{4 \times 23,260} = 0.63 \text{ volt.}$$

The highest voltage I have ever obtained on closed circuit is .36 volt, corresponding to an efficiency of 35 per cent.

INFLUENCE OF CARBON ON PERMEABILITY.

In his paper read before the Institution of Civil Engineers on "Magnetic Data of Iron and Steel," Mr. H. F. Parshall remarked that a study of the results of magnetic tests and their comparison with those of the chemical analysis showed a more or less intimate relationship according to the degree with which the modifying physical conditions might be controlled. In general, a greater degree of purity was an indication of high permeability, but as the different qualities of iron and steel merged into each other by insensible degrees, owing to variations in the processes of manufacture, chemical analysis might be taken only as an approximate indication of the magnetic properties. Carbon was the most important element entering into the composition of commercial iron, and within the limits that chemical analysis might serve as an indication of the physical structure, the permeability was inversely as the amount of carbon present. The limitation as to the state of physical structure was greatly affected by the state of the carbon, that is, whether free or combined; in cast iron, as well as in steel, the effect of graphite was second to that of the carbide, commonly known as fixed or combined carbon. Beyond a certain degree of purity, as in wrought iron and carbon steels, the treatment as to annealing and tempering became of first importance. The magnetic properties of some of the alloys of iron, nickel, or manganese were such as to show that the physical structure was the ultimate determining factor. The hysteresis loss was, in general, inversely as the degree of purity, but in comparatively pure irons it was determined principally by its treatment as to annealing, heating, and mechanical straining.

MAGNETIC FATIGUE.

BY ED. C. DE SEGUNDO, ASSOC. M. INST. E. E.

THE recent papers on "Magnetic Testing of Iron and Steel," by Prof. Ewing, and "Magnetic Data of Iron and Steel," by Mr. H. F. Parshall, read at the Institution of Civil Engineers, deal with the subject of magnetism from a commercial point of view in a most useful manner, in a manner which appeals very strongly to the engineering mind.

The reading of these papers at the Institution of Civil Engineers immediately after the most able James Forrest lecture delivered by Dr. Kennedy, cannot fail to be considered peculiarly à propos, inasmuch as the labors of these gentlemen in collecting, classifying and tabulating, so many experimental results obtained in exactly the spirit and in the directions which were referred to in Dr. Kennedy's lecture as of paramount importance to the advance of engineering science, may be considered an undesigned tribute to the truth and justice of the conclusions arrived at by Dr. Kennedy, who may justly be said to be the pioneer of exact engineering experimental science.

A very important matter, from a practical point of view, was dealt with during the discussion by Dr. Fleming and Prof. Ayrton, namely, the peculiar characteristic possessed by iron to deteriorate magnetically, if one might use the expression, under the influence of long-continued reversals of magnetism such as occur, for instance, in the core of a transformer. Every one is fully alive to the very great importance of transformation, particularly in dealing with electric light or power transmission problems involving supply in a scattered area or at points a very long distance away from the source of energy, and therefore this effect, which perhaps might be called "Magnetic Fatigue," is one which, it is easily recognized, would have a great influence indeed upon the economical aspect of the methods adopted in the solution of the above-suggested problems.

The analogy between the experiments of Wöhler on the influence of continued variations of stress upon the ultimate strength of various metals and the magnetic "sticktion" in the iron of a transformer core after some years of service, is interesting.

Wöhler showed that variations of stress, of which the higher limit was only a little in excess of that corresponding to a well-defined elastic limit in the materials under experiment, brought about fracture or rupture if only repeated long enough, but that if the variations, though perhaps changing from tension to compression, were well within the elastic limit, the material would suffer no degradation even after many millions of alternations of stress.

In the case of a transformer core, however, the effect of the deterioration is not similar; the material becomes more sluggish in its response to the inductive influence, it loses magnetic elasticity, and its magnetic inertia, so to speak, is increased, but it is analogous in that by long-continued reversals of magnetism, even as by long-continued reversals of mechanical stress, the material becomes less efficient for the purposes for which it was intended.

After all there is nothing surprising in this increase of hysteresis loss with time. Clearly the natural condition of iron is unmagnetized, and it is common experience that any interference with nature is not indulged in with impunity.

It will be remembered how Wöhler's results when first published completely modified our preconceived ideas and principles underlying the design of such structures, as, from the nature of the load they are intended to bear, may be subjected to rapid alternations of stress, either between the limits of low and high positive value, or between negative and positive limits. The line of experimental research suggested by Wöhler has by no means yet been followed to its extreme limit, not for the lack of enthusiastic and willing workers, but because of necessity such experiments must spread over a very considerable period of time, and although we know enough at present of the fatigue of metals to prevent a serious blunder in design, it cannot be safely said that experiments have gone so far as even to be within measurable distance of exhausting the field of research.

Analogy does not constitute logic nor yet legitimate argument, but it cannot be denied that analogy is extremely fascinating, in that it is so highly suggestive. In this particular connection we have two analogous phenomena which appear to arise from analogous causes. They are certainly brought about by analogous treatment. May we not, then, hazard the view that the analogy may be continued so far as to suggest to us that there is a limit to the value of "B," corresponding to the limit of elasticity in materials of construction between which alternations of induction, however rapid and however long continued, would not bring about the molecular change, or whatever it may be in the structure of the material, which

causes this disinclination on the part of the material to respond to the influence of magnetic lines of force?

It would certainly seem that Prof. Ayrton's terse remarks in the discussion on the papers above alluded to were pregnant with a meaning which perhaps did not appeal to the whole of the audience who heard him, and it may be said, with much justification, that further time and energy spent in the determination of the hysteresis loss in various different samples of iron are certainly of little value in arriving at the best material for transformer cores, as long as the laws governing the time value of "Magnetic Fatigue" are not known.

It is by no means unlikely that the more permeable specimens may be the very first to show a marked magnetic fatigue.

It would not be difficult to design and carry out a series of systematic experiments designed to reveal the existence of such laws (if they do exist), and with the facilities at our disposal in the numerous efficiently equipped electric laboratories which now exist in many parts of the country, it would be an interesting and instructive task, the results of which would be of untold value to the engineer.—London "Electrical Review."

MUNICIPAL ADVANTAGES.—HOW TO OBTAIN THEM.—I.[1]

THE author began by giving a number of extracts from his book, entitled "Discussion of Economic Principles Involved in the Law of Incorporated Companies Operating Under Municipal Franchises (1892)," and continued as follows:

When a municipality makes an investment in a plant for carrying on a business, it must first lay a tax to procure the funds. Funds for such purposes are generally raised by the sale of bonds; therefore, the tax is for the annual payment of the interest on the bonds and a small per cent. of the principal. If the service is performed without charge to its users, as in the case of street-cleaning, its entire cost must be paid by taxation. If, as in the case of the manufacture and distribution of gas or electricity, for the purpose of producing light, heat and power for the public and private use, a charge is made. If it is high enough to produce a profit, the amount of the profit enhances the cost of services to its consumers, for the benefit of those taxpayers who are non-users, many of whom are non-residents. If the charge fails to produce a profit, the amount of the loss, which must be paid by taxation, reduces the cost of the service to its users, and benefits them at the expense of those taxpayers who are non-users.

He would be a rash man who would undertake to prove that funds obtained by taxation are expended as economically by those in control of municipal affairs as funds acquired by the processes of private industries and business, are expended by those who have been obliged so to earn them. The reason municipal credit is good is not because municipal business is managed equally well with the best industrial corporations, but because a municipal debt is a first mortgage on all property within the municipal limits. The aggregate property is of such enormous value that the security is ample, and the power of taxation is so absolute that payment is certain.

Political corporate ownership and management does not utilize the natural force of self-interest legitimately. Industrial corporate ownership and management does. The users of the services rendered under such management gain the benefit of the economic value or self-interest. The cost of services to users, furnished at the cost of production by political corporations, all factors of cost being duly considered, is greater than the necessary charges for the same services rendered by industrial corporations. No person can be found who has closely observed how all public work is done, who will hesitate for a moment to affirm that private management, in comparison with public management, is at least 20 per cent. more efficient, saving, and economical in every way. This margin is the direct product of the legitimate utilization of the natural force of self-interest and indicates its economic value. This value is wasted when a profit-producing industry is transformed into a non-profit producing industry, by the legal enactments that transfer its ownership and management from an industrial to a political corporation. Such waste is like a leak in a dam constructed to utilize water power. It is an absolute loss of energy.

The utilization of the economic value of self-interest will create sufficient margin for profit to induce industrial corporations to undertake to supply every public service, if these corporations are granted the same conditions in their franchise as those given by the State, without question, to political corporations. In view of this fact, it is unnecessary for any municipality to bond itself for such purposes, or to assume the responsibility of the management of such industry.

Profit-producing industries are avenues to industrial independence and economic freedom for all who are engaged in them. For wage-workers, more than any others, the self-interest of the individual, the moral interest of society, and the group interest of the municipality, state and nation, demand that all avenues of industrial independence and economic freedom shall be kept open.

By the aid of corporate services, the conditions of life have been improved for every person. While they are not as good or as low in cost to their users as they would be if rendered in accordance with the economic law of labor and property, the advantages secured by them enable every person to enjoy more comfort, greater freedom, a higher degree of intelligence, and to acquire more wealth than was ever before possible. These services are more than self-sustaining.

They are assisting every person to make a profit for himself. They are the means by which the poorest members of society secure the services of the most intelligent and wealthy. They are tools of highest efficiency for the uses of industry, commerce and social life.

Instead of dividing the energies and resources of a municipality by competition between corporations and citizens, they should be united and used in a competition between municipalities for greatest excellence, and industrial, commercial, and social advantages. Substitute competition between municipalities for competition between citizens. The standard of excellence will be the best service at the lowest cost to their users, and the lowest municipal taxation.

That State which first succeeds in intelligently changing its system, or want of system of organizing or controlling municipal political and industrial corporations, by adopting a system in conformity with the outlines herein given, will soonest establish the conditions that will induce the greatest degree of prosperity and well-being for its municipalities and their inhabitants. So conditioned and so controlled, municipal industrial monopolies will be recognized as the friends and servants of the people, and will render the best services of which they are capable at the lowest obtainable cost to users.

A PROPHECY BEING FULFILLED.

Permit me to turn back to a statement made in a book I published in 1889 (2) under the title of "Economic Value of Electric Light and Power." It is as follows:

"Not many years compass before the progress of events will satisfy cities that have taken the ill-advised action of buying an electric lighting plant that, instead of gaining an advantage, they have created an obstruction to the proper development of an electrical service. To secure the full advantage of that service, they will, sooner or later, sell their plants to private companies, who will operate them under contract in connection with the private light and power service."

In a work under the title of "Municipal Ownership—Its Fallacy," published by M. J. Francisco, in 1895, it is stated that the following municipalities have seen their mistake and sold their lighting plants: Greenville, S. C.; Carrolton, Ga.; Stockton, Kan.; Lyons, Ia.; Marceline, Mo.; Marietta, O.; Michigan City, Ind.; Portland, Ore.; Tipton, Ia.; Titusville, Pa.; Moline, Ill.

The Council of Madison (Ind.) voted to sell the municipal lighting plant October 17, 1895, and many others are on the verge of doing so.

The most notable instance of the failure of a municipality to operate an industrial undertaking advantageously is furnished by the city of Cincinnati. On June 15, 1896, the sinking fund trustees of Cincinnati accepted a bid of $19,000,000 for the sale of the Cincinnati Southern Railway.

GOOD CITY GOVERNMENT.

I have recently examined a volume of the "Proceedings of the Second National Conference for Good City Government," held at Minneapolis, December, 1894, and of the "First Annual Meeting of the National Municipal League for Good City Government," held at Cleveland, May, 1895. The good intentions of those engaged in this movement cannot be doubted; that they will effect many reforms of high public value is well assured.

It is easy to see, however, that a long and difficult task lies before them to prepare municipal governments to undertake any enlargement of their functions. The reports made at these conventions from nearly all large cities agree that public business is not conducted with scrupulous care and honesty. Human nature is very much alike the world over. In Chicago a grand jury declares that the public offices are "honeycombed with corruption" and "many officials steeped in crime."

In St. Louis, the committee investigating the work on the partially completed city hall "continue fresh evidences of gross fraud in the construction, and the huge pile of granite and iron

[1] Abstract of a paper read before the Street Lighting Convention, New Haven, June 17.

will, it is said, have to be reconstructed." France has recently been stirred deeply by scandals connecting the Chamber of Deputies with the Southern French Railway Syndicate. In Tokio, Japan, the municipal council has been dissolved; three of the waterworks standing committee have been arrested, increasing the number of prisoners to thirty-seven in the great waterworks scandal of that city. Thirty-two cities in Massachusetts and five in Rhode Island inaugurated new governments on the 1st day of January, 1896. Nearly all of the mayors in their inaugural addresses urged that a check be placed upon municipal expenditures. Josiah Quincy, Mayor of Boston, said: "I shall at once ask the legislature to consider the postponed constitutional limitations of the indebtedness of cities, and the subject of securing such changes in the tax system of the commonwealth as are necessary for promoting the industrial development of the city." And just now the press of New York City is urging that "the streets ought to be repaved in the best possible manner before the end of Mayor Strong's term, in order that the people may see that intelligence is more desirable than ignorance in the conduct of public affairs, and be spared the horrors of a return to barbarism."

WRONG IN PRINCIPLE.

I have tried to show that municipal ownership is wrong in principle. If it is, it is foredoomed to failure in practice. I have had too much experience in dealing with statistics to permit myself to deal largely with data that I cannot verify. Every person who honestly undertakes an intelligent discussion of this subject feels the fatal lack of accurate data. None should be so inaccurate as to suppose, without a careful personal examination into all local conditions, that the results given for one town can be used as a standard for any other town.

One of the most notable examples of municipal ownership of a gas plant is found in Philadelphia. If the accounts of that venture were accurately written up, they would show it had been unprofitable in comparison with a service rendered by a private corporation.

The most notable example of the municipal ownership of an electric light plant is furnished by the city of Chicago. A careful study of this plant was made by Mr. Fred DeLand, of Chicago, the publisher of 'Electrical Engineering," last September. He found the cost (excluding allowance for taxes and insurance) for operating the municipal plant to be $153.48 per arc lamp per year. Unreliable quotations of the cost of operating this plant have damaged the electric lighting business of this country many times the value of the plant. It is a well-known fact that a private company is ready any day to contract to furnish lights at a less cost than the city can produce them from its own plant.

The most recent champion for the honor of demonstrating the economy of municipal ownership of an electric lighting plant is the city of Detroit. In 1893 legislation was secured permitting the city to bond itself for $600,000, for the construction of a municipal plant, that was to produce arc lights at $84 per year. The plant had been in full operation but three months when the city papers came out with startling headlines, "Dollars in Pocket," "Saving so far shown by the city lighting plant," "Average cost per lamp per month is only $7.20." Another paper makes the statement "CUT IN HALF." "Street arc lights costing a little more than $85."

The last contract made by the city of Detroit with a private company was at the rate of $137.80 per lamp per year. This was previous to the panic of 1893. At the time the city of Detroit took this action I stated that the act of the Legislature granting authority to issue bonds and erect the plant had been obtained on insufficient evidence; that the plant would cost more than $600,000, and that the lamps would cost more than $84 per year to operate. The plant cost about $650,000. Mr. Dow, the electrician in charge, states in a letter published in the Detroit "Free Press" that "the bond issue was $600,000, and the remainder of the capital was raised by direct tax." In a letter published in The Electrical Engineer for January 29, 1896, he states "operating cost, plus maintenance, interest, sinking fund to bonds, and a 5 per cent. theoretical depreciation is practically $100 per arc per annum, is substantially true." It will be observed that this "substantially true" statement allows but 5 per cent. for depreciation and makes no allowance for the taxes a private company owning the plant would have to pay. This certainly is a remarkable statement made by the city electrician, called out by criticisms of the flaming newspaper accounts of the great saving effected by the city plant, by those who know how to read between the lines.

The Detroit municipal plant has been running about nine months. Already there is a demand for an additional $200,000 for extensions and the "substantially true" cost of operating the lamps is far above the $84 which was the promised performance.

I will now place myself on record once more: If the accounts of cost are fully and correctly stated at the close of the first, or any other year of the life of this plant, it will be found that the cost per lamp is greater than the contract price now in force in New Haven (Conn.) and many other cities being served by private companies under term contracts. This being true, where is the vaunted saving effected by municipal ownership and management?

Mr. Dow makes one statement in his letter to The Electrical Engineer, which demands special attention. He admits that the steam plant and towers belonging to the Detroit municipal plant will require renewing within twenty years, and that the electrical apparatus and other construction will need to be replaced in less time, but he says: "I want the depreciation cared for in the same way in the public case as in the private. To add 5 or 10 or 15 per cent. of the investment on to municipal annual costs is not the way to estimate a 5 or 10 or 15 per cent. depreciation; because, in the municipal plan, the 5 per cent. stays in the hands of the taxpayers and is invested and reinvested and multiplied many times in the active business of each individual long before the twenty years expire. And because, conversely, the stockholders in the private company either reinvest their surplus over dividends (which is their depreciation fund) right in the company's business, or else divide it and use each man's share in his own affairs. The latter is the exact equivalent of the method in municipal lighting. The surplus need not be collected from the customers and divided among the stockholders because customers and stockholders are, man and man and interest for interest, the same persons."

This is most subtle sophistry. I regret to state that it has found approval by one Professor of Economics, Edward W. Bemis. It is here clearly shown that the eagerness of political managers to make prestige for effecting a large saving by the operation of a municipal plant leads then into the same error frequently committed by managers of private coporations in their eagerness to make large dividends.

The depreciation of a plant by use is as much a part of the cost of operation as is the coal bill or payroll, and should be fully included in every statement of cost. Any other course will lead to inevitable diaster.

In private corporation management, the omitting of this item of cost and a consequent showing of an abnormally large profit invariably produces two results.

First. It causes the city council and private consumers to make a common cause of a demand for reductions in price, and those restless spirits who seek the public good through every excuse they can find for "downing a monopoly" to agitate the cause of municipal ownership, the enormous (?) saving they show, as is now the case in Detroit, being entirely due to the omission of a part of the items of cost.

Second. Twenty years hence the municipal taxpayers and the corporation shareholders will not be "man for man, and interest for interest, the same persons" that occupy these relations to the undertakings to-day. If the cost of depreciation is not collected and set aside month by month and year by year, from the beginning, future taxpayers ana shareholders will be robbed for the benefit of those now in position to be benefited by the robbery.

Pursuing the course Mr. Dow so unequivocally recommends, the inevitable result will be that, year by year, the cost per lamp will creep up as the charges for repairs and renewal of apparatus and construction grow heavier and heavier, until it will pass the point at which there can be any pretense that the municipality is making a saving by owning and operating its electric lighting plant. This will be the condition when the reserve fund, now left in the pockets of the people with such a flourish of economic achievement, will be called up from the pockets of the taxpayers to pay for renewing the plant. With the wisdom that can come to many only through the teachings of a sad experience, they will then reconsider the doings of misguided enthusiasts of to-day, and long before the expiration of twenty years, the estimated life of the plant, they will sell it out to a private corporation and save money by obtaining their public lighting by contract from a private monopoly. There is nothing new about this. The process is perfectly familiar to those who have observed the course of events in all undertakings of a similar character. It is simply perpetuating in political management one of the worst features of private corporate speculation.

When a private corporation is financiered in this way, the first result is to send the price of stock way above par on account of the large profits shown. Those who understand correct economic principles sell out on top of the market, and those who do not, buy. When half the life o fthe plant is run, and the burden of expenses is increasing rapidly, there is a new set of shareholders who find the value of their shares depreciating, caused by the decrease of profits, and in many instances the entire disappearance of dividends. Then come assessments for the reconstruction of the plant, the appointment of a receiver,

the reorganization of the company on a basis scaling down the old capitalization of the company, to repeat the experience unless it falls into the hands of those who know enough to include the cost of depreciation in their operating expenses, and, knowing what it costs to operate a plant, to make a charge for their services sufficient to pay a legitimate profit. Every such experience adds to the number of those who, because they do not know why the result was brought about, are loud in their talk about bad management, corruption, and the freezing-out of shareholders.

OBITUARY.

SIR JOHN PENDER.

WE regret to announce the death of Sir John Pender which took place on July 7 at his residence at Footscray, Kent, England. The immediate cause of death was paralysis, but Sir John had been an invalid for more than a year and had indeed only just recovered partially from a long and severe illness. The stroke which attacked him a few days ago and eventually proved fatal was the third he had experienced during the past six months. Even then, such was his vitality, that it was believed and hoped he would linger somewhat longer than he actually did. He had recently resigned his seat in Parliament for the Wick Burghs and withdrawn from all but the most urgent business affairs.

Sir John Pender was the only son of the late Mr. James Pender, of the Vale of Levin, Dumbartonshire. Born in 1815, he had attained his eighty-second year and, although death is naturally to be expected at such an age, his disappearance will be widely recognized as an occasion for more than ordinary regret. He has laid his generation under obligations of a very special nature, for had not his generosity and stoutheartedness come to the rescue the development of ocean telegraphy would have been delayed for many years subsequent to the breaking of the Atlantic Cable in 1865.

Sir John's early history gave promise of great practical ability and an intelligent spirit of enterprise, though at first it had nothing to do with the application of electricity. Well educated and early put forward into business life he became the General Manager of a factory in Glasgow when little more than twenty years of age and was afterwards known as a successful merchant, both in Glasgow and in Manchester. In the latter city he rendered valuable service during the period of the cotton famine both by assisting in the organization of relief and by his own beneficence, keeping his workmen employed during the paralysis of the cotton industry.

Before that period Sir John Pender had begun to interest himself in submarine telegraphy, and he became one of three hundred and forty-five persons who each contributed £1,000 towards the laying of the original Atlantic cable in 1857, an undertaking of which the inception was due to the late Cyrus W. Field. The attempt to establish direct telegraphic communication between England and the United States was subject to repeated failures for a period of eight years when the cable of 1865 parted while it was being paid out from the capacious hold of the Great Eastern. The case seemed desperate. The Atlantic Company, of which Sir John Pender was a Director, suffered financial ruin. The public would subscribe no further capital, and the government would render no help. But Sir John still believed that success was attainable, and there were a few others whose confidence was also maintained. A large sum of money had already been thrown into the sea and it required robust faith to resist such discouragement.

But the faith was forthcoming, and when the Gutta Percha Company wanted a guarantee of a quarter of a million before undertaking to make the cable for a renewed enterprise, Sir John at once offered to become personally responsible for that amount. The guarantee was accepted and the Telegraph Construction and Maintenance Company was formed by the union of the Gutta Percha Company with Glass Elliot & Co., Sir John Pender, (then Mr. Pender) being the Chairman. Success of a twofold nature ensued, the new cable being satisfactorily laid, while the one which the Great Eastern had lost was recovered.

A striking allusion to the crisis at which Sir John Pender so happily intervened was made by the late Lord Derby eight years ago when Lady Pender was publicly presented with her husband's portrait. Speaking of the Atlantic cable his Lordship said: "It is not too much to affirm that but for Sir John Pender and a few others of whom he was chief, that enterprise would have collapsed and at best a long delay would have occurred before investors consented to risk their capital in such a speculation again." Admitting that the enterprise would have been accomplished at some date or other, Lord Derby argued that in such a case the loss of time represented by even one generation would have meant almost incalculable loss, material loss to England. In his further remarks it was shown how Sir John had made this particular victory the starting point of other enterprises scarcely less important and in their aggregate perhaps of even greater consequence than the laying of the Atlantic cable. Thus Sir John became Chairman of the company which laid the first line to India and was mainly instrumental in establishing communication with Australia and China. It was also due in a great measure to his exertions that South Africa became connected telegraphically with England. Energetically supported by the present Marquis of Tweeddale and the late Sir James Anderson an amalgamation of enterprises was formed by which oceanic telegraphy obtained a worldwide extension.

Possessing great discernment of character and keen commercial sagacity, Sir John Pender was highly qualified as an organizer and an administrator. He knew the value of scientific research and for that reason invoked the aid of such authorities as Lord Kelvin, Dr. Alex. Muirhead, Mr. Herbert Taylor and others in those matters which related to the working of telegraph cables. The staff whom he gathered round him were eminently qualified for their duties and the personnel of his companies throughout the world proved worthy of the positions so occupied. The extent of the work which had thus to be controlled is shown by the fact that the capital of the submarine telegraph companies over which Sir John presided was not much less than £15,000,000, while the aggregate length of the cables exceeded 73,000 nautical miles, bringing in a revenue last year of £2,153,000, the reserve funds standing very nearly at £3,000,000.

Not limiting his attention to submarine operations the same indefatigable worker and organizer was Chairman of the Metropolitan Elec. Supply Co. of London, which maintained last year upwards of a quarter of a million of lights and takes a foremost place among such undertakings. In respect to the telegraph cable companies of which Sir John was Chairman, it is to be observed that they have not merely lived, but grown, thus affording practical evidence of the ability with which they have been conducted, their value in the share market being a fair test of their soundness and success.

On such a man it was natural that honors should descend, though of these he had no excess. His public services were unquestionable and in recognition of these Queen Victoria in 1888 made him a Knight Commander of the Order of St. Michael and St. George, followed in 1892 by advancement to a grand cross of the same order. In 1870 the Prince of Wales was present at Sir John Pender's house in Arlington street to celebrate the completion of the connection, by ocean cables, of England with India. Twenty-four years later, when Sir James Anderson had passed away, Sir John presided at the Imperial Institute at the silver Jubilee of the formation of the company for the establishment of submarine telegraphy to the East and far East, and on this occasion he was again honored with the presence of the Prince of Wales. Some time ago when visiting Constantinople Sir John received from the Sultan the Grand Cordon of the Medjidieh, the honor being the highest that could be granted to an alien. Other rulers indicated their appreciation of Sir John Pender's labors by similar marks of distinction. Among the orders conferred were those of the French Legion of Honor, the Italian Knight Grand Cordon of the Crown, the Portuguese Order of the Rose and the Greek Cross of Commander of the Royal Order of the Savior. At quite a recent date the French government conferred upon Sir John its highest colonial order, that of Commander de l'Ordre Royal du Dragon d'Annam. Among the incidents of Sir John Pender's home career special reference must be made to his long connection with the House of Commons.

ELECTRIC PLANTS NOT EXEMPT FROM TAXATION AS MANUFACTORIES, IN MARYLAND.

An important decision was handed down in the U. S. Circuit Court last week in the injunction suit of the Frederick (Md.) Electric Light and Power Company vs. the Corporation of Frederick, to restrain City Register L. H. Nixdorff from levying upon the plant of the company for the payment of taxes alleged to be overdue. The opinion filed dismissing the application for an injunction on the ground that electricity is not a manufactured article and that electric light plants do not manufacture it, but merely distribute it, was written by Judge Lynch and concurred in by Chief Judge McSherry. This is the first time the question has been brought into the courts in the State of Maryland, and the decision is considered a very important one.

The electric light company will be compelled to pay about $500 back taxes on their plant. They claimed exemption from taxation on the ground that their concern was a manufacturing plant, and that the corporation of Frederick had exempted all manufacturing plants locating in the city from taxation for a period of five years.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Biographical:

KELVIN JUBILEE CELEBRATION.—Complete account with the address by Lord Kelvin.—"The Electrical Engineer," July 1, 1896.

FRANKLIN LEONARD POPE.—Biography in "Electrical Age," July 4, 1896.

Central Stations:

BRIGHTON CENTRAL STATION EXTENSION.—An illustration of the buildings in section and elevation.—London "Electrical Engineer," June 26, 1896.

HARTLEPOOL ELECTRIC TRAMWAYS.—The line has a total length of 2½ miles. Boilers, which are in duplicate are fed by an electrically driven three-throw feed pump. Two direct coupled dynamos and Willans engines with a speed of 450 revolutions are used, with a normal output of 120 amperes at 500 volts. Detailed description is given in London "Electrical Engineer," June 26, 1896.

Dynamos and Motors:

LANGDON-DAVIES SELF-STARTING, MONO-PHASE INDUCTION MOTOR. Detailed description with illustrations and curves.—London "Elect. Review," June 26, 1896. London "Electrician," June 26, 1896.

SAYERS' DYNAMO.—By M. Aliamet. Description with illustrations on the design of a hermetically closed dynamo.—"L'Electricien," June 27, 1896.

ON THE SEAT OF ELECTRODYNAMIC FORCE IN IRONCLAD ARMATURES.—By E. J. Houston and A. E. Kennelly.—It is shown in this paper that in the particular type of armature used, more than 98 per cent. of the entire torque was exerted on the iron, less than 2 per cent. being produced by the conductors.—"Elect. World," July 4, 1896.

Electro-Chemistry:

THERMO-ELECTRIC REACTIONS AND CURRENTS BETWEEN METALS IN FUSED SALTS.—By Thomas Andrews. This paper contains the results of extended experimental inquiries by the author on the subject of currents between metals in fused salts.—"Industries and Iron," June 26, 1896.

ELECTRICITY DIRECT FROM CARBON.—By Dr. Alfred Coehn. Read before the Berlin Elektrot. Verein. Author found that he could produce a solution of carbon; that from such a solution carbon may be separated as a cation and that an element may be formed of which carbon is the soluble electrode.—The Electrical Engineer, July 1, 1896.

Lighting:

COAST AND LIGHTHOUSE ILLUMINATION IN FRANCE.—By C. S. du Riche Preller. A description of the electric lighting, flash light, of the alternating current machinery used, of the annual cost of French coast lighting and also of incandescent gas light.—London "Engineering," June 26, 1896.

ELECTRIC LIGHTING AND RAILROADING IN THE UNITED STATES.—A table showing the number of hours of service per day, number of watt hours produced, quantity of fuel consumed, and the number of watt hours per pound of coal in 82 central stations.—"Revue Industrielle," June 27, 1896.

CONNECTING LIGHTHOUSES AND LIGHTSHIPS WITH THE SHORE.—Abstract of the fourth report submitted by the Royal Commission.—The Electrical Engineer, July 1, 1896.

HIGH VOLTAGE LAMPS IN ALTERNATING CURRENT PRACTICE.—By H. W. Couzens. Abstract of a paper read before the Municipal Electrical Association, in which author points out advantages of the alternating current system.—"The Electrical World," July 4, 1896.

Magnetism:

MAGNETIC FATIGUE.—By Ed. C. de Segundo. Author briefly reviews the lectures and works of Ewing, Parshall, Kennedy and Wöhler and points out the importance of determining whether "magnetic fatigue" follows a certain law, and if so, what that law is.—London "Electrical Review," June 26, 1896.—The Electrical Engineer, July 15, 1896.

Measurements:

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES.—By J. A. Fleming, M. A., F. R. S. A discourse delivered at the Royal Institution, June 5, 1896.—A great many details of experiments made with curves illustrating the results.—London "Electrical Engineer," June 26, 1896. The Electrical Engineer, July 8, 1896.

ON THE CONSTRUCTION OF A CAPILLARY ELECTROMETER. By R. Vigouroux. A short illustrated description of a newly constructed instrument.—"L'Electricien," June 27, 1896.

A NEW LORENZ APPARATUS.—A complete description of a new set of apparatus for the determination of resistance in absolute measure.—London "Electrician," June 26, 1896.

ELECTRICAL RESISTANCE OF ALLOYS.—By Lord Rayleigh. Author suggests the possibility of a thermo-electric effect existing between the substances composing the alloy, thus introducing apparent resistance, which in reality are counter e. m. f.'s. He finds a formula for this false resistance and applies it to an alloy of copper and iron.—London "Electrician," June 26, 1896.

MEASUREMENT OF VERY LARGE AND VERY SMALL ALTERNATING CURRENTS.—By Mr. Campbell. Paper read before the Physical Society, June 12, 1896. Author advocates the use of air core transformers for measuring voltages and currents which are either above or below the range of the instruments available. This method is briefly described and an abstract of the accompanying discussion follows.—London "Electrician," June 26, 1896.

Mechanical:

SIMPLE ELECTRIC PLOW.—Illustrated description of a plow designed by Israel Hogeland.—"Western Electrician," July 4, 1896.

ELECTRIC ORGAN AT THE STATE INDUSTRIAL SCHOOL, ROCHESTER.—This is an electric organ action; a storage battery is used in connection with it.—"Western Electrician," July 4, 1896.

Miscellaneous:

COST OF ELECTRICITY SUPPLY.—By Arthur Wright, borough electrical engineer, Brighton.—Author points out that no manufacturing undertaking can be considered to trade on a sound commercial basis, unless it has ascertained with some degree of accuracy the cost of supplying the commodity it produces; he shows how charges vary and then describes a modification of the Hopkinson method applied to the accounts of the Brighton Corporation.—London, "The Engineer," June 26, 1896. London "Electrical Review," June 26, 1896. "Industries and Iron," June 26, 1896.

Railways:

ELECTRIC TRACTION FOR TRAMWAYS.—By J. Allen Baker.—Author presents a number of statistics and records of progress made in various European cities; he also refers at some length to the successful systems used in the United States. An itemized table shows a total mileage of electric and other mechanical traction on the Continent of Europe to have been 515 miles on January 1, and 351 miles under construction at that time.—London "Electrical Engineer," June 26, 1896.

ELECTRIC PASSENGER CARS.—Some photographs showing the exterior and interior of vestibuled motor cars.—"Railroad Gazette," June 26, 1896.

CONTROLLING APPARATUS FOR STREET RAILWAYS. —Description of a controlling apparatus which is put up at the office of the Superintendent who can see at any time the position of any car, the number of stops or any irregularity taking place in the system.—"Die Elektrizität," June 27, 1896.

INTERNATIONAL PERMANENT STREET RAILROAD ASSOCIATION.—A detailed account of all the questions which are to be discussed at the ninth general meeting to be held at Stockholm in August next.—"Die Elektrizität," June 26, 1896.

ORGANIZATION OF THE SYSTEM OF TRAFFIC AND THE TECHNICAL CONDITIONS FOR ELECTRIC STREET RAILWAYS IN BERLIN. By Dr. M. Kallmann.—Lecture delivered before the Elektrotechn. Verein April 28, 1896. An interesting paper giving an insight into the demand which the German public makes on the car companies.—"Die Elektrizität," June 26, 1896.

CARS MADE OF ALUMINUM.—A short notice stating that the Directors of the French Government railroads have ordered some cars built in which aluminum is being used wherever copper and iron were formerly employed, except at the axles, wheels and couplings.—"Die Elektrizität," June 26, 1896.

THIRD RAIL ON THE NANTASKET BEACH ROAD.—Of special interest is an illustrated description of the third rail and a view of the contact shoe.—The Electrical Engineer, July 1, 1896.

ELMIRA STREET RAILWAYS.—A detailed account with many illustrations and diagrams.—"Electrical World," July 4, 1896.

OUTLOOK FOR THE ELECTRIC RAILWAY. By F. C. Armstrong.—Paper read before the Canadian Electrical Association, Toronto, Ont., June 18, 1896.—A general review of the progress made during the last few years.—"Western Electrician," July 4, 1896. "Electrical Review," July 1, 1896.

Roentgen Rays:

ROENTGEN RADIATIONS. By T. C. Porter.—Any arrangement by which a charge on the outside of the tube behind the cathode would be subject to intermittent removal greatly increases the fluorescence and photographic action of the discharge, as well as prevents the "fatigue" of the tube. Abstracted from a letter to "Nature" in London "Electrical Engineer," June 26, 1896.

FLUORESCENCE VISIBLE AND INVISIBLE.—An abstract of a discussion in the Société Française de Physique participated in by Mr. Guillaume, who pointed out that the theoretical difficulties which have been believed to block the way to an efficient fluorescence lamp do not really exist.—London "Electrical Engineer," June 26, 1896.

POLARIZATION. By S. P. Thompson.—A communication before the Physical Society, June 12, 1896. A large number of crystals have been tested under the Röntgen ray, but no polarization was detected.—London "Electrician," June 26, 1896.

BLEYER PHOTO-FLUOROSCOPE. By J. Mount Bleyer, M. D.—Apparatus for photographing the fluorescent screen.—The Electrical Engineer, July 1, 1896.

Telegraphy, Telephony, etc.:

STATISTICS OF DISTURBANCES ON LOW VOLT CIRCUITS DUE TO HIGH PRESSURE LINES. By Dr. Strecker. Presented before the Elektrotechn. Verein at Berlin. Report of 76 distinct cases between 1891—1896. Telephone lines were affected more than telegraph lines. Detailed account of the principal cases in "Die Elektrizität," June 26, 1896.

HOME TELEPHONE COMPANY'S SYSTEM, MOBILE, ALA.—An installation which differs widely from the ordinary Bell company's system. Line and station connections, calling apparatus, combined receiver and transmitter, switchboard annunciator lamp and magnet, testing plugs, etc., are described in detail and many illustrations furnished.—The Electrical Engineer, July 1, 1896.

EDUCATING OPERATORS IN THE HANDLING OF THE SWITCHBOARD. By W. F. Packard.—Paper read before the Association of Railway Telegraph Superintendents. Author points out the importance of operators being able to make quick repairs.—"Electrical Review," July 1, 1896.

COMBINED ELECTRIC LIGHTING AND TRACTION PLANT. By John Hesketh and John H. Rider. Paper read before the Municipal Electrical Association. The object of the paper is to show that lighting and railway plants should and can advantageously be combined.—London, "The Engineer," June 26, 1896. "Industries and Iron," June 26, 1896.

Transmission of Power:

EXTENSIONS TO OUTLYING DISTRICTS. By A. H. Gibbings. Paper read before the Convention of the Municipal Electrical Association. Author dealt with the cost of extending supply into the suburbs and houses scattered over a large area. He gives useful tables of rental of houses, shops, etc., in one particular street with the gas bills for each particular rental.—Short abstract in London "The Engineer," June 26, 1896.

NIAGARA FALLS. By T. C. Martin. Abstract of lecture delivered before the Royal Institution.—Appeared in London "Electrical Engineer," June 26, 1896.

ELECTRICAL TRANSMISSION IN SPAIN.—Power is obtained from a river with no natural fall. Dam and canal were built, the latter being 2 kilometres in length and 5 square metres in cross section. Effective height is 96 feet and minimum quantity of water is 6,000 cubic feet per minute. Turbines of 150 h. p., when running at 375 revolutions per minute, are coupled direct to the alternators. Shafts of turbines are horizontal. Alternators are single-phase type, 110 kilowatt, 6,500 volts, 50 periods per second.—London "Electrical Review," June 26, 1896.

ALTERNATING AND DIRECT HIGH VOLTAGE SUPPLY.—A summary of the remarks of the speakers at the Convention of the Municipal Electrical Association, with some additional considerations, in order to put the subject forward in an impartial manner.—London "Electrical Review," June 26, 1896.

THIRTY-FIVE MILE ELECTRIC POWER TRANSMISSION AT FRESNO, CAL.—7,000 horse-power are developed at the water wheels. Three-phase generators are used of 350 kilowatt capacity each. Detailed account in The Electrical Engineer, July 1, 1896.

BALTIC—TAFTVILLE TRANSMISSION PLANT. By H. E. Raymond.—This plant is situated in Connecticut and has two turbines of 800 horse-power and one of 300 horse-power capacity. Two 250 kilowatt, 2,500 volt, three-phase generators are used.—Details of plant in "Electrical World," July 4, 1896.

POWER TRANSMISSION BY POLYPHASE ELECTROMOTIVE FORCES. By Geo. White-Fraser.—Paper read before the Canadian Electrical Association. Begun in "Electrical Review," July 1, 1896, and to be continued in subsequent issue.

Wiring:

CONTROL BY MUNICIPAL AUTHORITIES OF CONSUMING DEVICES AND THE WIRING CONNECTING THEM TO THE MAIN. By C. H. Wordingham.—Paper read before the Institute of American Electrical Engineers. gives several of the principal rules and regulations of the Board of Trade and suggests the advisability of having an engineer employed who would for a small fee consult with anybody wishing to install a plant; or that the corporation itself should employ a staff of workmen to carry out wiring.—London, "The Engineer," June 26, 1896. London "Electrician," June 26, 1896.

EFFECT OF TEMPERATURE ON INSULATING MATERIAL. By G. F. Sevey, A. Monell and C. L. Perry. Paper read before the American Institute of Electrical Engineers. Deals with the effect of certain insulating materials, such as paper, cloth, oiled paper, oiled cloth. Tests were made and the conclusions drawn.—London "Electrical Review," June 26, 1896. "Electrical Age," July 4, 1896. The Electrical Engineer, May 13, 1896.

EFFECT OF TEMPERATURE ON INSULATING MATERIALS. By Chas. F. Scott. Communicated to A. I. E. E. Illustration of apparatus used, description of methods and conclusions on tests made.—The Electrical Engineer, July 1, 1896.

ELECTRIC LIGHT WIRING AND TESTING. By Newton Harrison, E. E.—One of the lesson leaves of the American School of Electricity. Enumeration of the possible troubles that may arise and methods for prevention and cure.—"Electrical Age," July 4, 1896.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JULY 7, 1896.

Alarms and Signals:—

COMBINED ANNUNCIATOR AND FIRE ALARM. M. Garl, Akron, O., 563,269. Filed Sept. 27, 1894.
Details of construction.

APPARATUS FOR SELECTIVE SIGNAL SYSTEMS. F. R. McBerty, Downer's Grove, Ill., 563,294. Filed Aug. 23, 1895.
The act of making connection with the line automatically determines the excitement of the signal to which it is desired to respond.

ELECTRIC POLICE SIGNAL SYSTEM. C. E. Scribner, Chicago, Ill., 563,324. Filed May 14, 1894.
Means for preventing telephonic appliances from interfering with the transmission of telegraphic signals.

ELECTRIC SIGNALING APPARATUS. F. W. Turner, Newton, and W. M. Chapman, Needham, Mass., 563,336 Filed April 18, 1891.
Adapted for police-signal purposes.

INDIVIDUAL CALLING APPARATUS. W. W. Alexander, Kansas City, Mo., 563,352. Filed April 8, 1893.
Details of construction.

ELECTRICAL SIGNALING APPARATUS. S. S. Bogart, Schraalenburg, N. J., 563,442. Filed Oct. 16, 1894.
Comprises an answer-back provided with a winding and checking mechanism.

AUTOMATIC FIRE ALARM. J. W. Frost, New York, 563,474. Filed Feb. 18, 1888.
The combination with a signaling mechanism, and an electromagnet normally controlling the same, of a closed circuit through the said magnet, the said closed circuit being looped between the magnet and the battery on each side, cross-connections, normally open, connecting opposite sides of each loop, and mechanically operated switches adapted to close said cross-connections.

IN AND OUT INDICATOR. J. P. Milbourne, Monton, England, 563,501. Filed Dec. 26, 1895.
Details of construction.

AUTOMATIC REPEATER. J. W. Frost, New York, 563,586. Filed Aug. 16, 1892.
An automatic repeater which shall be so combined with devices at the transmitting station as to accomplish automatically what has heretofore been done by an operator.

Storage Batteries :—

STORAGE BATTERY. W. J. Still, Toronto, Canada, 563,428. Filed Sept. 18, 1894.

A series of conducting-plates, all of the same polarity, interposed active material, elastic means for binding the plates together at right angles to their adjacent faces.

Conductors, Conduits, and Insulators :—

CABLE HANGER. A. S. Diehl, Chicago, Ill., 563,263. Filed Jan. 21, 1896.
A strap adapted to encircle the cable and carrying upon its upper end a hook.
MEANS FOR INSULATING ELECTRIC CONDUCTORS. T. Guilleaume, Mulheim-on-the-Rhine, Germany, 563,273. Filed March 19, 1895.
A naked conductor inclosed in and twisted angular tube of non-conducting material.
ELECTRIC CABLE. T. Guilleaume, Mulheim-on-the-Rhine, Germany, 563,274. Filed Nov. 2, 1895.
Employs grated or ground vegetable fiber or bark surrounding the conductor and inclosed by a braiding or tubular covering.
FLEXIBLE MICA INSULATING SHEET. C. W. Ferferson, Schenectady, N. Y., 563,379. Filed March 16, 1895.
Consists of layers of fibrous and mica sheets and gutta-percha tissue between any and every two of said layers.
INSULATING SUPPORT FOR RAILS OF ELECTRIC RAILWAYS. P. Haley, Chicago, Ill., 563,482. Filed March 9, 1896.
The combination with a suitably supported insulating block adapted to support a rail and formed with sockets in its lateral faces, of clamps having hooked portions adapted to grasp the flange of said rail, and lugs extending into the sockets in the insulating block and suitable means for connecting the clamps.
ELECTRICAL CONNECTOR. B. L. Toquet, Westport, Conn., 563,695. Filed May 13, 1896.
Rail-bond.
ELECTRICAL INSULATING SHEET. C. W. Ferferson, Schenectady, N. Y., 563,716. Filed March 16, 1895.
Consists of layers of asbestos and mica, and adhesive gutta-percha tissue between any and every two of said layers.

Distribution:—

SYSTEM OF ELECTRICAL DISTRIBUTION. C. P. Steinmetz, Schenectady, N. Y., 563,426. Filed Jan. 30, 1895.
For alternate current systems.

Dynamos and Motors :—

BRUSH FOR ARC DYNAMOS. H. H. Wait, Chicago, Ill., 563,337. Filed Aug. 20, 1895.
The combination with a main brush of an independently fed auxiliary brush situated at the tip of the main brush.
COMPOUND-WOUND MULTIPHASE GENERATOR. C. P. Steinmetz, Schenectady, N. Y., 563,427. Filed March 19, 1896.
Two separate armatures connected in quadrature and energized by different fields, independent circuits extending from each armature and independent compounding and regulating means in each of the circuits.
ELECTRIC MOTOR. E. J. Berg, Schenectady, N. Y., 563,440. Filed Oct. 8, 1895.
Means of indicating synchronism of an alternating current motor; one or more incandescent lamps connected across the field terminals.

Lamps and Appurtenances:—

ELECTRIC ARC LAMP. C. E. Scribner, Chicago, Ill., 563,315. Filed Jan. 2, 1893.
Two sets of carbons are provided, so that when one set is consumed the other set may be automatically brought into circuit.
INCANDESCENT LAMP. C. E. Scribner, Chicago, Ill., 563,319. Filed July 20, 1891.
The combination with an exhausted bulb of glass of a film of carbon deposited upon the inner surface of the bulb and leading in wires sealed into the bulb, making electrical connection with the film.
INCANDESCENT LAMP. C. E. Scribner, Chicago, Ill., 563,321. Filed May 9, 1893.
Means for hermetically sealing the bulb in such manner that the bulb and the filament may be separated for purposes of renewal.
PROCESS OF BUILDING UP CARBON FILAMENTS. F. S. Smith, Pittsburg, Pa., 563,329. Filed Aug. 29, 1892.
Consists in heating the filament in a rare medium, together with anthroquinone.

Miscellaneous:—

LIGHTNING ARRESTER AND AUTOMATIC FUSE BLOCK. T. L. Carleton, New Orleans, La., 563,257. Filed Feb. 28, 1894.
A conducting bar and a non-conducting bar, a series of contact wires connecting them, a spring-controlled contact arm to successively engage the contact wires and a brush making sliding contact with the contact arm.
APPARATUS FOR HEATING THERMOPILES. E. N. Dickerson, New York, 563,262. Filed March 8, 1892.
A device for heating thermopiles by a heated gas index pressure.
ELECTRICAL PRODUCTION OF CHEMICAL REACTIONS. W. Lobach, Chicago, Ill., 563,288. Filed Nov. 30, 1894.
Process of bleaching oils.
ELECTRICALLY CONTROLLED BOAT STEERING APPARATUS. C. E. Ongley, New York, 563,304. Filed Dec. 20, 1892.
Means for connecting the cable and rudder and a magnet in a suitable circuit normally holding said means out of engagement with the rudder.
CONTACT POINT FOR ELECTRICAL INSTRUMENTS. C. E. Scribner, Chicago, Ill., 563,326. Filed Aug. 17, 1895.
Details of construction.
COMBINED PESSARY AND WOMB-BATTERY. M. E. Keller, Fort Worth, Tex., 563,387. Filed July 31, 1895.
Details of construction.
MAGNETO-ELECTRIC MACHINE. P. J. Crouse and E. W. Millgate, Utica, N. Y., 563,453. Filed Sept. 7, 1895.
Details of construction.
THERMOSTAT AND CIRCUIT THEREFOR. J. W. Frost, New York, 563,475. Filed March 28, 1890.
A concavo-convex disc, confined at its edges, two or more contact pieces co-operating therewith, the said disc and the said contact pieces having an adjustable relation to each other.
PROCESS OF MANUFACTURING WHITE LEAD. A. B. Browne, Cambridge, and E. D. Chapin, Natick, Mass., 563,553. Filed Dec. 20, 1894.
The manufacture of white lead by the separation of an electrolyte with a solvent of lead and an alkaline hydrate, and then treating it into a solvent of lead and an alkaline hydrate, and then treating it by electrolysis.
PROCESS OF MANUFACTURING OXIDS OF LEAD. A. B. Browne, Cambridge, and E. D. Chapin, Natick, Mass., 563,554. Filed Jan. 28, 1895.
Similar to above.
MANUFACTURE OF WHITE LEAD. A. B. Browne, Boston, Mass., 563,555. Filed April 3, 1896.
MAGNETO-ELECTRIC GENERATOR. A. G. Leonard, New York, 563,599. Filed Aug. 10, 1894.
May be operated either by hand or by a passing train to generate electric currents at intervals.
APPARATUS FOR THREADING CONDUITS OR PIPES. T. J. Cope, Philadelphia, Pa., 563,360. Filed March 4, 1895.
Comprises a head, a tailpiece, a carrier, rods common to said head and tailpiece, and sleeves mounted on said rods and adapted to serve as stops for said carrier.
ELECTRIC HEATER. T. Grutting, St. Paul, Minn., 563,715. Filed Sept. 9, 1893.
The heating conductor's conductivity increases with increase of temperature, and a controlling conductor whose conductivity decreases with increase of temperature in series therewith.
PROCESS OF PRODUCING CALCIUM COMPOUNDS. T. L. Willson, New York, 563,527. Filed March 16, 1893.
Consists in mingling lime with a liquid reducing agent, such as liquid hydrocarbon, drying the said mixture and subjecting it to the heat of an electric furnace.
PROCESS OF MANUFACTURING HYDROCARBON GAS. T. L. Willson, Brooklyn, N. Y., 563,528. Filed Feb. 28, 1894.
Consists in treating calcium oxid in the presence of carbonaceous matter in an electric furnace, forming a calcium carbide and combining water with the said calcium carbide.
BOTTLE FILLER. W. H. Fahrney, Chicago, Ill., 563,464. Filed March 11, 1895.
Means for holding open the valve between the bottle and the supply until a predetermined point and then closing such valve.

Railways and Appliances:—

ELECTRIC RAILWAY. H. Brandenberg, Chicago, Ill., 563,254. Filed April 16, 1895.
Conduit system.
ELECTRIC RAILWAY. E. Lachmann, Hamburg, Germany, 563,282. Filed June 30, 1894.
An upper air-tight channel room with a slot in the side wall and a water trough above the channel cover.
AUTOMATIC BLOCK SIGNAL AND ANTI-COLLISION APPLIANCE FOR RAILWAYS. H. W. Harris, deceased, R. J. Harris, administrator, Raleigh, N. C., 563,374. Filed May 14, 1895.
An electromagnetic device located upon the locomotive connected with the brake system, and which is in electrical connection with the conductor along the trackway.
SPEED INDICATOR. T. O. Bateman, Fort Worth, Tex., 563,544. Filed July 20, 1895.
Especially designed for use on trolley cars.
TROLLEY WIRE FROG. M. F. Bean, Springfield, Mass., 563,446. Filed Jan. 29, 1896.
Details of construction.
TROLLEY CATCHER. C. F. Wilson, Brooklyn, N. Y., 563,531. Filed March 6, 1896.
Comprises a winding mechanism for receiving the trolley operating rope.

Regulation:

METHOD OF AUTOMATIC CURRENT REGULATION OF DYNAMO ELECTRIC MACHINES, 563,290. Filed Aug. 6, 1894.
Consists in maintaining two portions of the field at a uniform magnetic moment.
MECHANICAL MOVEMENT. E. A. Sperry, Cleveland, O., 563,424. Filed Nov. 11, 1893.
A single lever operates to control a motor.
REVERSING CONTROLLER FOR ELECTRIC MOTORS. A. C. Dinkey, Munhall, Pa., 563,575. Filed Sept. 3, 1895.
A rheostat having arc-shaped main contact plates through which the current always passes in the same direction, separated series of resistances, each series having two sets of contact blocks, and an arm arranged to move over said arc-shaped plates and said contact blocks in opposite directions and thereby reverse the current.
RHEOSTAT FOR ELECTRIC MOTORS. H. W. Leonard, New York, 563,600. Filed June 21, 1895.
Embodies a final protective step of high resistance so as to prevent the net effective electromotive force in the circuit from sending a destructive current through the rheostat.

Switches, Cut-Outs etc. :—

CIRCUIT ESTABLISHING CUT-OUT. A. L. Tucker and F. H. Loveridge, Chicago, Ill., 563,335. Filed Aug. 8, 1895.
Details of construction.
ELECTRIC SWITCH. C. G. Perkins, Hartford, Conn., 563,407. Filed April 1, 1896.
Embodies a rotary lettered disc, the lettering of which registers with a perforation through the cap after each turn of the handle spindle.
ELECTRICAL SELECTOR. S. S. Bogart, Schraalenburg, N. J., 563,443. Filed Jan. 5, 1895.
Details of construction.

Telegraphs :—

CABLE TERMINAL ATTACHMENT. A. T. Welles, Chicago, Ill., 563,342. Filed March 3, 1896.
The combination with connecting blocks of a casing of insulating material having plates above and below said blocks, an insulating compound filling the space remaining within said case, and means for connecting the safety fuses and the distributing wires, respectively, with said blocks.

Telephones:—

MULTIPLE SWITCHBOARD SYSTEM FOR TELEPHONE EXCHANGES. O. A. Bell, New York, 563,250. Filed May 19, 1892.
Circuits and mechanism whereby the individual annunciator of a line shall be automatically reset.
BRIDGING BELLS. C. E. Scribner, Chicago, Ill., 563,318. Filed March 6, 1891.
Details of construction.
MULTIPLE SWITCHBOARD SYSTEM FOR TELEPHONE EX-

CHANGES. C. E. Scribner, Chicago, Ill., 563,320. Filed March 5, 1892.
The combination with the core of an electromagnet of the magnetizing helix thereof, an additional normally-open-circuited coil encircling the same core and means for closing the circuit of said additional coil in short circuit.
TELEPHONE CIRCUIT. C. E. Scribner, Chicago, Ill., 563,322. Filed June 16, 1893.
Means for preventing "side tone" produced in a telephone receiver by vibrations of its own microphone.
TESTING APPARATUS FOR MULTIPLE SWITCHBOARDS. C. E. Scribner, Chicago, Ill., 563,323. Filed Nov. 13, 1893.
The combination with a plug circuit of a repeating coil having its helices included in series in one conductor of the circuit, and a key adapted to disconnect the repeating coil and close circuit directly in place thereof.
SYSTEM OF CURRENT DISTRIBUTION FOR SUBSTATION TELEPHONES. C. E. Scribner, Chicago, Ill., 563,325. Filed Feb. 28, 1895.
The telephone transmitters at the substations are supplied with current from a common source located at a central point.
TELEPHONE EXCHANGE SWITCHBOARD. C. E. Scribner and E. P. Warner, Chicago, Ill., 563,327. Filed Feb. 7, 1890.
A switchboard table provided with separately removable plug sockets arranged along the longitudinal center of the board and the spring-jack placed on opposite sides of said sockets.
SPRING-JACK FOR TELEPHONE SWITCHBOARDS. H. B. Thayer, New York, 563,333. Filed July 5, 1895.
Details of construction.
TELEPHONE TRANSMITTER. W. A. Moore, Brooklyn, N. Y., 563,395. Filed March 25, 1896.
Employs an oil-silk diaphragm.
TELEPHONE SYSTEM. J. Piel, New York, 563,614. Filed April 13, 1896.
Details of construction.
TELEPHONE SIGNALING CIRCUIT. J. S. Stone, Boston, Mass., 563,692. Filed March 18, 1896.
Provides means whereby the bell armature is made free to respond to the signaling current.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

THE "H. W. J." ELECTRIC CAR HEATER.

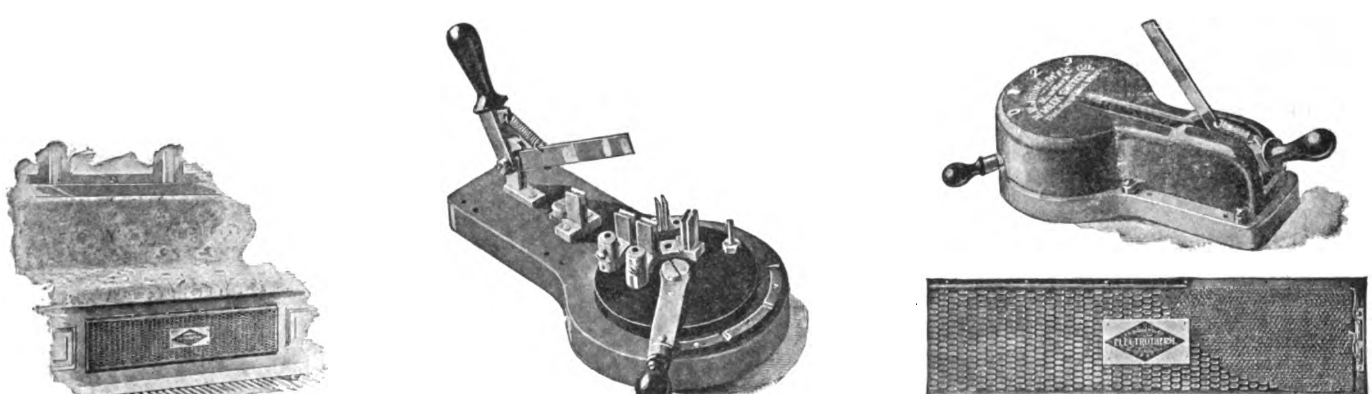
ONE of the causes of the short life and unreliability of the average electric heater is the ultimate breaking of the wire. This may be due to crystallization, as a result of prolonged vibration caused by the jarring of the car; to the movement of the wire over its supports as it elongates and contracts when heated and cooled; or to oxidation, which will be manifested when the wire is overheated, and as a result of the condensation of moisture when cold, and by standing idle for any length of time. Much trouble has also been caused by the difficulty of preventing short circuits between the bare uninsulated wires, and of keeping the wires securely attached to their insulating supports.

A novel departure in the arrangement of the resistance wires and insulation has been made in the "H. W. J.," or "Electrotherm," car heater, and the above difficulties have been practically overcome. The resistance wires, after being wound with asbestos cord, are woven into a mat or cloth with an asbestos warp. The wires are thus effectually insulated from each other, and the liability of short circuits obviated; the movements of the wires resulting from expansion and contraction are confined within their asbestos envelope, which, to prevent oxidation by moisture, is thoroughly waterproofed with a special insulating compound baked in. The mat thus prepared is attached to a backing of asbestos millboard, and confined in an ornamental perforated steel casing, as illustrated in the engraving. By this method of constructing an electric heater, a very large heated surface is exposed for both radiation and convection, and it becomes possible to obtain the most satisfactory results with a long length of wire heated by the current to a comparatively low temperature. The liability of "burn-outs" is thus practically obviated, and the durability of the heater is measurably increased.

The heaters are attached to the faces of the panels beneath the seats the full length of the car on both sides. Attachment is made by screws, and no cutting or other injury to the car is necessary. As an exceedingly large heating surface is provided, the car is heated with an evenly distributed temperature by heaters, none of which is overheated so as to cause discomfort to, or burn the clothing of passengers.

The regulating switch illustrated provides for these degrees of temperature represented by the consumption of about 3, 6, and 9 amperes. This method of electrically heating the cars has proved its simplicity and economy during the past season, and it is expected that many "H. W. J." heaters will be found in operation during the coming winter.

The "H. W. J." heaters are manufactured by the H. W. Johns Manufacturing Company. The Electrotherm, which is a flexible heating pad made for home and hospital use, in a manner similar to the car heaters, is also being furnished by them to meet the demand for the most modern and convenient means of generating and applying heat by electricity.



THE "H. W. J." ELECTRIC CAR HEATERS AND REGULATING SWITCH.

WILLYOUNG INDUCTION COILS WITH ADJUSTABLE CONDENSERS.

Mr. James G. Biddle, Drexel Building, Philadelphia, is meeting with marked success in introducing the new Willyoung induction coils with adjustable condensers. This apparatus is built upon correct, improved, scientific lines and is fully equal in grade of workmanship and efficiency of results to the best types, which have been made heretofore only in England and France. When properly handled each coil is guaranteed to produce a continuous discharge of the rated spark length without breakdown or other injury.

The adjustable condenser is a feature of great value, for it enables the discharge to be varied through wide ranges and adapts the coil to vacuum tubes of different degrees of exhaustion. The advantage of this condenser over the form previously used is precisely the same as that of an adjustable field rheostat over one of fixed value. While the Willyoung coils are superior for any work that requires such apparatus, the greatest demand at present is naturally for X-ray coils, and particular attention is devoted to this department. Each detail of construction is watched with utmost care, and the following remarks from a prominent purchaser indicate the manner in which the apparatus operates.

Mr. W. W. Griscom, president of the Electro-Dynamic Company, writes under date of June 26: "I am highly pleased by the behavior of the coil which you last sent me. I do not think it could be possible for a coil to work any better. It gives a splendid stream of sparks at six inches and occasionally a spark would strike across a distance of eight inches. I congratulate you on the success of the various experiments, and beg to thank you for your efforts in getting me the best possible coil, and for your kindness in adding the little practical improvements."

Messrs. Willyoung & Co. make a specialty of constructing coils of large size, and are also prepared to fill orders quite promptly. Mr. Biddle will be glad to furnish price lists and further particulars upon request.

CEILING FANS FOR ELEVATOR CARS.

A new and very novel application of an electric fan to the ceilings of the elevator cars of the Taylor Building, at 39 Cort-

landt street, has been made by the Globe Ironclad Motor Company which have offices in the same building.

The rotation is horizontal, thus throwing the air downward and affording a delightful breeze to heated passengers. The motor is so constructed as to be dustproof, rendering it particularly lasting for this purpose. Mr. Williams has certainly conferred a great favor on perspiring humanity by his ingenious device.

J. G. BRILL COMPANY'S PIVOTAL TRUCK.

THE truck which we illustrate herewith is built by the J. G. Brill Company, of Philadelphia, so that its wheels are independent of each other in their vertical motion, while the truck frame itself can rise or fall at the ends, or move sidewise bodily without imparting any of these movements to the body of the car. The general design of this truck is shown in the illustration, Fig. 1. The frame is a forging, the wheel pieces being of a form somewhat like that which is so effective in locomotive practice. To a bar of ample stiffness jaws are forged at the proper points, and from the outermost jaw at each end extension pieces are carried to which T-iron end pieces are bolted. On the wheel piece between the jaws and as close to them as may be practicable lugs are forged for carrying the spring links. Upon the inside of these wheel pieces, which are made of steel castings for electric service, brackets are cast to take the angle iron transoms. The strains upon the truck frame for a given weight of car and load are much less than in the ordinary construction. The swing links come close to the pedestals, relieving the wheel pieces from a large part of the strain which comes upon them when the load is carried by the transoms. Fig. 2 shows the motion of the truck with the new and with the old style of construction. The old style is shown on the right, and that of the new truck on the left.

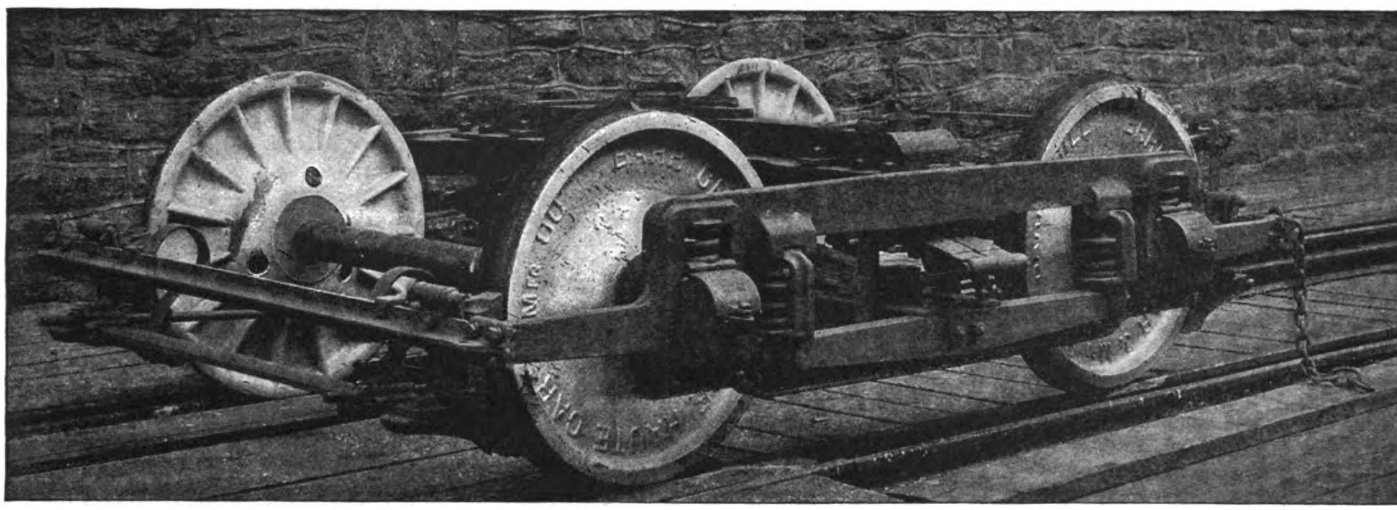


Fig. 1.—The Brill American Passenger Pivotal Truck.

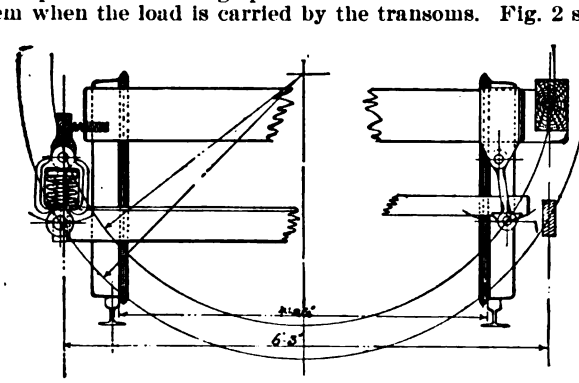

Fig. 2.—Brill Pivotal Truck.

In both cases the center plate is taken as the center of motion and supports the circles representing the lines of motion. With the old style of link the radius of motion is that of the inner circle. The radius of the outer circle is obtained by placing the hangers outside the wheels as shown. The motion, of course, will be slower in proportion to the greater radius and correspondingly easier.

One of the novel and most ingenious features of the truck is found in the equalizers. These are straight, forged bars, carried by spring links, or stirrups, upon their ends. At the centers they are solidly connected with the spring plank. The equalizer, spring plank and the swing bolster move together in the side motion. Its construction and disposition enable it to perform all that is possible for an equalizer.

The spring links are a novel feature of the truck. It consists of a steel stirrup in which there is a space for an 8-inch spiral. A follower is placed on top of the spring and an eyebolt is screwed into it. They differ from the ordinary link in position, action and in possessing elasticity. While they perform all the functions of the common swing link, they also cushion the side motion. For this reason the danger of jumping the track on curves is practically eliminated.

THE A. B. NOYES ELECTRIC CO.

The A. B. Noyes Electric Company, of St. Johnsbury, Vt., have issued a circular calling attention to the fact that they are extending their electric business and have made arrangements by which they are prepared to do first-class up-to-date engineering work, for which they shall make an especially low rate of charge.

They are manufacturing a highly efficient and well-built direct current dynamo for isolated lighting in shops, mills, etc., and have installed at the Hotel Look-Off, Sugar Hill, N. H., a complete plant consisting of 500 arc and incandescent lights and two electric motors running pumps.

Mr. Ernest Gonzenbach, the company's electrical engineer, has just completed the construction of the electric light and power plant for the town of Barton, Vt., which operates a distance of 14½ miles at 6,300 volts, and is the longest line of electrical power transmission in the Eastern States. They are consulting engineers for the St. Johnsbury Electric Company, and have recently drawn important plans for the extension of their system.

THE RUSHMORE PROJECTORS.

The high power marine projectors built by the Rushmore Dynamo Works, of Jersey City, N. J., have replaced nearly all the old reflector lights as well as many of the finest French and other projectors. The power and penetration of these lights far surpass the finest apparatus previously used in the navies. They are making these lights in large numbers, and with their improved lens-making plant have succeeded in reducing the price to less than obtained last year for the old style reflector lights.

They have sold over 100 lights this year for naval and commercial vessels, the acceptance of each light being subject to its giving entire satisfaction and so great has been their success that every light shipped has been promptly accepted. They have installed this season over fifty complete electric fountain lights, including fifteen for the Union Traction Company, for their handsome electric fountain at Willow Grove, Philadelphia, and they are now building a 100,000,000 candle-power projector for the tower of the new Siegel-Cooper building, New York City. This light will be visible fifty miles at sea.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

Vol. XXII. JULY 22, 1896. No. 429.

ELECTRIC LIGHTING.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST MILLENNIUM EXHIBITION.—I.

BY ALFRED O. DUBSKY.

ALTERNATING currents have come into general use during these ten years, not only for lighting purposes, but also, and more particularly of late, for transmission of power. It is quite natural that the history of their progressive development and their actual state should be of general interest, and the present exhibition at Budapest, the success of which surpasses all expectations, is particularly adapted for making the retrospect mentioned above. For it was on this same spot that, in the year 1885, the alternating current started on its triumphal march; it was only after this first practical experiment that it may be said to have reached the position of commercial importance. The employment of transformers with closed magnetic circuit, as well as the possibility of their parallel

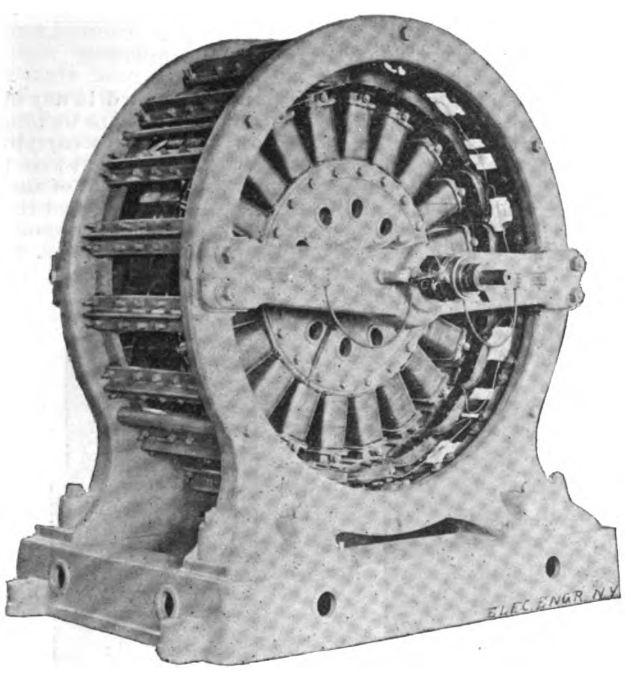

FIG. 1.—GANZ & CO. 80-KILOWATT SINGLE-PHASE ALTERNATOR.

working, are nowadays well known details. Nevertheless we should not forget that during more than thirty years we had no exact knowledge of the working of induction apparatus. Moreover, even after these first successes there were many who doubted the practical value of the above mentioned experiments.

It was at the last Budapest Exhibition, in 1885, that the possibility of the practical use of transformers was first clearly demonstrated. It was the natural continuation of the admirable work of Gaulard and Gibbs, but in a more practical direction. Almost the entire lighting of this exhibition was done according to the directions and plans of Messrs. Blathy, Zipernowsky and Déri, who created a system which during these past ten years has spread all over the world. There were then shown the first transformers with closed magnetic circuit employed for public lighting, and their parallel working never caused any serious difficulty from the first experiments.

An exhibition always demands very brilliant lighting and a comparatively large transmission of power. These are ideal conditions for showing the advantages of every system. During the evening it is the lighting which is of the greatest importance, but during the day when the different motors in the exhibition are running, the demand for power is the greatest.

Notwithstanding their real advantages, polyphase currents are not commonly employed for circuits serving only for lighting purposes or in cases when the demand for motors is a question of secondary importance. Modern polyphase dynamos with moderate armature reaction and most ingenious connection devices have diminished greatly the drawbacks of unequally loaded branches. Nevertheless, they have not wholly disappeared; but, on the other hand, it is true that these drawbacks are less noticeable, if the number of motors fed from the same circuits is large. This circumstance is due to the well-known equalizing action of working motors. Nevertheless, I dare say that for certain purposes single-phase currents have not lost anything of the importance which they had before the practical use of polyphase currents. In view of the facts mentioned above, both systems are duly represented in the present exhibition: Single-phase currents for lighting purposes and for a quite considerable number of different motors; polyphase currents for the transmission of power.

The lighting of the present exhibition is done in the same manner as the system of 1885: High-tension distribution with parallel working transformers. There is, of course, a very large difference between the transformer of 1885 and the apparatus at present employed at the exhibition. The former is of a form rather out of fashion, but is perhaps still well known from older descriptions.

I. SINGLE-PHASE CURRENT MACHINERY.—CENTRAL STATION.

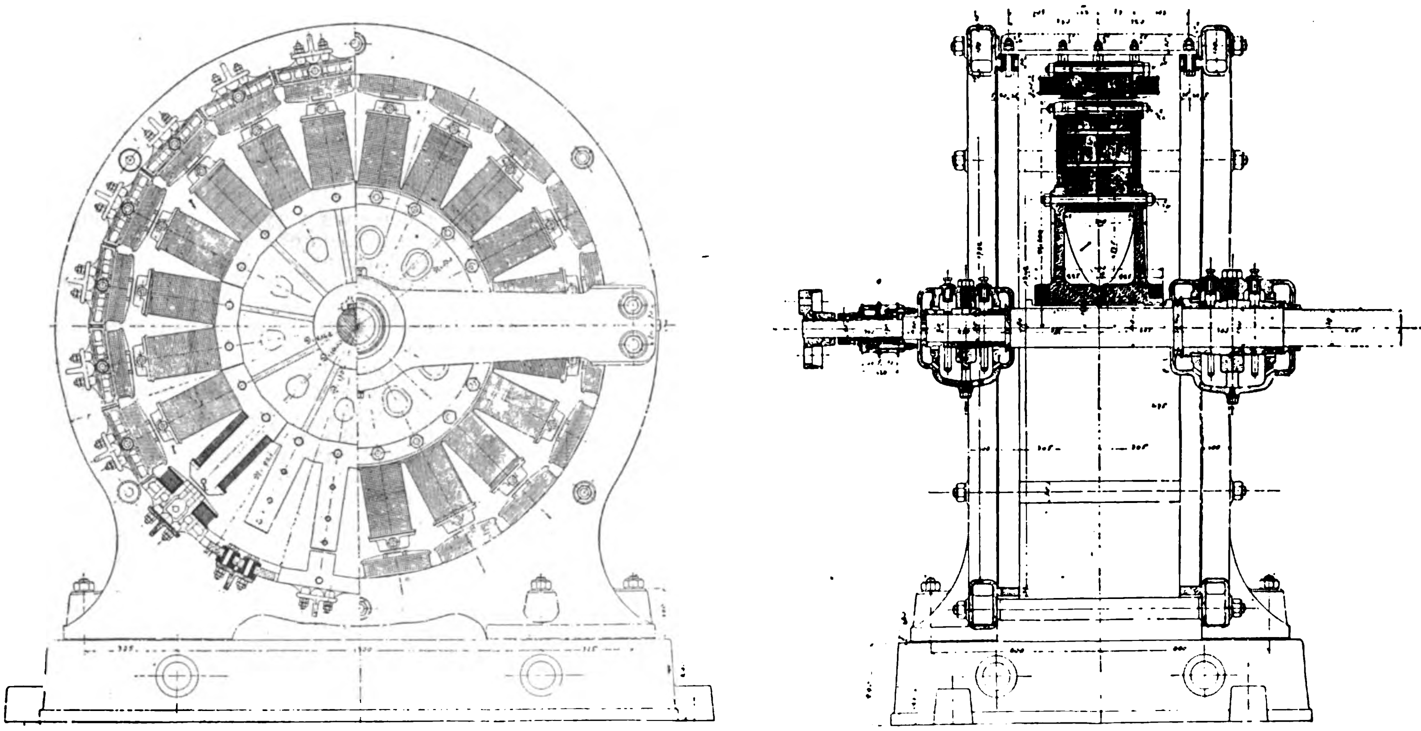
The alternating current central station for the lighting of the exhibition has two dynamos of about 160 horse-power each. They are both connected to the bus-bars and are coupled daily in parallel; moreover, two three-phase current dynamos, each of 200 horse-power, give one-half of their power on the lighting circuit in the form of a single-phase current. All these machines give light only for one-quarter of the exhibition; three-quarters of it are lighted by the two large central stations of the city of Budapest. The distribution is made at a pressure of 2,000 volts and there are different sub-stations and single transformers serving for distributing centers. I shall treat of the three-phase dynamos, which are of a very interesting construction, in a subsequent article, confining myself at present to the single-phase generators.

These generators are constructed by the well-known firm, Messrs. Ganz & Co. They are coupled directly to their steam engines and the exciting current is furnished by two continuous current dynamos, also direct connected to the generator shafts. The number of periods of the whole altenating plant is 42 per second, the lowest admissible for arc lighting. The advantages of a low frequency are too well known to require further elucidation.

The engraving, Fig. 1, shows one of the generators exhibited, which is of the same type as those employed in the exhibition lighting plant. It is of 80 kilowatt capacity; another, of 400 kilowatt, is the type employed in the large central stations of Budapest and Vienna. All these machines are of the same construction, namely, with stationary armature and revolving field magnets.

The engravings, Figs. 2 and 3, show the machine in elevation and section. The armature bobbins are placed on the outer ring of the machine, which is formed of L-shaped iron cores, consisting of insulated iron strips, which are pressed together by screws. The armature windings are put upon the several magnet limbs. The cores are fixed to cross-bars, which again are bolted on both sides of the circular-shaped frames of the machines. The advantage of this construction is, that any armature spool can be replaced by a new one at any time without disturbing the other parts of the machine.

The field magnets consist of a star-shaped core and the exciting bobbins are slid over the projecting arms. The core is built up of iron strips assembled in a manner that the joints in one layer are covered by the iron in the following layer. It is now quite easy to see how to replace the winding of any field mag-



FIGS. 2 AND 3.—GANZ & CO. 80-KILOWATT ALTERNATOR.—ELEVATION AND SECTION.

net. Dismounting the opposite armature bobbin we get an opening in a radial direction large enough to take off the field bobbin, if the screws serving to hold it are removed.

The machines of this type have all a relatively moderate armature reaction, and besides, the short circuit current through an ampere meter reaches only about two and a half times its normal load value, if the dynamo is not too much excited. Therefore, no damage to the winding can happen in regular work. I give in Fig. 4 a working characteristic at no load of the above described 80 kilowatt single-phase generator.

The machine was run at the ordinary tension of about 2,000

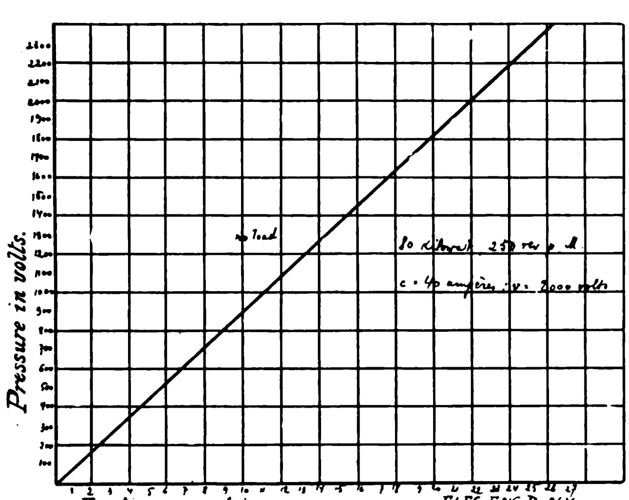


FIG. 4.—CHARACTERISTIC OF 80-KILOWATT ALTERNATOR.

volts. The pressure is drawn on the vertical line; on the horizontal line is noted the value of the existing current in amperes.

The constancy of the voltage even for widely varying loads is easily obtained by an automatic rheostat of the Blathy type. This apparatus consists of a wooden frame, Fig. 5, bearing the wire resistances. These terminate in ends which form a sloping surface and dip into a basin of mercury. The basin has an automatic vertical movement in both directions, depending on the terminal pressure at the machine. When it reaches its highest position each wire end dips into the mercury and all the resistance is short circuited; in its lowest position the bars are drawn out from the mercury, and all the resistance is inserted. In any other position there is always a different number of bars dipping in the mercury. The basin is fixed to a vertical tube carrying a piece of iron in its interior; at its bottom it is screwed to a float gauge dipping into a water tank at the bottom of the apparatus. The action of the float gauge is upward; just the inverse action is produced by a special bobbin placed around the iron core. This latter action is, of course, a magnetic one. There

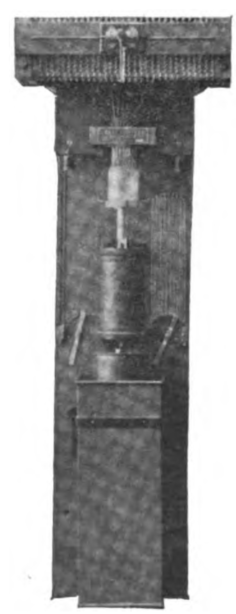

FIG. 5.

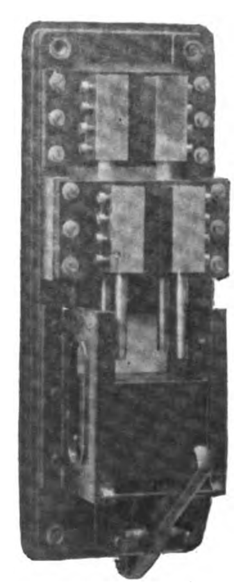

FIG. 6.

are regulating weights attached to the moving part and they are chosen in such a way that admitting a certain determined current in the bobbin the iron core should be well balanced in each position. If this current be changed the iron core will shift its position till the regular and normal conditions are reestablished.

The dynamos I have described above work very satis-

factorily with this mode of regulation. The variations of voltage produced by the sudden connecting of motors are very small, and even these are quickly balanced by the excellent equalizing action of these regulators.

The parallel working of the two lighting engines in the exhibition running nearly the whole day can be witnessed daily and is carried out without the slightest difficulty. Let us be sincere and admit that it is perhaps due more to the constructor of the steam engine than to the dynamo builder. The parallel working of the first generators made by Messrs. Ganz & Co. was a daily occurrence when it was still a much discussed question whether parallel working was practically possible. In the year of 1886 the alternators at Treviso could be coupled to the same bars; in this installation the dynamos were driven independently by belts. But in 1888 Rome had the first central station in the world where alternators driven by independent steam engines had to work in parallel upon the same network of distribution. The steam engines were fitted up with ordinary Porter governors and there were never any serious difficulties in regular working.

It is quite certain that the value of armature self-induction has a great influence upon the facility of parallel working, as it influences greatly the mutual elasticity of the alternators. But between certain limits, which should be carefully observed, it is chiefly upon the steam engine that the satisfactory parallel running of the generators depends. The other alternators of the exhibition specially built for power distribution, and having therefore a smaller armature self-induction and a comparatively high magnetization, have been connected as easily in parallel as the special lighting machines, which latter have a relatively smaller magnetization.

Parallel working at the exhibition is done by first loading the machine to be coupled in parallel by a variable resistance to the same degree as the other which is already working. A voltmeter indicates the moment when the two generators are in phase, at which time the coupling switch is thrown. Afterward the loading resistance is withdrawn by degrees from the main circuits.

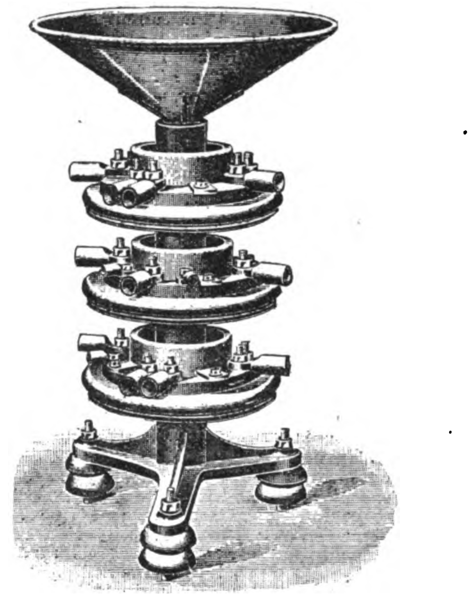
The switches used on the switchboard for high tension work are all mercury apparatus. They have very great advantages, as their manipulation is very easy and without any danger; they have been constructed for current intensities of 100 amperes and more. It is true that for strong currents these switches are heavy, but it is just this weight which assures the rapid break of the circuit. The apparatus shown in Fig. 6 is designed to carry 50 amperes. There are four contact pieces provided with long bars. The lower basin is made of ebonite and contains two mercury cups thoroughly insulated. The whole basin can slide in the vertical direction; raising it by lever shown causes the bars to dip into the mercury. By this means the bars enter into electrical connection.

THE WORDINGHAM PILLAR DISTRIBUTOR.

To secure equality of pressure it is desirable to inter-connect a distributing network at as many points as possible. The great drawback to such inter-connection is, however, the difficulty of localizing a fault should one occur, and with a view to providing for this it is essential that all linking points should be capable of rapid disconnection. This is by no means easy to provide for in a neat and convenient manner when there are many cables meeting in one point, and the difficulty is very largely increased when the distribution is effected on the five-wire system, since the number of cables is largely augmented. The necessity for some convenient apparatus for this purpose has led Mr. C. H. Wordingham (Municipal Electrical Engineer at Manchester, Eng.) to devise the apparatus illustrated on this page.

A central hollow cast-iron column standing on three oil insulators is fixed in the junction box. From this column project at five different levels three cast-iron lugs 120 deg. apart, cast in one with the column. Five cast-iron plates, each having three slots separated from one another by 120 deg., and three recesses on the under side placed between the slots, are provided. One of these plates is slipped over the pillar, the slots allowing it to pass the lugs until the bottom three lugs are reached. The plate is then turned through an angle till the recesses are opposite the lugs. The plate is then dropped down, and takes a firm seat. On the plate are placed two flat rubber rings which serve as a bed for a porcelain insulator of the form shown. This insulator is large enough to slip past the cast-iron lugs. Three slate wedges covered with india-rubber strip are placed between the insulator and the pillar, so that the insulator is firmly fixed. A substantial ring of gunmetal is now placed on the insulator; this ring is prevented from slipping about by means of four small brass pieces secured by bolts and rendered adjustable by means of slots. This ring has studs and tapped holes which admit of a large number of lugs into which cables are sweated, being affixed to it by means of nuts and bolts. A second cast-iron plate is now slid down the pillar and fixed on the next three lugs from the bottom, and an insulator and ring placed on it as before described. Three more cast-iron plates, each with its insulator and ring, are then fixed on the remaining lugs. A large funnel is slipped on to the top of the pillar. This serves to collect any water that may drip into the junction box, and so prevents it from falling on the apparatus; the water runs down the funnel through the interior of the column.

The illustration shows a three-ring distributor complete



WORDINGHAM PILLAR DISTRIBUTOR.

without any cables attached. Such a pillar distributor is capable of dealing with a very large number of cables. Each ring can readily have six ½ square inch cables and six smaller ones attached to it, that is to say, the pillar as a whole will deal with 70 cables. A considerable number of these distributors have been introduced into the Manchester network. It is quite easy to disconnect the five cables which pass down a street in as many minutes, and, in case of a fault, portions of the network from which a large supply is being taken can be broken with perfect safety. On one occasion as much as 1,700 amperes at 200 volts was successfully disconnected on one of these pillars.

PROPOSED CITY PLANT FOR PAWTUCKET, R. I.

Both branches of the City Council met June 27 for the purpose of listening to the report of Mr. C. O. Mailloux, electrical engineer, upon the feasibility of the city establishing a municipal electric lighting plant. The report was presented, and was long, exhaustive and yet unfinished. But the following summing up contains the gist of the whole: First, the use of arc lights is recommended for the street lighting. The candle-power should be limited to 1,200. The lighting of the outlying portions might remain as it is for the present. Second, the city could afford to install at least 350 arc lights to begin with. The present distribution of lamps is very faulty and should be thoroughly revised. Third, the city has sufficient use for indoor lights, and can operate these lights from its own plant at sufficiently low cost to justify it in providing the necessary facilities for the purpose. Fourth, the plant can be located near pumping station No. 1. Fifth, the cost of equipment will vary with the kind and character of equipment adopted and the number of lights operated, from $68,000 to $86,000 for the arc street lighting equipment alone. The incandescent lighting equipment will add from $5,600 to $6,300. Total cost of both equipments will range from $73,000 to about $92,000. Sixth, the cost of operating will range from a yearly total of $16,700 to $20,200 (in round numbers), according to the kind of equipment adopted, and the total number of lamps operated. The cost per lamp per year will likewise vary from $49.79 to $56.91. The total cost of alternating current production for the municipal indoor lighting will range from $1,000 to $1,500 per year.

The matter will soon come up for vote.

MUNICIPAL ADVANTAGES.—HOW TO OBTAIN THEM.—II.

BY ALLEN R. FOOTE.

WANT OF APPRECIATION.

The most serious aspect of the question is the spirit of antagonism against corporations that is being engendered in public opinion by persistent, well-meaning, but misinformed persons. In the volume referred to, published by the National Municipal League for Good City Government, there are some forty references to the franchise question by speakers from different cities, every one of whom speaks about the giving away of franchises, as though that had ever been done. A franchise is given away only when the municipality receives no consideration. The consideration of highest value is the benefit of the public advantage. This advantage is effective in the direct proportion of service rendered to necessary capitalization. It is not unusual to find the announcement that, to illustrate, a street railroad company has obtained a franchise by "paying a handsome figure. Gives a bonus of $250,000 and 38½ per cent. of gross receipts." A little later comes the announcement that the "bill is popular." "Belief that 3-cent fares will compel street railway companies to reform."

Again, these friends of the people advise "managers of steam and surface roads that they will add to their popularity and increase their revenues by making a 5-cent fare to all points within specified limits. If the railroads would cut down their fares to 5 cents, this territory would be speedily built up. The taxable property of the city would thus be added to, and the roads would find their profit in a steady increase of trade." These three phases of the question are all presented in one of the leading newspapers of the country within six months. Is it a wonder that there should be a spirit of antagonism to corporations when the public mind is dependent for instruction upon this kind of written-to-make-the-paper-sell information? In another city, an effort is being made to get a street car line constructed to a suburban park. In this instance the headlines read, "Valuation of property in the vicinity likely to be increased fifty times if the plans suggested are to be carried into effect." This is the talk now. When the road is in operation and the real estate owners have secured the advance of "fifty times" on the value of their property and the municipality has been benefited by a large increase in the valuation of taxable property, and the railroad is paying, say, 10 per cent. dividends, there will come the demand to "down this monopoly" by increasing its rate of taxation, adding to its burdens by compelling it to repave, repair, and clean the streets through which it passes, and to reduce its fares. The worst of it all is, because not properly taught, the honest-minded, but misinformed masses will support these demands.

Going to the other extreme, there are those whose appreciation of the advantages of the public services rendered by corporations is so great they advocate the policy of having the municipality take possession of all the street railroads, carrying passengers without charge, and provide for the cost of operation by general taxation.

JUST CAUSE FOR APPRECIATION.

All that is required to generate a true appreciation of the economic advantages derived from the services rendered by public service corporations is to have the exact truth told regarding them.

In New Haven, 1885, the electric light company furnished 31 arc lamps on a one-year contract at $237.25 per lamp per year. This company is now under a three years' contract to supply 400 lamps at $98.55 per lamp per year.

400 lamps at $237.25, price of 1885..	$94,900.00
400 lamps at 98.55, price of 1896..	39,420.00
Saving for pockets of taxpayers, per year	$55,480.00

The facts in relation to the New Haven Gas Company are as follows: The price of gas in 1873 was $3 per 1,000 cubic feet. Since March 5, 1895, it has been $1.25. The sale of gas for the year ending December, 1895, was 246,217,000 feet.

246,217,000 feet at $3.00, price of 1873..	$738,651.00
246,217,000 feet at 1.25, price of 1895..	307,771.25
Saving for pockets of taxpayers and consumers, per year	$430,879.75

We are justified in taking a broader view. Mr. Mulhall, the leading statistician of the world, states: "A saving of 3.56 a ton on freights which has been effected by means of railways, means a fall of 12 per cent. in the price of all commodities, without loss to any one."

The "Journal des Economistes," France, states the ordinary freight charges per ton on railways as follows:

	Price per 100 miles.
United States	$ .40
Holland	.78
Belgium	.80
Germany	.82
France	1.10
Russia	1.20
Italy	1.25
Great Britain	1.40
Average	.97.

This shows an average of a penny a mile, as compared with 8 cts. in 1850. But while, in every country the benefits resulting to the community from the construction of railways have been equivalent to an annual dividend of 40 or 50 per cent. on their cost, the results to the capitalists and shareholders who provided the necessary money have been by no means encouraging. If we take the average returns of net receipts for the years 1887-88, we find that only in two countries did they reach 5 per cent., the average for Europe being less than 4 per cent. (3.7), and for the world only a fraction over 3 per cent., as shown in the following table:

United Kingdom	4.1
France	3.8
Germany	5.1
Russia	3.3
Austria	3.1
Italy	2.5
Sweden	2.9
Belgium	4.6
United States	3.1
Canada	1.7
Spanish America	1.6
India	5.2
Australia	3.3
Egypt	4.1
The world	3.2.

This evidence, showing that public service corporations are entitled to high appreciation and would receive it, if the truth regarding them were fully impressed upon public attention by the friends of the people, may be closed by a reference to that shining mark of the advocates of government ownership of industrial monopolies, the Western Union Telegraph Company. Its average toll per message in 1868 was $1.047. In 1895 it was $0.307. The number of messages handled in 1895 was 58,307,317.

58,307,317 messages at $1.047, price of 1868.	$61,047,758.80
58,307,315 messages at .307, price of 1895.	17,900,345.70
Saving in the pockets of users, per year,	$43,147,413.10

This saving represents a dividend to the public of nearly 50 per cent. on the capitalization of the company, while the dividend paid to shareholders is only 6 per cent.

Facts such as these, and a correct understanding of the economic principles involved in the question of governmental vs. the private ownership and operation of industrial monopolies, will cause the demand for the municipal ownership of gas and electric lighting plants to disappear, and will counteract the unjust antagonism that has been and is still being engendered in the public mind by those who do not think accurately.

Here are indisputable instances of substantial dividends left in the pockets of the users of services supplied by public service corporations and of taxpayers. In the light of facts such as these, and the cold, stern records of experience that will certainly be made in the future, the "substantially true" saving promised by Mr. Dow to Detroit taxpayers, will be found, the longer and the more critically it is examined, to be of diminishing largeness.

I now reassert an affirmation made in 1890:

There is not a municipal-owned gas or electric light plant in the United States which private capital will not take over and operate under contract, at the same price the service is now costing the municipality, all factors of cost being correctly and fully considered, and all franchise rights enjoyed by the municipality being assigned to the purchasing private corporation.

One of my critics has said that I am right in the position I have taken on this subject, but that I am in advance of the times. In his opinion, after fifty years of discussion and many costly experiments, the question will be settled about on the lines I have indicated. If the public requires fifty years in which to educate itself to my position, I certainly cannot be held responsible for that. If I am right now, I shall be right then, and shall be glad to see you.

It is a difficult thing to cause a people to think rightly.

Electric Transportation.

THE SCOTT & JANNEY SINGLE-PHASE ALTERNATING RAILWAY MOTOR.

BY GORDON J. SCOTT.

KNOWING that it has been the endeavor of electrical engineers and inventors for some years to discover some means by which it would be possible to operate electric railway cars with single-phase systems, the following description of the Scott & Janney system will no doubt interest many who have been engaged upon similar work.

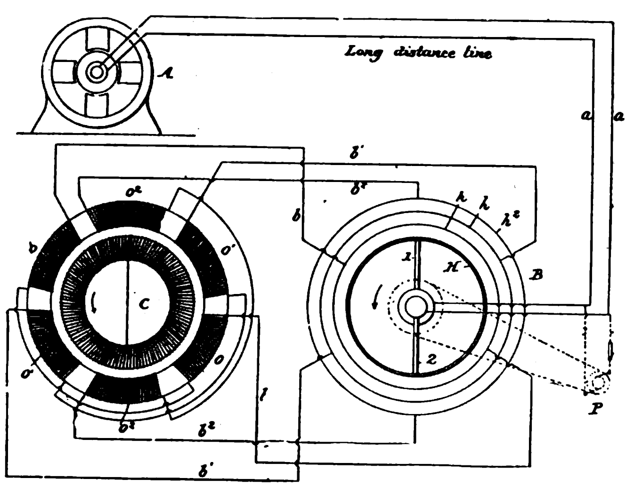


FIG. 1.

First, it may be advisable to tell in a few words why single-phase alternating current motors have not been employed upon railway cars.

There have been no single-phase motors built up to the present time which were load-starting in the full sense of the word, which were designed to run on a two-wire circuit without commutators and be economical. Even giving the self-starting (as distinguished from load-starting) motor its due, allowing it to self-start and run at synchronous speed, operating a direct-current dynamo and direct-current motors, the economy and regulation factors go side by side with each other, and go far toward making up the inefficiency of such portable central stations.

Alternating currents have little or no respect for commutators and brushes, and while it is possible to make single-phase motors with commutators it is a source of constant expense and annoyance to keep them going, and as railway motors they would rival some of the early types of street car motors in chewing up brushes and commutators.

The two-phase and polyphase systems of course can be employed, but the use of two trolleys is not to the liking of railway people in general, as one ordinarily satisfies the needs of all concerned. In addition to this the best polyphase motors hesitate when it comes to starting a loaded street car or stripping the teeth off a gear or pinion, and object to being forced. They are also very inefficient, except when running in synchronism, which they cannot always do.

In the course of our experiments we found that a two-wire system could be employed to do the work to the satisfaction of every demand made upon a railway motor. The motor which will be employed is a rotary field motor, single phase. We mention this now in order that there will be no misunderstanding, the difference between a rotary field and a polyphase motor being very decided, although it will be difficult for some to see it at a glance.

We have first, B, Fig. 1, what we have termed an "induction director," as upon this piece of apparatus the effectiveness of the system and of the motor in particular depends. The induction director takes the current from the line and acts, as its name implies, as the director over the motors connected with it. It may be connected in a great many different ways for different cases and results. Its chief duty is to create a rotating field in the motor or motors which are connected to it, which rotary field may have two, or one hundred, poles about a given armature, and which poles moreover rotate at any speed that the director may elect at the will of the motorman.

The velocity of the rotating field being a variable and being under absolute control, it is readily understood why a very great starting effort can be obtained. It is practically the same as if the frequency on any alternating polyphase system was variable, and the dynamo and motor brought up to speed at the same time. This, every one knows, would only do and is only done where all the power of a dynamo is absorbed by one motor or where all the motors on any circuit are shut down or all running at once, or, in other words, are not independent.

The theoretically perfect system of motor control is that in which the e. m. f. and current are both variable at will on any given motor without employing a resistance in the circuits to obtain such variation. This we are enabled to do with alternating apparatus as the C^2R loss on a street car equipment, even at the slowest possible speeds, is very small. The question of distance does not cut any figure for ordinary railways. A 100-mile railroad operated from one station can be as easily operated and more economically than the best direct-current railway of to-day; the enormous copper investment would be done away with. Alternating machinery of every kind is more durable than direct-current apparatus, on account of the ease with which the insulation may be placed.

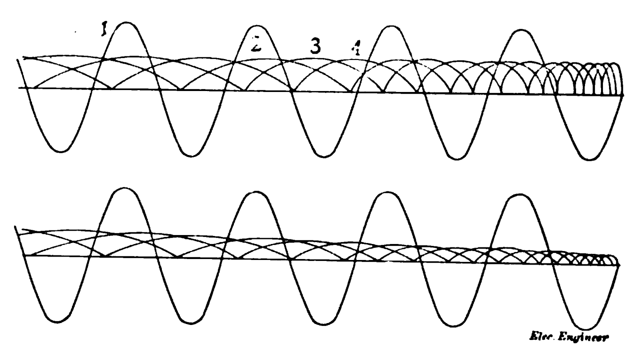
We will take for our present needs Fig. 1, which shows one of the ways in which our system can be operated. A shows the alternate current dynamo; a, a, are the two wires for long-distance transmission; P is a small variable speed alternate current motor which is employed to drive the primary circuit or the sliding contacts upon either of the circuits. The induction director, B, is an extremely useful piece of apparatus with which to deal with alternating currents. It is used to create a difference of potential electrically upon circular rings, H, and then by the proper connection of the circuits with windings upon a field arranged about a motor armature, to create differences of magnetic potential. This establishes poles in the field magnets which can be rotated at will about the armature, either fast or slow, and in either direction, and these poles can be made strong or weak, according to the demand upon the motor.

Another very important feature is the fact that the coils upon field and armature may be connected in series or in parallel, as desired, in order that a very great starting torque may be obtained with a small amount of energy, or that a very great speed may be obtained with a larger amount of energy.

Due to the fact that the points of greatest difference of electrical potential cut or pass through every point of circumference of 360 degrees at a constant average pressure, it follows that the magnetic potential will be of necessity as constant as the cause producing it, and the poles will pass through every point upon the circumference. There will be no position of the armature where it will not be acted upon by the field. There will not be the tendency in these motors to blow out the lines of force in the gap space as do all two-phase, three-phase, and, in fact, all motors of the induction type, in which the slip at starting is determined by the frequency and number of poles about the armature.

With our system the frequency has no relation to this slip, neither has the number of poles; the speed of the induction director controls this slip and allows the reaction between armature and field to be a maximum at all times for a given amount of energy applied.

It will be seen that in any piece of apparatus so designed that the points of greatest potential can be shifted along the length of the electrical circuit or circuits, without cutting the magnetic



FIGS. 2 AND 3.

lines, the frequency will not be changed. In the motors the curve of energy in each circuit will be positive, as it is not reversed, and as many different circuits may be run as are necessary to get the greatest average height. These curves are independent of the frequency which may vary through many cycles, while the energy curves are rising and falling once.

Fig. 2 is a diagram showing the frequency constant and the

energy curves (in this case we have three, indicated at 2, 3 and 4), variable with the speed, the areas showing the way in which the energy varies with the speed with constant e. m. f. (curve 1). With a variable e. m. f. the average height of the power line would describe a curve gradually approaching the zero line as the power required for an increasing speed decreases, Fig. 3, and then when limit of decrease is reached, the power required for a further increase of speed will increase and the power line will be a curve gradually reaching away from the zero line, which is also the base line of the power curve.

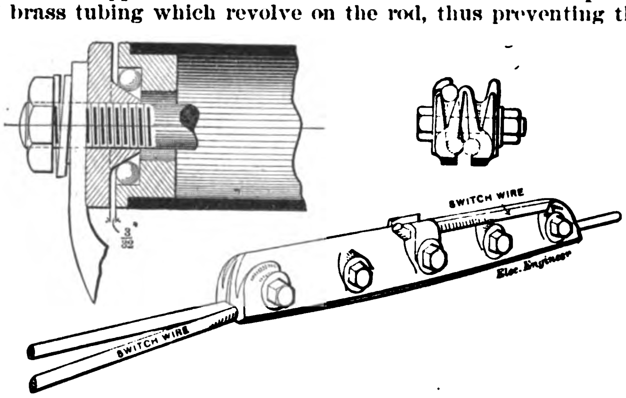
It is to be understood that Fig. 2 is a simple diagram intended to show the principle, not the actual performance, as it would require too much time at present writing to go into details.

THE NEW WALKER TROLLEY WHEEL AND TROLLEY LINE CLAMP.

The new trolley which the Walker Company has recently placed upon the market, a brief description of which was given in our columns last week, promises to be a great improvement over the old grooved wheel trolley. We give below a detail description of the trolley.

Instead of a wheel, this device has a roller 3⅝¼ inches long and 1¾ inches in diameter. This roller is made of seamless drawn steel tubing and is case-hardened. In each end of this tube is a cone made of case hardened steel, opposite which is an adjusting cone also of case-hardened steel. The bearings consist of twelve ¼-inch steel balls at each end of the roller, bearing between the two cones, as shown in Fig. 1. At a speed of five thousand revolutions per minute and a pressure of thirty pounds on the trolley wire, these bearings require no lubrication whatever, thus entirely avoiding the use of oil in the trolley bearings.

Through the roller passes a cold rolled rod which retains the cones in position and supports the roller by means of the ball bearings. The current is taken from the rod by means of small copper brushes which are secured to short pieces of brass tubing which revolve on the rod, thus preventing the



FIGS. 1, 2 AND 3.—THE NEW WALKER TROLLEY WHEEL AND CLAMP.

current passing through the ball bearings, thereby avoiding pitting of the latter due to the small contact surface.

The fork is made of malleable iron into which is fitted two pieces of 1-inch diameter seamless steel tubing which form the support for the rod passing through the roller. The ordinary trolley pole is used. The trolley has no lateral motion whatever, therefore is always parallel with the track, making it impossible for the roller to leave the wire. With this tolley switch plates on the wire are unnecessary.

Fig. 2 illustrates a trolley line clamp which is designed to attach the switch to the main trolley line, making a very substantial and inexpensive junction of the wires. The clamp is made of one piece of cast brass having two grooves running the full length of the clamp to receive the wires, as shown in the end elevation, Fig. 3, the wire slot being wide enough to admit of placing one wire in position and leaving room enough to place the other wire in position without disturbing the wire first placed. Then the clamp is closed up by means of four ⅝-inch bolts as shown in Fig. 2, which brings the two wires in close contact throughout the entire length, the switch wire being turned up over the end of the casting, lying in either groove as shown in Fig. 3; the wire continues to the center, where it passes behind the lug, which is turned down over the wire, thus preventing the possibility of pulling out the switch wire.

The bottom edges of the clamps near the end are rounded off to bring an easy rise from the bottom of the wire to the bottom of the clamp to allow the roller to have free passage under the clamp. This casting has two grooves at either end and two lugs in the center which make it unnecessary to have "rights" or "lefts," and the switch wire may be turned up from either side on either end and held in position as shown. The total weight of this clamp, including bolts, is 8½ lbs.

PROPOSED ELECTRIC TRACTION FOR BERLIN.

A paper was recently read by Dr. M. Kallmann before the Elektrotechnischer Verein, of Berlin, on "The Organization of Street Traffic." The author first drew up a picture of the rapid development of the street traffic of Berlin in the last twenty years, and stated that in the relatively small area of about twenty-three square miles, or about five times smaller than that of London, Berlin with about 1,750,000 inhabitants, has at present over 310 miles of horse and steam tramlines. These are worked by ten different companies. The concession of the largest expires in 1911. All the undertakings are considering at present the adoption of electric traction, and as there are about 33,000,000 car kilometres (20,460,000 car miles) run annually on the existing horse lines, it would take 17,000,000 kilowatt hours to operate the same electrically. The number of persons carried per car kilometre is five. Dr. Kallmann then dealt with the different systems of electric traction, and he comes to the conclusion that practically 90 per cent. of the lines can be arranged on the overhead system, leaving the remainder to be tackled by some other method. On the latter lines there could be employed either a conduit system or locomotives working with accumulators, or a mixed system as used in Hanover. As regards costs, Dr. Kallmann thinks electric traction would reduce the working expenses from 4.4 cts. to 2.8 cts. per kilometre. The cost of converting the lines would be about $5,875,000. If the supply of the current were carried out from one large generating station under the control of the municipality, the cost of energy would not exceed 2.4 cts. per kilowatt hour. As explained in a former necessary mains and feeders. The installers, being thus relieved of the erection of generating stations and cable networks, would be able to quicken the conversion of their lines. The cost of the power stations of a total capacity of 10,000 horse-power, which would be required for the working of all the existing horse lines, is estimated by Dr. Kallman at $1,500,000, and the cost of the necessary cables at $875,000. With a consumption of about 500 watt hours per car kilometre, and a tariff of 2.2 cts. per kilowatt hour, the cost of energy per car kilometre would be 1 cent.

A good idea of the working of a central station for light and power is given by the Hamburg station. According to the returns for 1895 the total number of units generated amounted to 5,500,000, of which about 4,000,000, or about 75 per cent., were used for traction. The total cost per unit generated was 1.58 cts., but it is expected that with the erection of 1,000 horse-power engines this figure will be reduced to 1.4 cts. or 1.3 cts. With a consumption of over 20,000,000 kilowatt hours for all the Berlin tramways the total annual expenses would be from $450,000 to $500,000, which the tramway companies would have to pay to the electricity works.

Dr. Kallmann all through his paper advocates the centralization of electric supply stations and their municipal ownership, and believes this to be a great advantage to electric tramway companies.

ELECTRIC TRACTION IN ROME.

The municipality of Rome has approved a measure compelling the Roman Tramways Company to entirely abolish horse traction and to substitute electric traction on its entire network, urban and suburban; the transformation to be completed within four years. The overhead trolley system will be adopted on most lines, with the Siemens underground conduit in the principal thoroughfares. The work will be entrusted partly to the General Electric Company of America and partly to Messrs. Siemens & Halske, of Berlin. The work is in active progress. The motive power will, it is expected, be derived from the Tivoli-Rome transmission, additional power being transmitted by polyphase currents. We learn in this connection that Messrs. Siemens & Halske have for some time past been making, and successfully using, shunt-wound motors for electric traction purposes at Halle, and these will probably be used in Rome. In the new motors the field is so

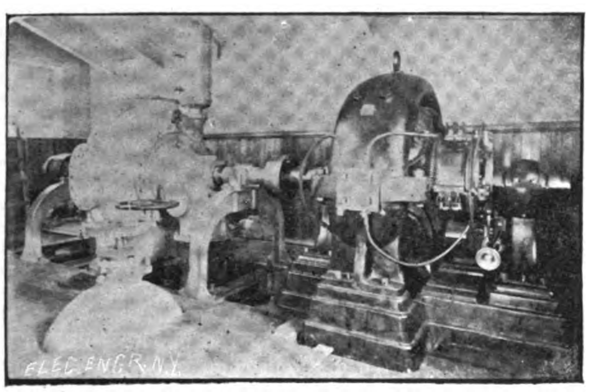
massive and the magnetism is so strongly retained after interruption of the exciting circuit, as to entirely do away with any evil consequences resulting from momentary interruption of the current. The cost of the shunt-wound motors is, however, some 15 or 20 per cent. greater than that of the usual series-wound ones.

POWER TRANSMISSION.

ELECTRIC POWER IN THE CLIFF PAPER MILLS, NIAGARA FALLS.

Several months ago we described the double use of the waterfall at Niagara in the mills of the Cliff Paper Co., first at the top of the cliff and again at the bottom near the lower level of the Falls, 250 feet below.

Greatly encouraged by the results obtained, the company recognized the fact that they could generate electric power very cheaply, and so, at the rear of the pulp mill they excavated back into the slope of the bank a sufficient distance to allow of the erection of a building 25 feet wide and 30 feet long for a generating room, and it is there that the new electrical plant has been installed. This plant, which went into operation on July 10, consists of two 150 horse-power generators made by the Card Electric Company, of Mansfield, O., and installed by F. W. Oliver Company, of Niagara Falls; they are attached direct to a 300 horse-power horizontal turbine made by James Leffel & Co., of Springfield, O., the



GENERATING UNIT, CLIFF PAPER CO., NIAGARA FALLS.

combination being illustrated in the accompanying engraving. The ordinary speed of the generators is 650 r. p. m., but they are so designed that they can be run at 800 r. p. m., if desired. The generators can be run single or in multiple, or either or both machines can be disconnected from the water wheel. The switchboard used in connection with them was designed and built by the Oliver Company.

The current is carried from the generators on 300,000 c. m. rubber covered cables up through the elevator shaft to the motor room situated on one of the lower floors of the paper mill. These motors will be three in number, two being of 100 horse-power each and one of 12 horse-power. The motors were made by the American Engine Company, of Bound Brook, N. J. Only one of the 100 h. p. motors has been installed so far, but the other is expected daily. These large motors will be used in operating the two Foudrinier paper machines while the small motor will run the machine shop connected with the mill. The water supply for the turbine which operates the generators is taken from the eight-foot penstock of the pulp mill through a 36-inch connection running under the floor of the new generator room and connecting with the Leffel turbine. This supply for the wheel can be shut off by means of a valve so as not to disturb the pulp mill supply. The two draft tubes from the turbine meet and extend as one through the wall of the pulp mill into the tailrace. Steadiness of motion is obtained by a Replogle governor..

In the matter of power the Cliff Paper Company's plant is thoroughly well equipped, for it has water, steam and electric power. The new electric plant will do away with the use of steam to the extent of 250 horse-power, and they anticipate a saving both in the matter of repairs and in their coal bill. For the time being they will continue to use steam in their drying machines, but it is probable that the future will see electricity occupying this field also. The present output of the Cliff mills is 25 tons of paper and 30 tons of pulp a day.

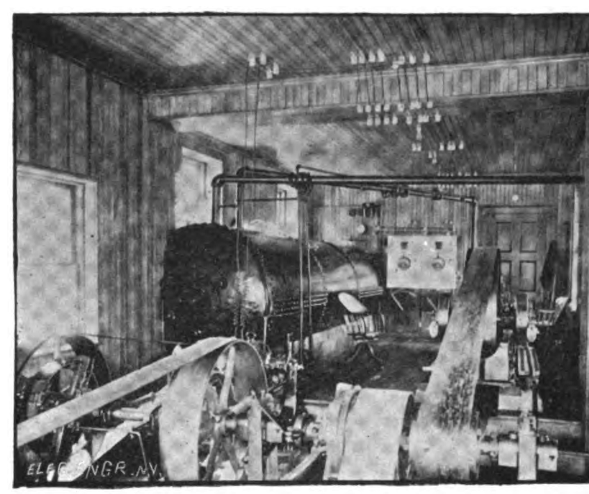
The power for running the mill plant is obtained from the Niagara Falls Hydraulic Power & Mfg. Co.

A DRAWBRIDGE OPERATED ELECTRICALLY AT UTICA, N. Y.

The bridge over the Erie Canal on Genesee street in Utica, N. Y., had for some time been the cause of much inconvenience to residents of that city and the canal officials, by reason of its irregularity of operation, until the method now in use was resorted to.

As originally planned, the bridge had one stationary center span and two lifts, one on each side. Each lift was to be raised by a 15 horse-power electric motor, carried on the lift and operating a vertical screw on the principle of the common screw jack, but this plan was abandoned when it was found to require about 75 horse-power on each lift to raise it. Compressed air was substituted by placing two cylinders under each lift and attaching their pistons thereto. An air compressor was located in the old weigh-lock building about a block distant and was operated by a turbine wheel taking water from the canal. This plan was only a partial remedy and during the periods of low water in the canal the bridge had to be "hung up," as the air compressor could not run.

To overcome these obstacles one of the 15 horse-power mo-



BRIDGE-LIFTING PLANT AT UTICA, N. Y.

tors which had been on the bridge was temporarily belted to the compressor late last season. This was found to work very satisfactorily, and in the spring an addition was made to the weigh-lock building and a permanent installation of the two motors was made by Messrs. Nightingale, Johnson & Co., of Utica, under the direction of M. H. Johnson, as shown in the accompanying engraving.

The installation consists of two 15 horse-power, 500-volt Thomson-Houston series motors and a 20-inch turbine water-wheel belted to friction clutch pulleys on a shaft which is also belted to a compound Norwalk air compressor. A white marble switchboard stands at one end of the room with the instruments, switches and regulating rheostats on it, and this, with a small circular pump and 72-inch by 18-foot air receiver, completes the equipment.

The bridge is normally operated by air at 260 lbs. pressure and no difficulty or hitch has been experienced in its operation since the installation was completed. This is quite a model plant in all details and is an instance of the great flexibility of electricity, as, after being abandoned in the first instance, it was again resorted to as the only means of procuring reliable and economical operation.

MR. J. W. BRAID has been appointed chief of the Electricity Department of the Tennessee Centennial Exposition. He has had a room fixed up in one corner of the Minerals and Forestry Building, and there he has a force of men preparing electrical fixtures for use hereafter. Particular stress is being laid on this department by the management of the exposition.

TELEPHONY AND TELEGRAPHY.

MR. DELANY ON GOVERNMENT TELEGRAPHY.[1]

IT is a curious fact that while great improvements have been made in telegraphy, and notwithstanding that telephony has come and covered the earth with its wires within the past twenty years, the arguments put forward against postal telegraphy have not changed in the slightest degree.

It is significant that none of the improved methods of telegraphy now in use originated within the controlling telegraph organization, all having come to it by purchase of competing lines, or from individuals outside. I refer to these matters because the opponents of government telegraphy have invariably advanced the argument that government control would discourage invention and improvement in systems. With the exception of its own Wheatstone system, all the great improvements used by the British post office are importations.

According to the report of the British Postmaster General for the year ending March, 1895, 66,189,000 messages, averaging 15 words each, were transmitted at an average cost of 15 cents, and, in addition, there were transmitted 5,400,000 press dispatches, averaging 120 words each, at a cost of 9 cents, or nearly 14 words for a cent. Nor is this all. There were 1,600,000 railway messages, averaging 25 words in length and representing 25 cents in value, transmitted free.

The press rate in this country averages about one-half a cent a word.

Now, as the deficit for 1895, in England, including interest account, amounted to a little over $2,500,000, it will be evident that had the free messages been paid for at regular rates and press dispatches paid for at a rate bearing the same proportion to the regular rate that such dispatches are charged for in this country, the British telegraphs would show a good balance of profit. In 1870, when the government took control, the business amounted to but 7,000,000 messages, an increase of more than tenfold in twenty-seven years, while the rates have been reduced from a maximum of about 4 shillings to a uniform rate of 6 pence.

The British operator has had two increases of pay since 1881, while his American brother has had four reductions, and to-day the British operator is better paid for the same amount of work, and by his environment occupies a higher plane of comfort and contentment, than the American operator. Good behavior and diligence in his duties warrant him a life position, from which the whim or caprice of none can drive him. His increasing years of service are taken into account in various beneficial ways. He has his yearly vacation. He is not cut off in sickness, and, most important of all, he is not "turned down" in old age, but is retired on a pension, proportioned to his years of service. I can not conceive of a stronger incentive to a government system of telegraphy in this country than the example of thorough efficiency and success presented by the British post office.

No telegraph operated by the government in any country is conducted with a view to pecuniary profit. The aim is to spend all surplus earnings in improvements and extensions, and if none are necessary, then a surplus is prevented by a reduction of charges.

No one acquainted with the executive officers and heads of departments of telegraphs in this country can charge them with incompetency or lack of clear vision. They are experienced and able officials, familiar with all the details of their business. It is, therefore, strange that the wealthy few who control and dictate the policy to be pursued have not deferred more to the opinions of these managers, and been satisfied with a slower inflation of their shareholdings. The ability to so manage a vast concern as to earn dividends on a capitalization at least double what it should be, and this in times of great depression in business, commands admiration, but surely the wealthy owners have cut out a hard task for these men. They have been so hampered as to warrant the conclusion that the most primitive methods were the conditions most desired, and that difficulties in the way of cheap telegraphy should always be encouraged in order to maintain a great discrepancy between the cost of sending a message by wire and one by train. It has always seemed to me that the natural desire for great profits could have been met much better by a policy of encouragement of improvements, warranting cheaper rates and insuring an increase in business which would more than compensate for the reduction in charges. I doubt very much whether telegraphy could be carried on any cheaper by the government than it is now conducted by the companies if the same methods of operation are to be retained. Expertness of the operator has reached its highest development. Machine methods are as old as hand manipulation, but in this country they have not been used to any considerable extent and their development taken advantage of. A wrong start has been adhered to persistently, owing in a great measure to overconstruction of competing lines and multiplication of wires; and so long as one company gathered all the others in as fast as they came along, there were wires to spare, and therefore, as those in control argued, there was no use for increasing speed. Besides, wires afforded a basis for stock issuing. If this convenient mine could have been ignored, it would have paid the companies much better to have abandoned the poorly constructed lines and concentrated traffic on a comparatively small number of well-constructed lines of high conductivity operated by machinery. The companies can hardly be blamed now for not taking down thirty poor iron wires and putting up one good copper conductor in their stead, even though it is now entirely practicable by machine working to make the single wire carry more messages for average distances than the thirty hand-worked wires, even when quadruplexed, so that four messages may go simultaneously.

The argument of those whose interests compel them to defend them by disparagement of improvements, which must surely render their great network of wires unnecessary and useless, is that machine working would be slower than hand working. With plenty of wires, no practical telegrapher will deny that a single short message can be sent by hand in the same time that it takes to perforate or prepare it for transmission by the machine system. The average layman is by this fact frequently deceived into grave error and by not pushing the comparison further. If the message be a long one, or if there are a thousand messages to transmit, it might take two days to get them off by hand, whereas, if there are a sufficient number of perforators, the whole lot could be transmitted in a few minutes. A perforating operator will prepare messages at the same rate of speed that a Morse operator can transmit them by hand, and a transcribing operator will typewrite them as rapidly as a sound-reading operator can receive, while the machine transmitter will send the dispatches as fast as 70 to 170 perforators can prepare them, or afford on an average, according to length of circuit, the same carrying capacity as 70 to 170 circuits worked by the present Morse system. One man could send them as fast as seventy men could prepare them.

Mr. Chairman, without machine transmission, government telegraphy, under the provisions of this or any other bill would not be practicable, and the rates stipulated may be seriously questioned on the basis of present hand methods of operation. In expressing this opinion I have no fear of contradiction from any disinterested telegrapher. I do not think that any government management could possible conduct a telegraph service on a cheaper basis at the present capitalization and by the present methods than it is now conducted, without the use of a machine system.

Twenty years ago the highest average of transmission over a single wire was, by the quadruplex system, about fifty words per minute; the telephone was only thought of for local use over distances of a few miles. Now it is practicable to telegraph 2,500 words a minute between Washington and New York, and 1,000 words a minute between New York and Chicago, while the telephone carries speech 1,500 miles.

The Wheatstone system has an average of about 150 words a minute. The English Wheatstone system is used between New York and Chicago. The average by hand is about fifty words a minute. In view of what has already been done, I do not think that any telegraph electrician will dissent from these propositions: That with machine transmission and chemical recording by the method referred to, over a copper wire weighing 850 pounds to the mile, and with an ordinary current power such as is used for quadruplex working, 1,000 words per minute can be plainly recorded over a distance of 1,000 miles, or, say, from New York to Chicago, and that over such a line 2,500 words per minute can be plainly recorded from New York to Washington and between other points throughout the country in the same ratio, according to distance. Last October, over an actual line, having but 130 pounds of copper to the mile (Philadelphia to Harrisburg and return), 216 miles, 940 words per minute were plainly recorded in dots and dashes, the current used being but 120 volts. This trial was conducted in the presence of a board of well-known electrical experts. With this system 8,000 words per minute have been recorded over an experimental line.

Here Dr. Delaney submitted estimates of cost and earnings of a line of two 1 ohm per mile copper wires between New York and Chicago operated at 1,000 words per minute.

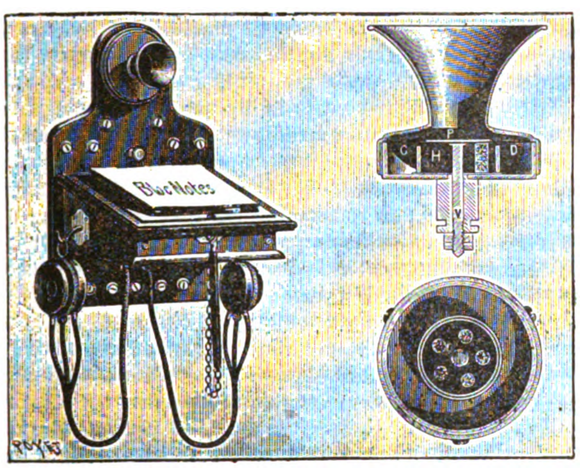
I think generally, with reference to my experience in regard to this matter, that $25,000,000 applied to wires such as I have described in this statement would give greater facilities for carrying telegraph dispatches in this country than is now furnished by the wires of the Western Union Telegraph Company. It might not reach all the small offices now reached by

[1] Abstract of Argument before U. S. Senate Committee.

the Western Union Telegraph Company, but it would cover the large points which would take more than three-fourths of the traffic. I am unable to understand why Congress has not long ago authorized the Postmaster General to fix a maximum rate for telegraphic letters, and contract with the lowest bidders for their transmission, especially between cities separated by any considerable distance.

THE BLOC-NOTES TELEPHONE.

We illustrate in the accompanying engraving the "Bloc-Notes" telephone, which is shown complete at the left-hand side of the engraving, and also the microphone which is shown in detail. This belongs to the granular carbon class of instruments and is composed of a small carbon cylinder, H, which is perforated by five channels filled with granular carbon. This cylinder is insulated from the metallic case forming its exterior envelope by a sheet of mica. A strong screw, v, provided with two nuts, fastens the cylinder against the bottom of the box. The vibrating plate, CD, of very thin carbon, is held in place by the outside cover to which the speaking trumpet is attached. This plate is then adjusted in such a manner as to be in contact with the granules of carbon contained in the holes of the cylinder, while the latter, on the contrary is insulated from the plate.



THE "BLOC-NOTES" TELEPHONE SET.

With the apparatus thus constructed the current enters by the screw, V, and passes by way of the cylinder, the granules, the vibrating plate, and goes out through the body of the metallic case.

The packing of the granules cannot take place. It is very easy to displace them and to give the microphone its original sensitiveness by simply turning the apparatus around upon its axis. The dismounting is done with equal facility.

It remains to mention the receivers, which are very light. They weigh scarcely 180 grammes. Each is fixed by a special attachment independent of the conductors, which are thus relieved of all strain.

Models of this instrument have been in use in the Central Telephone Exchange, in Paris, for three years, where they have given excellent service.

DIFFICULTIES OF CHINESE TELEGRAPHY.

According to the "Statesman's Year Book," all the principal cities of China are now connected with one another and with Pekin, the capital, by telegraph. Recent visitors to China say, however, that telegraphing there is a laborious and an expensive process.

The Chinese have no alphabet, and their literary characters number many thousands, so it is simply impossible to invent sufficient signals to cover the written language. This difficulty was obviated by inventing a telegraphic signal for each of the cardinal numbers, and so numbers or figures might be telegraphed to any extent. Then a code dictionary was prepared, in which each number from 1 up to several thousands stood for a particular Chinese letter or ideograph. It is, in fact, a cipher system. The sender of the message need not bother himself about its meaning.

It is very different with the receiver. He has the code dictionary at his elbow, and after each message is received he must translate it, writing each literary character in place of the numeral that stands for it. Only about an eighth of the words in the written language appear in the code, but there are enough of them for all practical purposes.

Men of ordinary education have not sufficient acquaintance with the written language to be competent telegraph receivers, and the literati are not seeking employment in telegraph offices any more than our college professors are. So the government recruits its employés with much difficulty.

There is another great disadvantage in the Chinese telegraph system. All over the world the movement of railroad trains are regulated by telegraph. Railroads have been introduced into China to a very small extent, and there is talk of greatly extending the service. But how about running the trains?

The Chinese Government will not take foreigners into its service, and the educated men of China, who alone among the people have sufficient knowledge of the written language to be intrusted with the actual running of trains, would refuse most emphatically to be either train hands or station agents.

THE OFFICIAL CABLE CODE NOT COMPULSORY.

The International Telegraphic Convention sitting at Budapest has finally decided not to compel the use of the official vocabulary for cablegrams in code to and from countries beyond Europe, known as extra-European business, in which, of course, is included the United States.

Protest against the compulsory use of the vocabulary was made by the representatives of the British Government, supported by similar protests from various commercial exchanges of the United Kingdom and of the United States, presented by representatives of the transatlantic cable companies. This result was brought about by the joint movement of the interested telegraphic administrations and companies.

ASSESSMENT OF THE N. Y. AND N. J. TELEPHONE CO.

The application of the New York and New Jersey Telephone Company for a reduction of the assessment valuation of its personality was considered last week by the Brooklyn, N. Y. Board of Assessment and Assistant Corporation Counsel Rollin C. Breckinridge. The valuation has been fixed by the Board at $641,000 and the company claims that it should be reduced to $387,000. Henry Sanger Snow, treasurer of the company, submitted statements in support of the application. The company strikes out from its taxable assets $845,000 invested in patents; $307,000 of capital stock not paid in on May 30. It includes in its debts accrued taxes including the expenses of the subway commission. It includes in the debts certain trust funds, dividends deposited in trust, and also an item of several thousands of dollars to the credit of an unknown stockholder. It seems that there are some shares of stock which have been sold, but the owner is not to be found, and the company has deposited in a trust fund the moneys and dividends upon the stock, and deducted them as a debt. Those items are not included in the gross assets.

THE INTERSTATE LOCAL TELEPHONE ASSOCIATION.

This association now includes in its membership a network of exchanges in West Virginia, eastern Ohio and western Pennsylvania, twenty-five in number, with about 15,000 instruments and subscribers. These towns have been admitted to membership: Youngstown, O.; Sistersville, W. Va.; Richmond, Va.; Indiana, Pa.; Steubenville, O.; Greensburg, Pa.; Apollo, Pa.; Zanesville, O.; Altoona, Pa.; McKeesport, Pa.; Carnegie, Pa.; Braddock, Pa.; Johnstown, Pa.; Latrobe, Pa.; Blairsville, Pa.; Mercer, Pa.; Wheeling, W. Va.; Newark, O.; Barnesville, O.; Bellaire, O.; Fairmont, W. Va.; Mannington, W. Va.; Grafton, W. Va.; Wellsburg, W. Va.; Martin's Ferry, O.; Bridgeport, O.; Pittsburgh, Pa.; Allegheny, Pa. The last meeting of the ways and means committee was well attended and all the members of the committee were enthusiastic for success.

The McKeesport company has been in operation since 1890, has made a 50 per cent. cut in the rates that prevailed before, and is paying a dividend of 20 per cent. Last week the Youngstown company ordered 500 additional telephones; it will make a 42 per cent. reduction in existing rates in the Ohio town, and expects to be able to pay a 25 per cent. dividend. The independent company organizing in Pittsburgh expects to start with 500 telephones.

CONTENTS.

THE NORTHWESTERN ELECTRICAL ASSOCIATION.

The report of the meeting of the Northwestern Electrical Association, which we print in this issue, is most gratifying evidence of the vitality of that association, and more particularly of the necessity of similar associations in every State of the Union. The unscionable work of so-called "parent companies," whose actions have in the past been anything but of a parental nature, have long since forced upon local companies the necessity of protecting themselves from unwarranted competition, and latterly the municipal plant craze has well-nigh filled to the brim their cup of bitterness. It is just such local associations as the Northwestern that can by the gathering of statistics and intelligent co-operation of its associated companies prevent the establishment of competing municipal plants. It will require, indeed, a hard campaign of education to counteract the present populistic tendencies, but we are convinced that sufficient material is already at hand to make such a campaign effective. At this convention Mr. Beggs again inveighed broadly against the usefulness of the National Electric Light Association, if anything, more strongly than he did at the late meeting in New York. We do not at all agree with Mr. Beggs' views in this respect. The N. E. L. A. has a mission quite as useful and far broader than any mere local organization can fullfil. We need only cite as a single instance its "Wiring Rules," which have become the model on which the rules of the National Board of Fire Underwriters are based, and which, indeed, they have appropriated almost bodily, albeit without due credit. No local organization or any number of them could have accomplished this work, of such enormous import to all local companies. As to some of Mr. Beggs' individual criticisms, they are not to be laid at the door of the Association, as such, but to its management. Possibly more good could have been done in the past if the officers and committees appointed for the purpose had given more of their time to the business of the association. We believe, however, that this remissness has been recognized, and that henceforward a more active participation in the work of the Association will be noticeable on the part of those responsible for its management. It would,indeed, be a pity if an organization embracing representative companies over the entire Union should have lost its reason for existence after having performed yeoman service in welding together many heretofore conflicting interests, and by its very presence acting as a check to many threatened aggressions of the "parent companies" in the past. By all means let the organization of State associations continue, but let the National Electric Light Association continue as the mentor, and, as it were, the clearing house of them all.

GOVERNMENT TELEGRAPHY.

NATIONAL legislatures throughout the world generally have some sort of perennial proposition to deal with—something that is always downed, but never dies. In England it has long been the "Deceased Wife's Sister" act; with us it is postal telegraphy. One is opposed by the bishops for no apparent good reason, the other by the life peers of existing enterprises from motives that are plain enough. But while the sister-in-law measure was fought out in the upper house with great earnestness, every year, and has at last been crowned with success the blessings of postal telegraphy have, with one or two exceptions, been but lukewarmly supported in either branch of Congress. Postal telegraphy has been vicissitudinous from the very beginning, when Cave Johnson in the House of Representatives, in 1843, met the proposal for an appropriation of $30,000 in aid of Morse's patent, by an amendment providing that half the amount asked for should be spent in the investigation of mesmerism, and no better evidence of the early tendency of postal telegraphy to mutative traits could be wished for than was afforded by this fine old scoffer, when, as Postmaster General, a few years later, he made a most vigor-

ous protest against the transfer of the few miles of line then in operation from government to private control. Reference to a few extracts from an argument by Mr. Patrick B. Delany, before the Senate committee on post offices and postroads, just prior to the adjournment of Congress, which we print on another page, may not convince everybody of the soundness of State paternalism which it is proposed to apply to telegraphy, but there can be no doubt that this question has been lifted out of its usual state of flabby inanition and has taken a new lease of life which promises to keep it in the front rank of activity until it is permanently disposed of, one way or the other. In a few words, Mr. Delany has foreshadowed more discomfort and worry for telegraph and telephone interests than all the academic platitudes of previous impractical advocates of postal telegraphy. Mr. Delany says he cannot understand why Congress should not authorize the Postmaster General to fix a maximum rate for telegraphic letters between cities, and contract for their transmission with the lowest bidder. This is a most disquieting suggestion, entirely out of harmony with the calm security heretofore extractable from the customary request for a large appropriation of money by the government for construction of lines. It is indeed hard to see how goldbug, silverite of populist can find valid objection to a proposition for quickening the mails in the ratio that the speed of electricity bears to that of steam, so long as the price is sufficiently low, and the government is not asked to spend a dollar. Nor is this all the torments hinted at in Mr. Delany's argument. He thinks it would be a good thing to compel telegraph companies to note on each message delivered the time of filing at the place of its origin, as is done in other countries. This must be viewed as the refinement of cussedness by the owners of systems which have guarded this knowledge as a needless requirement and placated public longing for precise detail by marking on each message the time of its arrival. This has enabled the public to keep compassionless tab on the messenger boy in his wanderings, but left to the widest range of speculation any estimate of how long the message has been on the way.

We are no more in favor of government telegraphy than of municipal control of electric lighting stations, but it would be closing one's eyes to patent facts to ignore the force of some of the contentions put forward by Mr. Delany. That the present systems of telegraph and long-distance telephone lines are not worked to anything like their full capacity during the twenty-four hours of the day, is self-evident, and the proposition for the government to contract for their utilization during "light load" hours is one worthy of the most serious consideration. Presented in this way the project has at once removed from it the objections and dangers of a government monopoly and places the telegraph and telephone companies on the same footing as the railroads occupy with respect to the Post Office Department. Far from opposing such a scheme, we see no reason why the telegraph companies should not welcome so large an certain an increase in their present volume of business.

GERMAN CENTRAL STATION STATISTICS.

WE have in the past pointed out the thoroughness of the published statistics on German central stations, from which much useful information may be gleaned. The most recent of these is due to the labors of the "Vereinigung der Vertreter von Elektricitätswerken," an organization composed of the representatives of central stations. These statistics, although they cover only thirty-six stations, are nevertheless of more than usual interest, as they cover details not touched on in any others of like nature which have come under our notice, due, no doubt, to the minute care bestowed on them and their absolute trustworthiness. Of the thirty-six stations embraced in the statistics, eighteen are under municipal management. Considering conditions in Germany, where the tendency toward government control is very strong, this is not a very high figure. The prices at which light and power is furnished vary widely. To private customers the figures range from 8¾ to 22 cents per kilowatt hour, while current for power is furnished from 4½ to 10 cents per kilowatt hour. These figures, which are higher than those in the United States, are of still greater importance, considering the fact that 10 cents in Germany go a great deal further than they do here, in most cases. The reason probably lies in the greater economy with which the Germans utilize their circuits. To illustrate our meaning we may take the case of the Edison Illuminating Company, in New York City. Reducing their entire system of incandescent lamps, arc lamps and motor service to a basis of incandescent lamps, this company have an equivalent of 485,000 lamps on their system. The average utilization of this entire number is about 1½ hours per day. If all their customers were more economical, possibly as economical as the Europeans—where the load lines at 10 o'clock in the evening show that the majority of the inhabitants have retired or where people find an inherited delight in sitting in the twilight, thus postponing the rise of the load line in the central stations—the average utilization of the New York Edison Company's current would probably go not much above one hour. In that case, the prices would necessarily have to be higher, since the fixed charges would not change appreciably.

Twenty-five out of the thirty-six stations have accumulator plants in connection with their system, an enormous percentage from our point of view, especially in view of the fact that seven of the remaining plants utilize alternating current. The total number of cells installed is 6,780, with 63 cells as the lowest and 544 cells the highest number in any one station. The total capacity of these in kilowatt hours is 13,509 with 475 kilowatt hours capacity in the smallest, and 1,746 kilowatt hours in the largest installation.

The number of customers supplied in twenty-eight out of the thirty-six cities is 11,644, in which Vienna with 2,708 is included.

One table gives the losses in accumulators, transformers and network in per cent. per year, some of which are worth noting. In one town, Neuhaldensleben, the total losses are 40 per cent., 20 per cent. being in the accumulators. It has a three-wire system, with distribution on wood on poles. One hundred and thirty-four storage cells are installed in this station, with a capacity of 101 kilowatt hours and two shunt dynamos, with 76 kilowatt capacity, as generators. The total number of customers is 128, using 2,900 incandescent and 36 arc lamps. The average utilization per kilowatt is 28 hours per year. Comparing this with the station showing the smallest losses: Elberfeld, with a three-wire system with iron armored cables laid underground, has no accumulators, but twelve dynamos with a total capacity of 660 kilowatts. The average utilization for every kilowatt furnished is forty-nine hours per year. The total number of arc lamps supplied by thirty towns is 20,181, the number of incandescent lamps being 328,913. It is again interesting to compare this latter figure with that of the Edison Illuminating Company in New York, which supplies 240,000 incandescent lamps at the present time. All figures presented thus far appear extremely low as compared with those covering like points in this country, but it should be considered that Berlin is not included in this list. In looking over the data on drop along the mains we find remarkable uniformity. In the three-wire systems the drop varies from 1½to 3 volts per side, while a few stations give figures varying from 2 per cent. to 3 per cent. Another question of preeminent importance is the cost of the feeders and mains in comparison to the current furnished. The weight of the copper varies from 4.95 to 24.7 kilogram per 100 watts, an average of 10.05 kilograms. This applies to the direct current installations. In the alternating current plants the weight of copper is on an average 4.31 kilograms per 100 watts delivered. Finally, the statistics show that one kilogram of coal will supply on an average 271 watt hours, varying from 70 to 493 in the various plants. The average yearly increase for current furnished is over 43 per cent., which shows the constant growth of the German installations.

SOCIETY AND CLUB NOTES.

FOURTH SEMI-ANNUAL CONVENTION OF THE NORTH-WESTERN ELECTRICAL ASSOCIATION, HELD AT MARINETTE, WIS., JULY 15-17, 1895.

THE convention was called to order by the president, Mr. W. B. Baker, of Waupaca, Wis., at the courthouse, at 9 a. m.

The secretary called the roll and the following members answered to their names:

Active Members—W. A. Baker, Waupaca, Wis.; A. O. Baker, Sheboygan, Wis.; W. P. Bragg, Monroe, Wis.; A. C. Bunce, Milwaukee, Wis.; Loren W. Burch, Madison, Wis.; Chas. Cuno, Oconomowoc, Wis.; Ed. Daniel, Menominee, Mich.; Fred DeLand, Chicago, Ill.; G. W. Hanley, Marinette, Wis.; J. H. Harding, La Porte, Ind.; H. C. Higgins, Marinette, Wis.; P. H. Korst, Racine, Wis.; R. F. Kountz, Neillsville, Wis.; I. P. Lord, Waupaca, Wis.; T. R. Mercein, G. S. McLaren and E. G. Mullen, Milwaukee, Wis.; C. C. Paige, Oshkosh, Wis.; G. B. Wheeler, Eau Claire, Wis.; O. B. Williams, Whitewater, Wis.; L. E. Kerns, Madison, Wis.

Associate Members—C. O. Baker, F. N. Boyer, H. D. Latimer, W. W. Low, Geo. Whyte, Chas. E. Wilson and James Wolff, all of Chicago.

Corporation Members—Crouse-Tremain Carbon Company, Fostoria, O.; DePere Electric Light and Power Company, De-Pere, Wis.

PRESIDENT'S ADDRESS.

The president remarked that the benefits derived from the semi-annual convention of central station managers, as well as supply men working under nearly the same conditions, had been felt by all who had attended, and that the association would soon be a power that would be felt beyond their limits. A gentleman recently remarked that while the Northwestern Electrical Association could learn from the National Association, on the other hand, there were many things that their little association could teach its superior.

Within the past month he had received two letters from gentlemen in different parts of the State, asking if the association could not come to their rescue. The situation in one case was this: In one of their cities the only lighting plant in the place was furnishing street lights to the city; the city desired to operate its own plant, but not being in a position where it could bond itself for building the plant, it was attempting to make arrangement with parties, to build a plant and bond it and float the bonds and turn the plant over to the city at a nominal figure of one dollar, subject to the bonds.

The president also suggested that the secretary keep a record of the rates charged in each city within their limits, so that whenever a member desired information regarding rates in other places he had only to write the secretary and obtain the necessary statistics. Reference was also made to the insurance question.

The secretary then read the secretary and treasurer's report.

Mr. Lord, of the legislative committee, reported progress. There had been no session of the legislature since the last meeting; there would be one the coming winter, when they would try to do their duty.

Mr. F. DeLand ,of the programme committee, reported pap rs as follows: "Rights of Electrical Companies," by W. Clyde Jones, of Chicago; "The Insurance of Electrical Plants," by R. H. Pierce, of Chicago; "Insurance," by C. C. Paige, of Oshkosh, and discussion on that subject by Wm. H. Merrill, of Chicago; "The New York Convention and Exposition," by Thos. R. Mercein, of Milwaukee; "Alternating Current Motors," by Prof. D. C. Jackson, of Madison; "Lightning Arresters," by W. R. Garton, of Chicago.

Mr. Paige, chairman of the insurance committee, reported that no meetings of the insurance committee had been held, but that he expected to meet the full committee here, and that they would probably later get up some report and recommendations. He had prepared a short paper on the subject which would recommend some action in that direction.

Mr. Hanley, of the entertainment committee reported on the entertainment provided for the members, including a trolley car trip to Lakeside, a dance at the Oakwood Beach Club, a trip to Menominee and a banquet at the Hotel Marinette.

The committee on reclassification of membership reported that it was not yet ready to present a formal report.

The committee on resolutions submitted drafts of resolutions on the death of Messrs. Hall, Gunderson and Sullivan, which were adopted.

The following applications for membership were presented: Henry L. Doherty, general manager Madison G. & E. Co., Madison, Wis.; H. M. Kellogg, superintendent municipal plant, Adrian, Minn.; Foree Bain, consulting engineer, Chicago; G. E. Fish, Little Rock, Ark.; G. M. Sanborn, electrical contractor, Indianapolis, Ind.; S. E. Christie, traveling salesman Dearborn Drug and Chemical Works, Chicago, residence Racine, Wis.; C. E. Van Bergen, secretary Hartman General Electric Company, Duluth, Minn.; A. A. Cross, general manager Superior Light and Power Company, West Superior; R. J. Randolph, Excelsior Electric Company, Chicago, Ill. The gentlemen named were duly elected.

The paper by Mr. W. Clyde Jones, on "The Rights of Electrical Companies," was read, in the absence of Mr. Jones, by Secretary Mercein.

The paper on "Insurance of Electrical Plants," by R. H. Pierce, was read, in the absence of Mr. Pierce, by Mr. Cutter.

Mr. Merryman, vice-president of the Marinette Electric Light and Street Railway Company, was introduced to the association and inquired as to the feasibility of transmitting energy from different sources varying from three to fifty miles distant.

Mr. John I. Beggs, of Cincinnati, suggested the employment of a competent engineer to determine the question.

He was at the present time unfortunately trying to hold up a plant located by one of the best engineers of this country, where they are considering the advisability of spending a million dollars to build a new plant, notwithstanding the plant in question had only been built five years. There was no excuse for the blunder in wrongly locating this plant; but for the reason that factors which should have been taken into account carefully were not at all considered, they found themselves in this predicament. The engineer looked at the site, thought that would be a good place to install an electric light station, and so they, following his advice, sunk one and one-half millions of dollars! He did not suggest that an engineer tell them whether it was profitable to build the plant—the business man must decide that—but to get the engineer to make the calculations as to the cost of copper, how much one would lose in transmission, etc., questions of that kind; then they should apply his calculations commercially. The technical part was the least part, yet it was very essential.

Before adjourning the president invited all to look over the articles exhibited by the electrical supply men in an adjoining room. The president also stated that he had had handed to him a list of twenty-eight towns in the State of Illinois, giving their population, number of lamps used and other statistics.

Mr. DeLand referred to the work compiled by Mr. W. J. Buckley, honorary member of the Northwestern Electrical Association, the subject of which book is electric lighting plants. This book showed the prices up to a year ago. A new edition was now being gotten out which would show rates to the beginning of the present year.

Mr. Kountz thought that the information in the book would not be entirely satisfactory to them, because the cities were located all over the Union, while the association was composed mainly of men in Wisconsin, Michigan and contiguous territory. He should like to get information particularly regarding their own territory, especially Wisconsin.

A suggestion was made that traveling salesmen could assist in obtaining this information if they were furnished with blanks, and that they could without much trouble to themselves obtain statistics which were desirable from the plants as they visited them on other business.

Mr. DeLand offered to present a copy of Mr. Buckley's book to the secretary.

Adjourned to meet at the same place Thursday, July 16, 1896.

THURSDAY'S PROCEEDINGS.

The president called the meeting to order and Mr. Hanley offered a motion covering penalties for non-payment of dues. Five new members were also elected.

A paper was then read by Mr. Mercein on the subject of the New York N. E. L. A. Convention and exposition, which was received with great applause.

The next paper read was that on "Alternating Current Motors," by Prof. D. C. Jackson, of Madison, read by Mr. Cutter.

Mr. J. I. Beggs, being called on to discuss Mr. Mercein's report on the N. E. L. A. meeting, said that he had challenged the National Electric Light Association to show a single thing that they had ever done for the benefit of central stations; he still held that challenge open. If the central stations of this country would stand united together, there would not be so much effort made by the representatives of manufacturing companies to exploit municipal plants. The first seeds in these cases were usually sown by some over-zealous representative of some manufacturing company producing apparatus. (Ap-

plause.) He defied any man throughout all this Northwest to say that the Edison General Electric Company under his management ever attempted for the purpose of selling apparatus to exploit an opposition company. He did not know of a single thing that was done by the National Electric Light Association at its recent session in New York City, that would interest any representative of a local central station here or anywhere else in the United States. Most of the papers read, as Mr. Mercein had well said, were too technical and too high flown for practical application. What was wanted was the practical talk of men who were dealing with conditions as they arose day in and day out.

"I have come here at great personal inconvenience, and it has taken two days for me to reach here, because, in the first place, I was very much interested and pleased with your annual meeting that I was fortunate enough to be able to attend in Milwaukee six months ago, and I was so much impressed with the earnestness of this association and the work that it was capable of doing, and in the second place because of my interest in central station business. As you know, I have had experience on both sides, and still have, yet I do not hesitate, no matter with whom I may come in conflict, to say that we should stand together to show to manufacturers of apparatus that their interests lie in allying themselves with central station people."

Mr. Beggs stated that they had passed very strong resolutions in the Ohio State Association, pledging the members of that association to discriminate against any concern interested in exploiting an opposition plant in the territory of any central station lighting company. (Great applause.) Scarcely any of the resolutions passed by the National Electric Light Association, he said, amounted to anything, because the membership of that association was too meager and unrepresentative. They represented a few large companies in a few large cities, but the large companies in the large cities are in many instances controlled by the very people that are interested in exploiting this apparatus; but it is the hundreds of small companies all over this country that can make themselves felt and should make themselves felt. Therefore, he suggested the passage of resolutions by all these local associations to the effect stated. Mr. Beggs advocated the gathering of statistics for the State of Wisconsin, and their careful sifting to avoid the drawing of false conclusions. He referred in complimentary terms to Mr. Ferguson's paper on "Acetylene," read before the N. E. L. A. at New York. He advised following the example of the Association of Edison Illuminating companies, namely, to crowd all business into, say, the first two days, having two sessions a day, instead of one, using the evening and all of the third day, if desired, for entertainment purposes.

Mr. Beggs said that those operating unprofitable stations should not despair. When he took hold of his present station, two years ago, at Cincinnati, it was losing $2,000 a month. It was now earning $7,000 a month.

Mr. Debell referred to his experience in Sheboygan, where he nearly lost a city contract on false figures as to the cost in another town.

The president thanked Mr. Beggs on behalf of the society for his remarks.

Mr. W. R. Garton's paper on "Lightning Arresters" was then read.

Mr. Schuette feared that an attempt would be made to repeal the law which prevented cities from building their own municipal plants if there were another plant offered for sale, and he believed it would be well to notify all electric plants to join in the next meeting to arrange to be represented at Madison all the time to guard their interests.

Mr. Beggs thought it advisable for the local companies to form a very close union, but certainly it would be injudicious, unbusiness-like and improper, not to say offensive, to institute or make any attempt at instituting a boycott of manufacturers entering territory already occupied. But the number of large manufacturers with whom they dealt was small, not to exceed five or six, and there were not so many sprouting up as there used to be, because there was not the great amount of money in the business that there formerly was, and the price at which apparatus was now obtained was not such as to invite manufacturing companies to enter a town as they formerly used to, put in some apparatus, take one-half of the price in bonds and the other half in cash. In regard to the prices charged for lights, he did not think it was very difficult to-day to demonstrate to almost any municipality that the price at which they were willing to render them service was about as low as they could possibly render it themselves, and in many instances it was much lower. The price of electric lighting had now gotten down, as a general rule, throughout the country, to between $80 and $90 for a 2,000 candle-power lamp, burning all the dark hours (not a moonlight schedule). His idea was not to urge upon the association to adopt the method of meeting competing manufacturers, in any offensive way, but if they understood that the companies were dormant the manufacturers were ready to take advantage of their position; but if a manufacturer knew that fifty or sixty companies were standing together to prevent their business being injured, this very fact would prevent in all probability his entering into competition with them.

Mr. Beggs added that they must be careful not to enter into any competition which would have a tendency to demoralize prices, such as is now being attempted to be done in Columbus, in order to get a city contract. He thought one of the fairest operated municipal plants ever put up in this country, the one in which the statistics have been more reliable, more accurately kept and all the factors taken into account in the fairest manner, is the plant located in the city of Detroit, operated by the municipal government there. As a matter of fact, very few of those present were getting as much for an arc lamp as it was costing the city of Detroit to-day. According to Mr. Dow's very accurate and systematic statistics, it is shown that it is costing the city of Detroit nearly $90 per lamp per annum to run their plant. Statistics of that kind taken around, freely disseminated, would show the fallacies of exploiters of apparatus.

The central station people of this country, continued Mr. Beggs, were far more powerful to-day than the manufacturing companies. The electric lighting stations of this country had within themselves all the elements necessary to manufacture their own apparatus if they were provoked to it, and if provoked they would do their own manufacturing. (Applause.) Some years ago when this opposition selling was being done to a greater extent than now, by manufacturers, there was $8,000,000 of capital pledged by lighting companies to manufacture apparatus.

"These manufacturers well know our power," said Mr. Beggs. "There are few manufacturers of electric apparatus to-day that are not bankrupt, particularly the large ones, and I say it with all due respect. The two largest manufacturing combinations in the United States are bankrupts to-day. On the other hand, most of the electric lighting companies in this country are not only not bankrupt, but they are making a fair return upon their investment, and we have it in our hands, gentlemen, to say to these people what is fair business practice, and to require them to recognize fair business principles, in dealing with us who have been their customers during all the years of their business. I do not mean to carry this plan out in any offensive way, but you can accomplish a great deal by moral suasion when you know you are backed up by reason, good judgment and ample capital. There is ten times more capital represented in our local companies than in manufacturing companies. In fact, the manufacturers are dependent upon us, we are not dependent upon them. (Applause.) The sooner that position is taken and understood by the central station people, the sooner we will get that respect paid to us to which we are entitled (Applause.) There is to-day so little difference between standard apparatus of various makers, that it is hard to tell which is preferable. Standard apparatus is also more easily purchasable now than formerly; bonds and licenses have become relaxed, and all that it is necessary for us to do is to stand firmly together."

Mr. Beggs stated that the Association of Edison Illuminating Companies had forced the largest manufacturer of incandescent lamps in this country to admit now that they did not know what they had been producing; that they had not been getting one-half the effective light that was guaranteed; they were now laying down the conditions under which they shall manufacture lamps for them.

Their demand was for "constant economy," allowing a variation of 10 per cent. on candle-power, which meant that the lamp may be 17.6 candle-power or 14.4 candle-power, but the watts and voltage must be constant. Most Edison licensees were running 3.1 watt lamps, and were making a demand for a 2½ watt lamp, because a 20 candle-power lamp was needed to-day to compete with the present status of gas and the Welsbach burner, and they needed a 20 candle-power lamp without any increase in the cost of production or to the consumer. He considered the 4 watt lamp a monstrosity. They would guarantee a large output of lamps to the company that could give them a 2½ watt lamp that will last 300 hours standing up under a candle-power of from 12.2 to 20; but there was not a lamp manufacturer in the country that dared to take up that proposition.

Mr. Buckley stated that the question of a 2½ watt lamp was brought up especially because every lamp manufacturer spoken to regarding the lamp, invariably and strenuously insisted that the lamp could not be made. It was simply a question whether central station men would use and burn lamps which these large manufacturers made a considerable profit on, or whether they would gather themselves together, increase their investment, and make a lamp on which a profit could be made.

Manufacturers claimed that such a lamp costs from 3 to 5 cents more to make. The companies coud afford to pay more for such lamps, though they did not want to do it.

Mr. Beggs suggested that for each 5 per cent. that the lamp falls below standard there should be 10 per cent. deducted from the price of the lamp. In his specifications he provided that if the lamp was 10 per cent. higher that the specifications, he would pay 5 per cent. more for it, and so on up until it reached 100 per cent. more than the specifications required, when he would pay 50 per cent. more. Mr. Edison was at the present time working on a very high voltage lamp. It was a very difficult thing to produce, but he had never known anything in this business that was absolutely required that was not forthcoming. He expected the 2½ watt lamp within the next two years.

The report of the Committee on Ways and Means was next read, and its principal reference was in regard to the payment of a special indebtedness to Mr. Lord incurred on behalf of the Association.

Mr. Low moved that steps be taken by contribution and subscription to liquidate the debt of the Association, and a considerable amount was subscribed at once by representatives of a number of central stations.

Adjournment was then taken to 2 p. m.

At 2 p. m. the convention was called to order by the president, and a paper on "Insurance," by Mr. C. C. Paige, was read. A long discussion followed by Messrs. Paige, Wheeler, Kountz and Cuno, in which it was brought out that the worst trouble to contend with regarding insurance rules in wiring was the constant change.

The report of the special committee to consider the recommendations in the president's report was then read by the chairman, Mr. Doherty.

Mr. Harding then related the experience of the Logansport company, where, in order to kill the competition of the company, the city, which had installed a plant, chopped down the company's poles.

A motion was then carried that the thanks of the Northwestern Electrical Association be tendered to the entertainment committee consisting of Messrs. Higgins, Hanley and Daniels, and through them to the good people of Marinette and Menominee for the courtesy and generous hospitality which had been extended to the members of this convention during the present session.

A number of applications for membership were then presented and granted.

The meeting then adjourned to 9 o'clock July 17, 1896.

FRIDAY'S SESSION.

The Chair called the meting to order Friday morning and appointed a committee for solicitation of new membership.

After transacting some routine business Mr. Kountz moved that the legislative committee be discontinued, and that a committee be appointed to be known as the Protection Committee. Carried.

The convention then adjourned sine die.

CONVENTION NOTES.

On Tuesday, July 14, at 10:30 p. m., a considerable contingent of the delegates and others arrived in the special car on the Chicago and Northwestern Railway, which left Chicago at 3 p. m. that day, and picked up additional members at Milwaukee and other places en route. The journey was most enjoyable.

On Wednesday a large party of the visiting delegates were taken by electric cars to Lakeside, a beautiful pleasure resort on Green Bay, some three miles from Marinette. Here various sports in the shape of log rolling, tub races, boating, and foot races were indulged in. In the evening a large number of the visitors were again taken to Lakeside and into the grounds of the Oakwood Beach Club, where a large dancing party, composed of the most prominent people of the twin cities of Marinette and Menominee, were assembled to entertain the visitors, which they did right royally.

At 3 p. m. on Thursday a train of three electric cars on the Marinette line conveyed a considerable number of the visitors as far as the line separating the two cities, when a change was made to President Daniell's road, the Menominee Street Railway. The party were taken to the Scaling Gap, a short distance outside of the city, where they made a stop of some time and watched with considerable interest the marking of the logs as they passed the gap down the river to the sawmills. The Leisen & Henes brewery was then called at, where the visitors were shown through by Mr. Henes, each one receiving a good sample of the excellent brew.

The same evening at 9:30 a banquet was given at the Hotel Marinette to the delegates by prominent citizens of the two cities. The menu was most excellent, and the floral decorations were also of a very elaborate character, to which was added an excellent orchestra. At the conclusion of the banquet several fine addresses were delivered in response to toasts. Among the most notable were "Marinette," Mayor J. J. Sherman; "Menominee," Mayor J. W. Wells;" "Our Retainers," Lawyer E. C. Eastman; "The Northwestern Electrical Association," President Baker; "The Ladies; Why Should They Be Absent?" Mr. Thos. Mercein; "The Electrical Press," F. L. Perry, and several others.

Mr. George W. Hanley, secretary of the Marinette Electric Light and Street Railway Company, acted as toastmaster in a most able manner. Between the speeches some vocal selections, which largely contributed to the pleasure of the occasion, were rendered by Mrs. H. E. Tanner, Miss Sullivan McGilan, Mrs. Clarke, of Menominee, and Mr. Geo. W. Taylor.

Friday, the third day, was devoted to visiting the paper and sawmills in the vicinity, and also a pleasant sail was taken in Mr. E. C. Eastman's yacht.

So ended the fourth semi-annual convention of the Northwestern Electrical Association, which will long be remembered as the most successful and pleasant held since its birth in the same city of Marinette, when one of the hospitable entertainers, Mr. H. C. Higgins, was elected first president.

It is worthy of special mention that with the exception of the ride over the Menominee line, the entire expense of the entertainments provided was borne by the Marinette Railroad Company.

EXHIBITS.

Mr. Jas. H. McGill, who is quite a prominent figure at conventions, showed a line of samples of street railway supplies manufactured by the Ohio Brass Company, of Mansfield, O., and also some of the goods of the Akron Insulator and Marble Company, Akron, O.

Mr. George Whyte, secretary of the Lescher-Macomber Whyte Company, Chicago, was conspicuous among those who were out to have a good time, and also kept his weather eye open for business.

The Sunbeam Lamp Company, Chicago, showed a nice line of their well-known incandescent lamps.

The Cutter Electric Manufacturing Company had on hand on of the I. T. E. automatic circuit breakers, which was examined by several of the delegates with considerable interest.

The Lakon Company, Elkhart, Ind., were also on deck with matter pertaining to transformers.

Mr. L. W. Burch, of the People's Electric Company, Madison, Wis., was around lively as a bee expatiating upon the many advantages to be gained by purchasing Northern Electrical apparatus, Standard telephones, "Raven Core" wire and the many other specialties carried by this young and progressive concern.

Mr. Jos. M. Hill, Chicago, was also to the fore, as usual, talking Columbia lamps and Wagner transformers.

Messrs. Fred De Land, W. P. Sullivan, F. L. Perry and J. O. S. Church were the representatives of the electrical press present.

The interests of the Anchor Electric Company, Boston, were ably taken care of by their Western manager, Mr. C. O. Baker.

Mr. George Cutter, a familiar figure at such gatherings, was around, and had some of his specialties on view.

Mr. Franklin H. Brown, of the DeWitt-Brown Cedar Company, Menominee, Mich., was also around, and distributed his company's circulars.

The K. McLennan Company, Chicago, made a liberal distribution of matter bearing on Gale's Commutator compound, of which they are the manufacturers.

The Dearborn Drug and Chemical Works, Chicago, gave souvenirs of perfumed envelope sachets and pencils. Mr. S. E. Christie represented them.

Mr. W. A. Dennis, of the Paul Perrizo, Jr., Cedar and Lumber Co., Marinette, was around, and helped materially to make things enjoyable for the visitors.

The Crouse-Tremaine Carbon Co., Fostoria, O., were represented by Mr. L. C. Anderson.

The Central Electric Company, Chicago, had Mr. H. D. Latimer on hand to look after their interests.

The General Electric Company were ably represented by Messrs. A. C. Bunce, F. N. Boyer and P. A. Clisdell, who were prominent figures during the convention.

The Electric Appliance Company were to the fore, as usual, and showed an exhibit of Shaefer transformers and meters and other electrical devices. The worthy president, Mr. W. W. Low, was hustling around as usual, and contributed more than his share to the success of the occasion, being at the same time very ably assisted by his active lieutenant, Mr. W. Wilson.

The Fort Wayne Electric Corporation had their usual hospitable exhibit of a nature suited to refresh the inner man, and Room E, Hotel Marinette, received quite a good share of attention from the delegates and others present. Mr. W. J.

Buckley and Mr. C. E. Wilson dispensed the hospitalities in a most commendable manner.

The New York Insulated Wire Company were represented by their genial Chicago manager, James Wolff. To say that Mr. Wolff kept things a-humming would be only an inadequate description of the part he took in making things a great success on this very enjoyable occasion.

Others who had representatives present included the Chicago General Fixture Company, L. W. Kittman; Julius Andrae & Sons, Milwaukee, Herman Andrae; Wilson-Clark Co., Milwaukee, E. G. Mullen; Henry L. Doherty, general manager Madison Gas and Electric Co., Madison, Wis.; the Milwaukee Board of Underwriters, Geo. S. McLaren, electrician; Hudson Jones; W. R. Fairchild, city editor of the "North Star," Marinette; E. W. Leroy, city editor of the "Daily Eagle," Marinette.

ROENTGEN RAYS.

APPLICATION OF PHOTOGRAPHY BY ROENTGEN RAYS TO ANALYTICAL RESEARCHES ON VEGETABLE MATTER.

BY FERNAND RAMVEZ.

Photography by means of the X-rays can render precious services in analytical research, and especially in the analysis of vegetable articles of food, where it will detect certain of the most frequent falsifications—those effected by the addition of mineral substances.

This method offers manifold advantages; it requires only small quantities of the substances; it leaves the specimens completely intact; it allows us to effect in a very short time a great number of examinations (about a quarter of an hour sufficing for a series of specimens). Lastly, the proof obtained is a piece of convictive evidence quickly demonstrated, easily understood even by persons strangers to any analytical operation.

The experiments which I have made refer to three samples of falsified saffron, taken in trade. These products consisted of mixtures in different proportions of pure saffron and saffron coated with barium sulphate. The filaments of the latter were found surrounded with a shell of mineral matter. The adulteration was very skillfully masked, and could not be suspected on a mere inspection of the merchandise.

I arranged on one and the same sensitive plate, inclosed in black paper, quantities of the three adulterated samples almost equal. No. II. contains 62.13 per cent. of mineral matters, No. III. 28.69 per cent., No. IV., 22.21 per cent., and along with them a specimen of pure saffron. The whole was submitted for three minutes to the influence of the rays emanating from a Crookes tube.

The pure allowed itself to be traversed by the X-rays and produced on the proof merely shadows scarcely visible, not acting, so to say, upon the paper of the positive proofs. The three falsified samples acted strongly upon the sensitive plate, marking very distinctly the filaments coated with barium sulphate, while the stigmati of the pure product, which were mixed with it, appeared only as scarcely perceptible shadows analogous to those of the former product.

The photographic proofs which accompany this note show the distinctness of the results obtained, and enable us to foresee the services which this method will render in its future applications.—Comptes Rendus.

ACTION OF X-RAYS ON HIGHER ANIMALS.

The action of Röntgen and other rays on the higher animals has been studied by Professor Stefano Capranica (Atti R. Accad. dei Lincei). The subject selected for observation was Mus musculus, and the experiments referred chiefly to the quantity of carbon dioxide exhaled in the process of respiration. Professor Capranica states the following conclusions: (1) The amount of CO_2 is the same in darkness as in diffuse daylight. (2) The respiration of Mus musculus is greatly affected by strong sunlight, even when all heat rays have been screened off; and the effect is the same for rays from all parts of the spectrum. (3) Artificial lights, such as the electric light or incandescent gas, act like sunshine when concentrated on the animals, but have no effect when merely used to light a room. (4) The light from Geissler's tubes has no effect. (5) Röntgen rays have no action on the quantity of CO_2 eliminated from the animal, whatever be the condition of the latter; that is, whether fasting or after feeding, whether previously kept for several hours in darkness, or vice versa. (6) What was observed with each of the six moles experimented on was strong excitement, which continued for several hours after the experiments with Röntgen rays had ceased. The moles, after being exposed to Röntgen rays for one hour, ran about in a nervous and excited way, and would not eat. (7) This excitement Professor Capranica attributes to the electrical effects of the Röntgen rays. (8) Experiments on cold-blooded animals (Coronella) give, as yet, no appreciable results.

ON THE DIFFRACTION OF THE ROENTGEN RAYS.

BY L. CALMETTE AND G. T. HUILLIER.

We have the honor of submitting to the Academy some photographic proofs obtained with the Röntgen rays by means of the following arrangement:

Very near the Crookes tube there is a screen, E, of brass perforated by a slit, the width of which has rarely reached a half mm. A second metal screen, E′, is formed of a plate provided with two slits or pierced with a window in which is fixed a metal rod of 1 mm. in diameter. This screen is placed at the distance, a, behind the former. Lastly, a photographic plate, enfolded in two leaves of black paper, is placed at the distance, b, behind the second screen, E′.

The following table indicates, for each proof, what is the screen E′ used, and the value of a and b + a:

No.	E′.	a. Cm.	b + a. Cm.
1.	Rod of 1 mm. in diameter............	5	19.5
3.	" "	5.5	20
5.	" "	8.9	30
7.	Two narrow slits, separated by a cylindrical rod of 1 mm. in diameter....	?	?

On the proofs 1, 3, 5 the shadow thrown by the metallic rod is bordered on each side by a light band which shows a maximum of intensity. Within this shade we observe a zone less dark, which seems to indicate that the Röntgen rays penetrate into the geometrical shadow. Lastly, in proofs 3 and 5 we see, in like manner, a maximum of intensity along the margins of the window in which the rod is placed.

In the proof No. 7 we perceive, in the middle of the two white bands, a fine dark ray, while in the shadow of the rod which separates the two slits there is seen a light ray.

If we compare these results with those obtained with light in the same conditions, the slit being relatively wide and the intensity weak, it seems difficult not to ascribe them to the diffraction of the Röntgen rays.

The proofs obtained in these experiments—which we propose to continue—are not yet so distinct that we can measure the wave length with any precision. But we are still led to believe that this wave length is greater than that of the luminous rays.—Comptes Rendus.

X-RAYS IN CONSUMPTION.

A number of well-known physicians of Chicago have been treating an almost hopeless case of consumption with a direct application of X-rays through the lungs, and although they are not prepared to state positively that the disease has finally found its cure, some of them are forced to the conclusion that the result has been wonderful. One signs his name to the declaration that the effects "so far are but little short of the marvelous." They are all conservative. They speak only of the changes actually recorded and waive final judgment until the patient shall have been subjected to the new discovery for a second period of five weeks.

Prof. H. P. Pratt, who carried on the first experiments with Prof. Hugo Wightman, prepared his electrical apparatus and his special Crookes tubes for the application. The patient, whose face was withered and full of wrinkles, came into the laboratory supported by his mother. His temperature was 103½, pulse 100, respiration 34. His chest was bared, the tube placed in direct contact with the flesh. The exposure was for three hours. At the end there was a decrease of two degrees in temperature, the pulse leaped to 120 and the respiration fell to 22. This record was made in the presence of several physicians, and the boy was allowed to go home with no other remedies than such stimulants as would have been given to all patients under the same circumstances.

With subsequent treatments a continual improvement has taken place during five weeks. Signed statements of the doctors who have attended the treatment of the young man are published in the Chicago "Times-Herald."

AWARDS FOR X-RAYS.

The Natural Research Department of the Animals Institute, London, are offering gold medals and other prizes for improvements in the X-rays to aid the diagnosis of disease and lameness, and for the best developed photographs of the limbs and internal organs of human beings and the lower animals.

LITERATURE.

ELECTRIC LIGHTING. Vol. 1. The Generating Plant. By Francis B. Crocker, E. M., Ph. D. New York: D. Van Nostrand & Co., 1896. 444 pp., 6 x 9. Cloth. Price, $3.

As its sub-title states, this is a work intended for engineers, students and others interested in the installation or operation of electric plants. One is at once relieved on thumbing its pages preliminarily by the absence of all reference to the elementary laws of electricity, which most authors of similar works in the past have considered it their religious duty to inflict upon their readers. Professor Crocker has wisely left that to other books specially devoted to the subject and plunges at once into medias res, after a short introduction and a ten-page chapter on general units and measurements, for which we forgive him in view of his omission of the elementary principles.

In the chapter on classification and selection of electric light systems the author not only gives the usual categorical types of systems now in use, but adds his own comments on the advantages and disadvantages of each, and in this regard we think he has performed a duty from which most other writers have shrunk for fear of giving offence in certain quarters. This chapter is followed by one on location and general arrangement of electric lighting plants, and the buildings required for them, which contains many useful hints for construction of foundations and walls and the methods of driving dynamos.

The possible sources of electrical energy are then taken up, and the various forms discussed. Animal, wind, wave and tide-power, primary batteries, thermo-electric batteries, etc., are passed over with appropriate mention, while naturally more extended space is devoted to the steam and gas engine. The author concludes that so far as the direct generation from coal is concerned, the outlook is not particularly encouraging, and tnat there is no great hope of a radical improvement in this direction in the near future.

We will, therefore, he believes, have to content ourselves with the gradual, but steady improvement of the means which we already have. He does not, however, by any means, give up hope that future discoveries may point to a way of producing electrical energy more cheaply than is possible at the present time.

The importance of the subject warrants the author in devoting a short chapter to the particular consideration of the steam engine and its general principles of operation. The value of this chapter is unquestionable, as it places in strong relief the limitations to which the present type of steam engine is subject, and will place in the hands of many who have hazy ideas on the subject the basic arguments with which to meet the crank, who regularly turns up with devices for increasing steam engine efficiency many hundred per cent.

In the same way steam boilers used for electric lighting come in for their share of consideration, and enough of their principles are given to enable the central station manager to determine whether he is getting the best that can be gotten out of such apparatus. The chapter also contains illustrations of the principal types of boilers now in use, together with accessory apparatus, such as water purifiers, feed-water heaters, fuel economizers, etc. We also notice brief, but comprehensive, paragraphs on steam piping, and the testing of steam boilers, and in the succeeding chapters the author enters more elaborately into the principal types and detailed construction of steam and gas engines, water wheels, windmills, etc., which contain a great deal of useful information in a very small space. The mechanical connections between engines and dynamos then come in for a couple of chapters, in which we find descriptions of the methods of direct coupling, belting, rope driving, tooth and friction gearing, as well as a number of peculiar forms of connection, such as magnetic and hydraulic gearing.

In a book devoted to work which depends upon the dynamo electric machine for its very existence a chapter on the principles and construction of dynamos must necessarily find a place, and the author has, therefore, very properly given an excellent review of the construction of such machines, treating the subject almost exclusively from the practical standpoint. This is followed by a description and illustration of the various types of machines now in general use, and with a chapter on their practical management, which contains a large number of practical hints and wrinkles.

The accumulator, that rapidly increasing adjunct to electric generation and distribution, is next taken up, the principal types being described, together with their management and their application to electric lighting, such as regulators, transformers, and as accumulators to maintain uniform load, etc. While treating this part of the subject dispassionately—as Professor Crocker treats every subject on which he writes—one cannot but feel that he is no friend of the storage battery. Other chapters on switchboards, including switches, fuses, circuit breakers, and on electrical measuring instruments and lighting arresters bring to a close this most excellent volume. We must also note the presence of a good index and numerous references to original sources of information throughout the book.

Most works of the nature of the one before us, in fact, nearly all, without exception, have treated the subject from what might be called the academic standpoint, rather than from the practical; but we are certain that no one could lay down Professor Crocker's book without the satisfying feeling that he had obtained some genuine practical information directly applicable to every-day work. As such we are certain the book will find a genuine welcome, and we hope that the volume to come, which will treat of some of the broader aspects of the subject, among them the financial side of electric lighting, will soon make its appearance.

OBITUARY.

PROF. STOLETOW.

The death is anounced of Professor Alexander G. Stoletow, the well-known Professor of Physics in the University of Moscow. Stoletow was born in 1839, and was educated at the Universities of Moscow, Heidelberg, Göttingen and Berlin, working from 1862-65 in the laboratories of Kirchoff and Weber. He was appointed lecturer in physics in the University of Moscow as far back as 1866, becoming professor in 1873. Professor Stoletow was a member of the first Electrical Congress held in Paris in 1881, and was a member of the jury of the Paris Electrical Exhibition, held in the same year; he was also vice-president of the 1889 Electrical Congress.

Professor Stoletow's chief electrical papers are: "On the General Problem of Electrostatics"; "On the Magnetization Function of Soft Iron," which contained the first explanation of the susceptibility curve; "On a Determination of Maxwell's "v" by the method of repeated discharge of an air condenser of known dimensions; "On Contact Electricity"; "On Kohlrausch's Measurements of the Mercury Unit of Resistance;" "On Actino-Electrical Phenomena," a series of papers on the dispersion of electricity under the action of ultra-violet radiations, and "Ether and Electricity," an address at the meeting of Russian naturalists in 1890.

PERSONAL.

THE RUMFORD MEDAL AWARDED TO EDISON.

In 1885 the American Academy of Science awarded the Rumford premium to Thomas Alva Edison for his investigations in electric lighting, and the presentation of the medal took place at its last meeting. Vice-President Goodale made the presentation speech, which was responded to by Professor Trowbridge on behalf of Mr. Edison, who was unavoidably absent.

THE Albert medal of the Society of Arts has been awarded to Professor David Edward Hughes, F. R. S., "in recognition of the services he has rendered to arts, manufactures, and commerce by his numerous inventions in electricity and magnetism, especially the printing telegraph and the microphone."

DETERMINING MERCURY IN ITS ORES.

In the "Journal" of the American Chemical Society there is a short paper in the joint authorship of W. B. Rising and V. Lenher, describing an electrolytic method for determining mercury in cinnabar. The mercuric sulphide is treated with hydrobromic acid, in which it dissolves very readily; the solution is nearly neutralized with caustic potash, pure potassium cyanide added in sufficient excess to redissolve the precipitate which is at first formed, and the solution is electrolyzed by means of a weak current; the operation is carried out in a platinum dish, which acts as the negative electrode, and on this the mercury becomes deposited. The advantage of hydrobromic acid over aqua regia is, that it dissolves cinnabar at low temperatures, so that no loss of mercury by volatilization occurs. Results are given showing the accuracy attainable.

MISCELLANEOUS.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES—II.

BY J. A. FLEMING, M. A., D. SC., F. R. S., M. R. I.

HAVING thus defined our scale of temperature, we proceed to embody the whole of our results in the following tables:

ELECTRICAL RESISTIVITY OF PURE METALS ANNEALED.

Metal.	Resistivity in C. G. S. units at 0 deg. C.	Percentage increment, 0 deg. to 100 deg. C.	Atomic volume.
Silver	1,468	40.0	10.04
Copper	1,561	42.8	7.10
Gold	2,197	37.7	10.04
Aluminum	2,665	43.5	10.56
Magnesium	4,355	38.1	13.76
Zinc	5,751	40.6	9.12
Iron	9,065	62.5	7.10
Cadmium	10,023	41.9	12.96
Palladium	10,219	35.4	9.12
Platinum	10,917	36.69	9.12
Nickel	12,323	62.2	6.94
Tin	13,048	44.0	16.20
Thallium	17,633	39.8	17.20
Lead	20,380	41.1	18.27
Mercury	94,070	—	—
Bismuth	108,000	—	—

ELECTRICAL RESISTIVITY OF ALLOYS.

Alloy.	Composition.	Resistivity in C. G. S. units at 0 deg. C.	Percentage increment, 0 deg. C. to 100 deg. C.
Aluminum-copper	94:6	2,904	38.1
Aluminum-titanium	—	3,887	29.0
Aluminum-silver	94:6	4,641	23.8
Gold-silver	90:10	6,280	12.4
Copper-aluminum	97:3	8,847	8.97
Copper-nickel-aluminum	87:6½:6½	14,912	6.45
Platinum-rhodium	90:10	21,142	14.3
Nickel-iron	95:5	29,452	20.1
German silver	$Cu_6Zn_3Ni_2$	29,982	2.73
Platinum-iridium	Pt_4Ir	30,896	8.22
Platinum-silver	1:2 $PtAg_4$	31,582	2.43
Platinoid	—	41,731	3.1
Manganin	—	46,678	0.
Iron-manganese	88:12	67,148	12.7

These results were embodied in a chart on which the vertical distances represented the resistivity, or specific resistance, and the horizontal distances represented platinum temperatures. The curves thus obtained indicate the manner in which the specific resistance varies with temperature for each substance. The first thing which strikes us is that the lines for the pure metals all converge downward in such a manner as to indicate that their electrical resistance would vanish at the absolute zero of temperature, but that no such convergence is indicated in the case of alloys. We have found that the slightest impurity in a metal changes the position of this resistance line. In the next place, note that the order of conductivity is different at low temperatures to that at ordinary temperatures. At 0 deg. C. pure silver is the best conductor, but at —200 deg. pure copper is better than silver, and the position of mercury is, of course, very different. Again, the lines of some metals are very much curved. The principal magnetic metals, iron and nickel, have lines which are very concave upward, and this is a characteristic apparently of many magnetic alloys. The mean temperature coefficient of these magnetic metals between 0 deg. C. and 100 deg. C. is much larger than that of other metals, and the percentage decrease in resistance in cooling them from + 200 deg. C. to —200 deg. C. is greater than in the case of any other metals.

It is worth noting, in passing, that these magnetic metals, iron and nickel, have smaller atomic volumes than any other metal, and that, generally speaking, the worst conductors amongst the metals are those that have the large atomic volumes and large valency. Next, turning to alloys, we may make mention of a few general facts with regard to their resistance. If to one pure metal we add a small quantity of any other metal, the result is always to raise the resistance line almost parallel to that of the predominant constituent. Thus, in our chart, the alloy consisting of 6 per cent. of copper with 94 per cent. of aluminum is parallel to the aluminum line but higher up. Three per cent. of aluminum added to 97 per cent. of copper yields an alloy with a resistance line parallel to that of copper, also higher up. When two pure metals are alloyed together in various proportions there is generally some proportion in which the resultant alloy has a maximum resistivity, and except in the case of alloys of zinc, tin, lead, and cadmium with each other the resistivity of the alloy is greater than that of either of its constituent metals. In the case of many well-known alloys the proportions which give high, if not the highest, resistivity are those which correspond to definite and possible chemical combinations of the metals with each other—as, for instance, in the well-known platinum silver alloy in proportions 33 to 66, which corresponds in proportion with the combination $PtAg_4$; the iron-nickel alloy in proportion of 80 to 20, which corresponds with the combination $NiFe_4$; the patinum-iridium alloy 80 to 20, which corresponds with the combination $IrPt_4$; and the copper-manganese alloy 70 to 30, which corresponds with the compound Cu_2Mn—all of which are, as far as valency is concerned, possible compounds. It is, however, found that very high resistivity generally involves in alloys a want of tenacity and ductility, and when we reach such limits as 100 microhms per cubic centimetre we begin to find the solid alloys becoming less useful on account of this deterioration of their useful mechanical quality.

We have especially studied the electrical resistance at low temperature of a large series of steel alloys containing varying proportions of nickel, aluminum, chromium, tungsten, and manganese in them. We find that the effect of adding the other elements of the alloy is always to shift up the resistance line nearly parallel to itself, so that the resistance lines of all the iron alloys are nearly parallel to that of the iron line, only the absolute value of all the ordinates is increased. This is equivalent to saying that the effect of the added material is to increase the specific resistance, but not to alter the slope or form of the resistance curve. Amongst these steel alloys there are two or three that are very interesting. A nickel-steel alloy sent to us by Mr. Hadfield containing 19 per cent. of nickel exhibits some very extraordinary properties. Nicket-steel alloys with large percentages of nickel can, as Dr. Hopkinson has shown,[1]

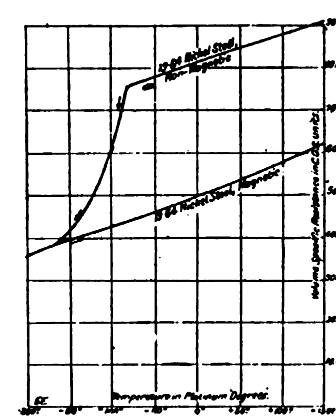

FIG. 6.

exist over wide limits of temperature in two different physical states, in one of which they are strongly magnetic, and in the other of which they are feebly magnetic; and they pass from the non-magnetic to the feebly magnetic on cooling to low temperatures. Here, for instance, is a sample of the 19 per cent. nickel steel in the non-magnetic condition. If it is cooled in liquid air, we can make it pass instantly into a magnetic condition. In the first state it is fairly ductile and plastic, but in the second state it is very hard and brittle. Moreover, its electrical resistance is permanently altered on undergoing this change. In the non-magnetic state it has a high resistivity of about 81,500 C. G. S. units per cubic centimetre at 0 deg. C., but on cooling in liquid air and becoming magnetic it is found to have decreased to about 47,200 C. G. S. units when taken at 0 deg. C. It is perhaps more correct to say that this alloy can exist in an infinity of different physical states, because we have found that the lower it is cooled in temperature the lower its resistivity can be made to be when measured again at ordinary temperatures. On heating up the alloy again to a bright red heat, it goes back into the non-magnetic ductile state.

The chart (Fig. 6) shows how the electrical resistance varies between the limits of —200° C. and 100° C. when the alloy is taken through a cycle of temperature beginning at 100° C. in its non-magnetic state. The 29 per cent. nickel steel exhibits the same characteristics in a less marked degree. A close study of this interesting material shows that there is room for much valuable work upon it yet. A manganese steel brought to notice by Mr. R. A. Hatfield, having about 12 per cent. of manganese in it, is also capable of existing in two states—a magnetic and a practically non-magnetic variety. The magnetic variety, which is much more brittle, is, however, in this case, formed by the prolonged slow heating of the non-magnetic variety out of contact with air. In the non-magnetic condition the material has a very high specific resistance at 0° C.—about 65,700 C. G. S. units per cubic centimetre; but the magnetic variety has a much lower specific resistance, viz., about 51,400 C. G. S. units at 0° C. In all these cases it is

[1] See Proc. Roy. Soc., 1890 Vol. 47. P. 138.

interesting to note that the change of the alloy into the magnetic variety is accompanied by a decrease in resistivity or increase in conductivity; in an increase in brittleness. We have tried cooling this non-magnetic variety of manganese steel in liquid air, but have not been able in that way to make any change in its condition as regards magnetic susceptibility. There is a particular alloy of copper 84 per cent., manganese 12 per cent., and nickel 4 per cent., called manganin, which at ordinary temperature exhibits but little change of resistance with change of temperature. On taking the curve of its resistance over wide ranges of temperature, we find that its curve is very concave downward, and the vertex of the curve lies at

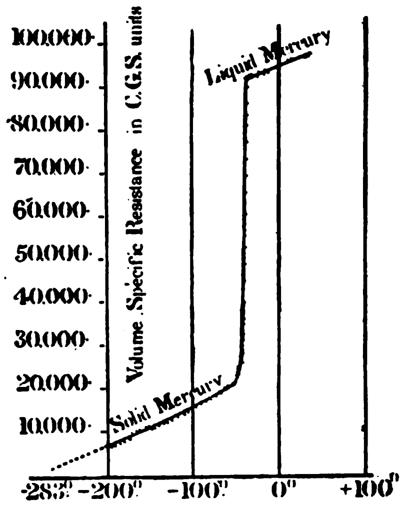

Fig. 7.

about 16 deg. C. Hence at ordinary temperatures small changes of temperature make no change in its resistance, but above this point its temperature coefficient is negative, and below it is positive. All alloys in which a negative temperature coefficient has been observed are probably instances of the same mode of variation of resistance. It may be noted, in passing, that the element manganese when present in an alloy seems to have a great tendency to produce high resistivity and small temperature coefficiency. Returning, then, to the pure metals, we may ask, What is the meaning of the fact that in their case the resistance lines all converge so as to indicate that the electrical resistance would vanish at the absolute zero of temperature? We know that the passage, as we call it, of an electric current through a conductor heats it, and that by Joule's law the rate of production of heat in the conductor is proportional to the square of the current strength and to the total resistance of the conductor. Suppose we take two wires, say, of iron and a certain copper-nickel-aluminum alloy, of the same size and length. These wires will at + 100 deg. C. have the same resistance. A unit current flowing through them will, therefore, generate heat in them both at the same rate. Cool them both down, however, to the temperature of liquid air. In the case of iron the resistance is reduced to one-fifteenth of its value at .200 deg. C.; in the other case it is reduced by only 10 per cent. Hence, at the low temperature the alloy dissipates energy for the same current nearly 13½ times as rapidly as the nickel.

It is a logical deduction from all we know to conclude that if we could reach the absolute zero of temperature, the pure metal would not dissipate the energy of the current at all. Imagine two iron wires, then, stretched through space, say, from the earth to the moon, and kept everywhere at the absolute zero of temperature. We could transmit any amount of electrical energy along them without dissipating any of it as heat in the wires. As a consequence of this, any pure metal cooled to the absolute zero of temperature would become a perfect screen for electro-magnetic radiation, and would be perfectly impenetrable to electro-magnetic induction. We can show this increase in the power of electromagnetic screening by metals when cooled in the following way: A suitable coil of wire is placed between the poles of an alternating current magnet and a small incandescent lamp connected with the coil. When the magnet is excited it induces currents in the coil, and the lamp glows up. A cap of aluminum is made of such a size as to drop easily over the coil. This aluminum is not of sufficient thickness or conductivity to screen off the induction when it is warm. If, however, we cool the aluminum cap in liquid air and then drop it over the coil, the lamp for one instant goes out, but it comes in again as the metal cap instantly warms up. This shows us, however, that if the cap were at the absolute zero of temperature it would be a complete screen for the induction. In fact, these experiments furnish us with a new definition of what we mean by the absolute zero of temperature. It is the temperature at which perfectly pure metals cease to have any electrical resistance.

In the conduction of currents at ordinary temperatures, as we generally know it, two effects are inseparably connected with the conveyance of energy by this process. One is the dissipation of some of the energy as heat in the conductor, the other is loss of potential or fall of electric pressure, and which is one of the factors in the equivalent of the energy so dissipated. If, however, the conductor is at the absolute zero of temperature, there is no dissipation of energy in it, and neither of these consequences would be present. There would be no heat produced in the conductor and no fall of potential along it either for large or small currents. What, then, under these conditions is the function of the conductor? The answer is that it becomes a mere boundary, serving to limit the electro-magnetic field and determine the direction in which the energy transmission is taking place. These experiments, therefore, may be regarded as forging one more important link in that chain of evidence which compels us to look for the processes concerned in the conveyance of energy by an electric current, not inside the conductor, as we call it, but in the dielectric, or medium outside. We may, then, ask how is it that different bodies have such various dissipative powers when acting in this way as the boundary of an electro-magnetic field? The only suggestion on this point I venture to make here is as follows: Materials of high specific resistance have all probably a very complex molecular structure. The alloys of high resistivity are not probably merely solidified mechanical mixtures of metals, but chemical compounds; and even in the case of elementary bodies like carbon and sulphur they may have, owing to their high valency and tendency of their atoms to auto-combination, a complex molecular structure. This structure may bestow upon them the power of taking up energy from the electro-magnetic medium, just as gases with a highly complex molecular structure are very absorbent of radiant heat, which, if the electro-magnetic theory of light is true, is only another form of electro-magnetic energy. All we know at present about the processes at work during the time a conductor is traversed by an electric current is that there is a magnetic field outside the conductor and also within the mass of the conductor, and that some mechanism is at work absorbing energy through the surface of the conductor and dissipating this as heat in the interior. The resistance of a conductor is best defined as the number expressing the rate at which it dissipates electro-magnetic energy per unit of current. For the same current—that is, for the same external magnetic field—conductors dissipate this energy at very different rates. Some, like silver and copper, which have the lowest rates, are elements of low valency and molecular volume, and have probably a simple molecular structure. Others, like alloys of high resistivity, have in all probability a more complex molecular structure. Both this last, as well as the molecular mobility characteristic of the liquid state, are conditions which bestow the power of taking up rapidly and dissipating the energy of the electro-magnetic field, and this has to be kept supplied from energy-transforming sources. We cannot, however, at present construct profitably further mechanical hypotheses to account for this difference in the presence of our great ignorance about ether, molecules, and energy.

In passing from the liquid to the solid state there is generally an immense increase in the conducting power of metals. This is well shown in the case of mercury. A glass tube a metre in length was formed into a spiral coil and filled with pure mercury, suitable connections being provided at the ends. This coil was embedded in a mass of paraffin wax, and a platinum-wire thermometer placed in contact with it. The whole mass was then reduced to the temperature of liquid air, and observations taken of the resistance of the mercury as it heated slowly up after being removed from the liquid air. The curve in Fig. 7 shows the manner in which the resistance increases with great suddenness between —41 deg. and —36 deg. as the metal passes into the liquid condition. The resistance becomes four times greater between —50 deg. and —36 deg. in the course of 14 degs. rise of temperature, and while in the act of pasisng through the melting point of the mercury at —38.8 deg. C. This chart shows that the resistance of the mercury in the solid state tends downward, so as to indicate that its resistivity would completely vanish exactly at the absolute zero of temperature. It is interesting to note also that the portion of the resistance curve belonging to mercury in the solid state is sensibly parallel to that portion of it in the liquid state.

MR. GEO. H. ALMON has been granted a franchise by the city of Barre, Vt., to establish a telephone exchange there. The city has 10,000 inhabitants and is five miles from Montpelier. He also has a franchise for the same purpose from the town of Waterbury and hopes to get one from Montpelier also.

THE JACQUES CARBON BATTERY.

BY C. J. REED.

IN The Electrical Engineer of April 13, 1896, a description is given of the Jacques "Carbon Consuming Primary Battery" so called. From the description and data given, it seemed evident to the writer that the electrical energy derived from this cell, instead of being evolved directly from the carbon, was produced by a thermo-electric junction. To determine this question three experiments were performed, the results of which indicate clearly that the action is thermo-electric.

The apparatus used in the first experiment is shown in Fig. 1. It consisted of a sheet-iron cup, L, having a long iron handle, to which a wire, W, was soldered. The free end of the wire was connected to one terminal of a Weston voltmeter, V. The cup was half filled with pure caustic soda and heated by the flame of a Bunsen burner, B. The other terminal

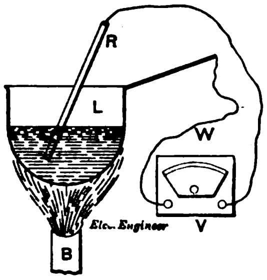

FIG. 1.

of the voltmeter was connected by a flexible wire to a conducting rod, R, the end of which was at frequent intervals inserted into the fused soda.

Rods of carbon, nickel, copper, iron, German-silver, lead, and cadmium were used. The reading of the voltmeter was taken as quickly as possible after bringing the rod in contact with the alkali. The rod was withdrawn after each reading and allowed to cool.

Readings were taken in this manner at intervals of one minute from the time the alkali fused until it attained the highest temperature and afterward until it cooled to the point of solidification. The results are shown in Fig. 2, in which the ordinates represent electromotive force, the unit being 0.01 volt, and the abscissæ represents time in minutes from the beginning of the experiment. The temperature gradually increased from 66° C., at which the alkali melted, to

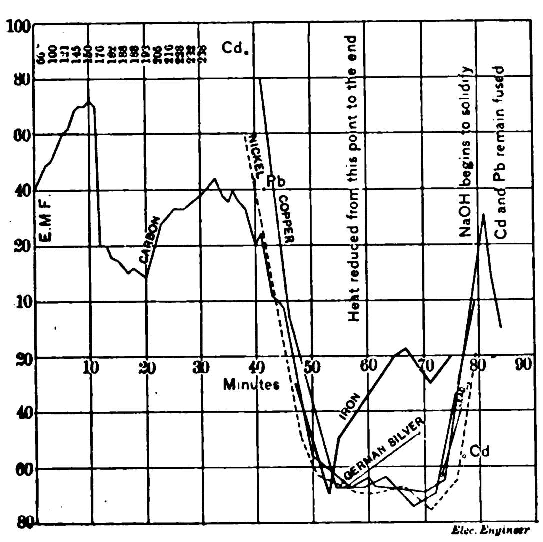

FIG. 2.

nearly a red heat. It was then gradually reduced by turning down the flame and finally removing it.

It is well known that sodic, as well as potassic, hydrate contains considerable water, which, after fusion, is gradually evaporated as the temperature increases, until, at a red heat, the water is nearly, though not quite, all expelled. A mercurial thermometer was used at the beginning of the experiment, the last reading being taken at 238° C., as shown in Fig. 2 at the end of 18 minutes.

In this experiment readings were not taken with the metal rods during the first 38 minutes, the original intention being to use only the carbon rod. The general coincidence, or at least, similarity, of the carbon curve with the metal curves, so far as they were taken, indicates clearly that there is no essential difference between them, and that the seat of electromotive force is the same, whether the rod be of carbon or of metal. The maximum electromotive force obtained from some of the metals is noticeably greater than that obtained at any point from the carbon.

Only two observations with the cadmium rod and three with

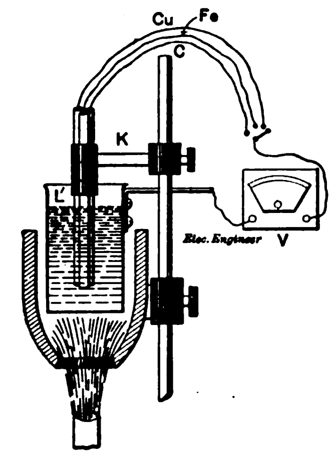

FIG. 3.

the lead rod were made, in all of which the metal melted almost immediately on touching the alkali. The first reading of the cadmium, taken at the thirty-ninth minute, showed it to be positive to the cup and the electromotive force to be 0.9 volt. The second reading at the seventy-seventh minute showed it to be negative to the cup and the electromotive force to be 0.58 volt.

The first reading of the lead rod at the forty-second minute showed the lead positive and the electromotive force 0.4 volt. The second and third readings at the seventy-third and seventy-eighth minutes showed the lead to be negative and the electromotive force to be 0.64 and 0.30.

The reversal of polarity or change from positive to negative at a temperature a little below a red heat is particularly in-

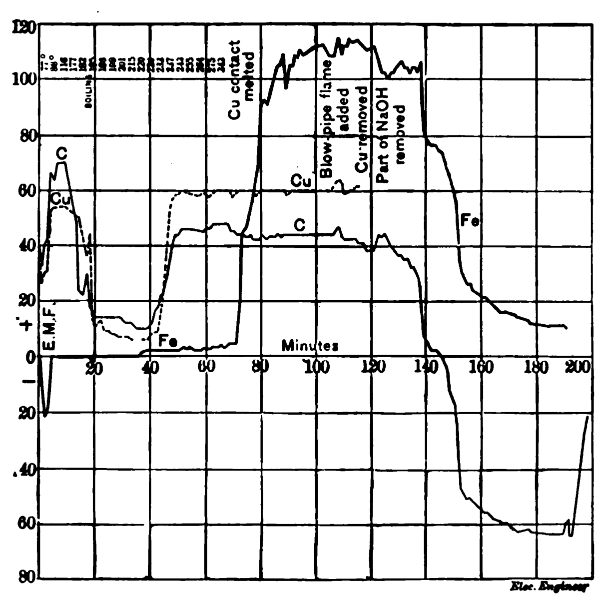

FIG. 4.

teresting and is, the writer believes, a sufficient proof that the action of the cell is thermo-electric and not galvanic. It is in accordance with the thermo-electric behavior of all substances, but cannot be reconciled to any rational theory of galvanic or chemical action. It cannot be possible, therefore, that the energy of the current in the case of carbon is derived from the consumption of the carbon rod. A careful examination of the carbon (arc-light carbon) rod before and after the experiment and also after prolonged use in other

experiments showed not the slightest indication of any change such as combustion would produce. The finest lines on its surface, formed in the process of manufacture, were unaltered by the experiments, and that part of the rod which had been immersed in the alkali could not be distinguished by its appearance from that which had not been immersed.

The curve for the iron rod indicates that the rod and cup, both being of iron, do not constitute the elements of the thermo-electric junction. A reasonable theory would be that the junction between the heated cup and the alkali is the

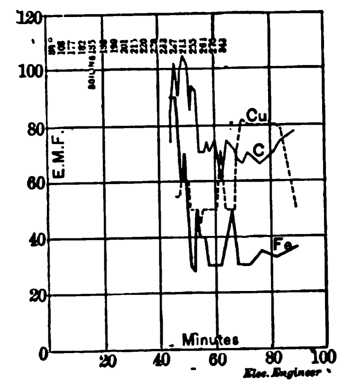

FIG. 5.

thermo-electric junction and that the rod acts merely as a conductor to connect the alkali with the external part of the circuit. On this theory we should expect what we find by this experiment to be the case, namely, that the substitution of rods of various metals for the carbon rod makes no essential difference in the result.

It will be noticed in Fig. 2 that after about forty-five minutes the polarity of all the rods reversed from positive to negative, and that the rate of change of electromotive force at that point was very rapid. After fifty-eight minutes the flame was turned down and the temperature gradually reduced. As the temperature fell the electromotive force also fell, and after seventy-eight minutes the carbon again reversed, becoming positive. It reacned a positive maximum of 0.31 volt and again reversed, being —0.10 when the alkali became entirely solid. The cadmium and lead that had melted off the rods and dropped into the cup still remained fused when the experiment came to an end after eighty-four minutes.

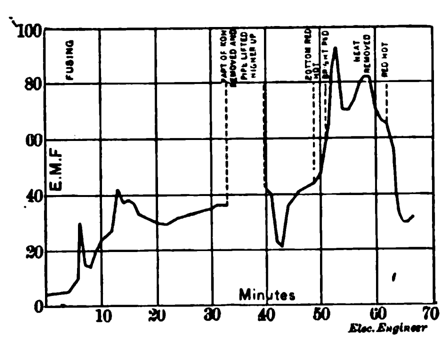

FIG. 6.

During the course of this experiment it was noticed that on dipping the conducting rod into the alkali with the voltmeter connections closed, the deflection of the needle, instead of remaining constant, changed rapidly and irregularly as the end of the rod became hot. The highest reading obtainable was the one recorded and used in constructing the curves of Fig. 2.

In order to compare more accurately the results obtained from rods of different materials and to make the comparison under conditions as nearly uniform as possible, a second experiment was performed with the apparatus shown in Fig. 3. The cup, L, was of sheet-iron, cylindrical in form, 2 inches in diameter and 2½ inches deep. It was filled to a depth of 2 inches with impure caustic potash. The cup was partly inclosed in a plumbago crucible of larger diameter, the bottom of which was removed. The handle of the cup was connected, as in the previous experiment, with one terminal of the voltmeter.

Three rods, one of carbon, one of copper and one of iron, each 12 inches long and ¼ inch in diameter were insulated by sheet asbestos and held close together in a vertical position by a suitable clamp, the lower ends of the rods dipping into the fused alkali. Each rod was connected by a separate wire to one contact piece of a three-point switch connected to the voltmeter, as shown in Fig. 3, in such a manner that connection through the voltmeter could be rapidly changed from one rod to another.

The alkali was first fused in the cup and allowed to cool. The rods were then brought in contact with the solid mass and the flame of the Bunsen burner was applied. The copper and carbon rods indicated a positive electromotive force immediately, which increased until the alkali fusea, when it reached 0.40 volt and the temperature of the mass was 77° C.

From that point a reading was taken every minute from each of the three rods, the contacts being made in rapid succession, first with the carbon, next with the copper, and then with the iron. At the end of forty-eight minutes the water was nearly all expelled and the fused mass became quiet. At the same time the temperature began to rise rapidly. The last reading of the thermometer taken at thirty-eight minutes was 343° C. After seventy minutes the solder joining the top of the copper rod to the conducting wire melted and contact was afterward made by hand.

At 104 minutes the blowpipe flame was substituted for the Bunsen burner; but it was found that the temperature could not be further increased on account of the rapidity with which the heat was conducted away by the copper rod. The copper rod and a part of the alkali were, therefore, removed a few minutes later. The temperature then rapidly rose to a bright red heat, while the electromotive force of both the carbon and the iron fell, the carbon reversing and attaining a negative maximum of 0.65 volt. The results are graphically shown in Fig. 4.

The curves show that the highest electromotive force was produced by the iron rod and that at a certain temperature a little below a read heat it gave 1.15 volt.

This remarkable electromotive force can be due only to the difference in temperature between the two junctions of the alkali and iron the lower and hotter junction being that of the alkali and iron cup, the upper and colder junction being that of the alkali and iron rod. The difference of temperature between these two junctions could not under the circumstances have been very great, probably not over 100° C., and possibly very much less. Hence, the thermo-electric power of this junction between iron and alkali must be enormous, compared with that of thermo-electric couples composed of any two metals.

During the interval between the forty-fourth and the eighty-ninth minute observations were also made by momentarily dipping into the alkali cold rods of copper, iron and carbon. These readings, when compared with the simultaneous readings of the hot rods, show that the electromotive force is greater with the cold than with the hot rods. Curves from the readings of the cold rods are shown in Fig. 5.

The average of all readings for each of the hot and for each of the cold rods taken during this period is given in tabular form below.

	Hot.	Cold.
Carbon.	.41	.80
Iron.	.14	.42
Copper.	.57	.58

While these figures should be relied upon only as a qualitative guide, they are sufficient to show that the greater electromotive force is obtained with the cold rods; or that the electromotive force is increased by increasing the difference in temperature between the upper and lower junctions.

The blast of air used by Dr. Jacques undoubtedly contributed towards increasing this difference in the temperature, and, hence, the electromotive force of his battery. The writer found also that a jet of illuminating gas has the same effect. This would seem to dispose of the theory that the electromotive force is a result of an oxidizing effect of the injected air upon the carbon rod.

In the third experiment the apparatus shown in Fig. 3 was used, the rods being replaced by a long piece of iron gas-pipe which was bent into a narrow U, the bottom of the U dipping into the alkali. A blast of cold air was continually blown through the pipe and pure caustic soda was used. The results are shown in Fig. 6.

At the end of half an hour it was found that a red heat could not be obtained, even by using the blast-lamp, on account of the cooling effect of the air passing through the iron pipe. The electromotive force reached only 0.40 volt. A por-

tion of the sodic hydrate was, therefore, removed and the gas-pipe was raised up until it barely touched the fused caustic. The temperature then rapidly increased to a bright red heat and the electromotive force rose to 0.94 volt, the highest that could be obtained. In this experiment, as in the previous one, the iron pipe remained positive to the cup; while in the first experiment the iron rod became negative at a high temperature.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

PROF. STOLETOW.—Obituary with a list of his chief electrical papers.—London "Electrician," July 3, 1896. "Electrical Engineer," July 22, 1896.

WILLIAM SELLERS.—Biographical sketch with portrait.—"Cassier's Magazine," July 1, 1896.

Central Stations:

SOME CENTRAL STATION ECONOMIES.—By P. G. Gossler. Paper read before the Canadian Elec. Ass'n. The paper deals principally with results obtained from the partial reconstruction of a large plant.—"Electrical Engineer," July 8, 1896.

MUNICIPAL OWNERSHIP OF ELECTRIC AND GAS PLANTS.—By Allen R. Foote. Paper read before the Convention of Street Lighting Officials, New Haven, Conn., June 18, 1896. Arguments against municipal ownership. "Elec. World," July 11, 1896. "Electrical Engineer," July 15, 1896, et seq.

THE CENTRAL STATION IN GRAZ.—By Josef Pojatzi. Details of plant, describing the generating plant, distribution network, street lighting. "Zeitschr. f. Elektrotechn," July 1, 1896.

ELECTRICAL INSTALLATION AT ODESSA.—By Alexander Branner. Short description of installation. The plant was built by the city, run at a loss, was then leased to a private company and will go back to the city after 15 years. "Zeitschr. f. Elektrotechn," July 1, 1896.

Dynamos and Motors:

PHENOMENA OF COMMUTATOR RESISTANCE.—By H. J. Edsall and M. C. Rorty. Abstract of a thesis, Cornell Univ. Description of method, with summary of results obtained. "Electrical Engineer," July 8, 1896.

STUDY OF A THREE-PHASE MOTOR.—By C. W. van Law and H. S. Simpson. Abstract of a thesis, Cornell Univ. "Electrical Engineer," July 8, 1896.

THE DIRECT-COUPLED GENERATOR AT STOCKWELL POWER STATION.—Detailed description with elevation, partly in section, of the Willans-Siemens direct-coupled railway generator plant at the Stockwell station of the City and South London Railway.—London "Electrician," July 3, 1896.

POWER FACTOR.—An explanation of its significance in actual practice.—London "Elect. Review," July 3, 1896.

Educational:

SCIENCE AND ENGINEERING.—By Thomas Curtis CLARKE, President Am. Soc. C. E. Author shows the necessary relations between science and engineering. "Railroad Gazette," July 10, 1896.

Electro-Chemistry:

DIRECT PRODUCTION OF ELECTRICITY FROM COAL.—By G. H. Stockbridge. Author reviews Dr. Jacques' method, mentions the work done by his predecessors in this field of research, but mentions that the efficiency noted for the Jacques apparatus is the efficiency of the generating cell, irrespective of the expenditure of heat for maintaining the cell at a suitable temperature, and of power in running the air pump which supplies it with oxygen.—"Engineering Magazine," July, 1896.

TRANSFORMATION OF THE ENERGY OF CARBON INTO OTHER AVAILABLE FORMS.—By C. J. Reed. Paper read before the Franklin Institute, May 26, 1896. A review of all principal methods, known at the present time for converting the energy contained in carbon into the numerous forms of energy that are directly available to man.—"Electrical World," July 11, 1896, "Journal of Franklin Institute," July, 1896, "Electrical Engineer," July 15, 1896.

Electro Physics:

ADMITTANCE AND IMPEDANCE.—By F. Bedell, Ph. D. Paper read at the meeting of the Physical Society, June 26, 1896. Author discussed the application of the mehtod of vector diagrams to the solution of questions connected with alternating currents. He shows how, by a consideration of the loci of the different lines on such a diagram, many problems may be solved simply.—London "Engineering," July 3, 1896.

PROPERTIES OF A BODY HAVING A NEGATIVE RESISTANCE.—By S. P. Thompson. Paper read before the Physical Society, June 26, 1896. Author discusses observations made by Frith and Rodgers in a paper read at a previous meeting. A number of prominent engineers took part in the discussion.—London "Engineering," July 3, 1896.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES.—By J. A. Fleming, M. A., F. R. S. A discourse delivered at the Royal Institution, June 5, 1896. Results of investigations made conjointly with Prof. Dewar during the last four years.—"Electrical Engineer," July 8, 1896, et seq.

Lighting:

INTERVIEW WITH MR. C. P. FELDMANN, OF COLOGNE, ON ELECTRIC LIGHT MAINS.—Some opinions on underground mains.—London "Electrical Engineer," July 3, 1896, et seq.

A PRACTICAL EXPOSITION OF ELECTRIC LIGHTING.—By W. A. Anthony. A discussion of Prof. F. B. Crocker's recent book on Electric Lighting.—"Engineering Magazine," July, 1896.

ON THE CAUSE OF CONTINUOUS SPECTRA IN EXHAUSTED TUBES.—By Dr. W. H. Birchmore. Writer has among his collection of vacuum tubes a particular one which presents remarkable phenomena when subjected to the action of an electric current. These are light phenomena and are described in detail in "Electrical Engineer," July 8, 1896.

SOME FAULTS IN ARC LAMP CARBONS.—By W. M. Stine. Author mentions some troubles found in carbons, but finds that unsatisfactory working often lies in the lamp. Iron and silicon should never be in the carbons.—"Electrical World," July 11, 1896.

ELECTRIC LIGHTING ON THE STEAMER ADIRONDACK.—A compound wound 50 kilowatt generator is directly coupled to the engine. Two large and one small units are installed. Total capacity is 1,750 lights and 1,300 are in constant use.—"Electrical World," July 11, 1896.

ELECTRIC STREET LIGHTING.—By M. J. Francisco. Abstract of a paper read June 19, 1896, before the Convention of Street Lighting Officials, New Haven, Conn. A discussion on municipal ownership, giving results observed in different places.—"Electrical World," July 11, 1896.

ARC LIGHTING FROM ALTERNATING CURRENT LIGHTING STATIONS.—By Frank Lewis. Author points out the advantages of this method, such as the independence of each lamp, and compares the alternating with continuous current arc.—London "Electric Review," July 3, 1896.

Magnetism:

IRON-ANTIMONY ALLOYS.—By Pierre Weiss. Communicated to Soc. Franc. de Phys. These alloys hold a position between the large class of feebly paramagnetic bodies and the group of iron and nickel combinations having strong magnetic properties. Hysteresis diagrams were made with a view of comparison with the Steinmetz formula and found to agree well in some cases, but for an alloy of 53 per cent. of iron the exponent was about 2.17, this figure falling gradually to the standard as the proportion of iron increased. Short Abstract in London "Electrical Engineer," July 3, 1896.

Measurements:

CALIBRATION OF SLIDE WIRE BRIDGD.—By A. C. Benecke. Description of a simple method.—"Electricity," July 8, 1896.

RESISTANCE OF THE ARC.—By Prof. W. E. Ayrton. A letter in connection with Prof. Thompson's paper on negative resistance. The writer disagrees with Prof. Thompson and quotes communications by Mrs. Ayrton on the subject. Prof. Thompson's answer follows the letter.—London "Electrician," July 3, 1896.

Mechanical:

ELECTRIC FIRE ENGINE.—By Chas. Brezol. This consists essentially of a force pump of the usual type, driven by a two-pole motor, geared down to give the necessary speed re-

duction. An illustrated description appeared in "L'Energie Electrique," and reference to it is made in the London "Electrical Engineer," July 3, 1896.

Railways:

STATION FITTINGS.—By Philip Dawson. In the series on "Electric Traction." Author has arrived at the discussion of switchboards, describing the instruments to be placed thereon, the requirements for a testing room, and closes with a discussion on the protection of telephone and telegraph wires.—London "Engineering," July 3, 1896.

RAILWAY BLOCK SIGNALLING.—By J. Pigg. Writer traces the Block system from its beginning and discusses signals for ordinary working, for emergencies, and for special purposes.—London "Electrical Engineer," July 3, 1896, et seq.

ELECTRIC TRACTION.—By R. St. George Moore. A review of its application and a comparison with other methods. —London "Electrical Engineer," July 3, 1896.

BRIDGES FOR ELECTRIC RAILROADS.—By Chas. F. Stowell, C. E. A warning to railroad companies, and some figures to show the amount of weight a bridge has to stand if it is used to carry motor cars.—"Railroad Gazette," July 10, 1896.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JULY 14, 1896.

Alarms and Signals:—

ANNUNCIATOR SYSTEM FOR BUILDINGS. J. M. Arthur, Detroit, Mich., 563,724. Filed April 1, 1896.
Means for indicating at a central station such as an annunciator whether each door in the building is locked or unlocked.

AUTOMATIC FIRE ALARM SYSTEM. J. Young, Chicago, Ill., 563,832. Filed Aug. 8, 1895.
Two circuits extending throughout the district to be protected, signal devices in each circuit, and means for intercepting a signal when but one of said signal transmitting devices is operated.

RAILWAY SIGNAL. C. Hansel, Easton, Pa., 563,924. Filed Dec. 4, 1895.
Means for indicating at the signal station the position of the semaphore.

SPEED AND DIRECTION INDICATOR. G. A. Tower, Richmond, Va., 564,168. Filed March 21, 1896.
Adapted for use on shipboard to positively indicate in the pilot house the direction in which the propeller is turning.

Conductors, Conduits, and Insulators:—

ARMORED INSULATING CONDUIT. R. T. Elwell, Hyde Park, Mass., 564,174. Filed Jan. 28, 1896.
Consists of a metallic armor tube, and an inclosed insulating tube of pliable rubber having sufficient hardness to retain its tubular form and resist fracture when bent.

Dynamos and Motors:—

ROTARY TRANSFORMER. E. Thomson, Swampscott, Mass., 563,895. Filed Dec. 21, 1893.
Means for self-regulation.

DYNAMO ELECTRIC MACHINE. W. Cooper, Schenectady, N. Y., 563,911. Filed April 18, 1896.
A field magnet structure provided with laminated pole-pieces, certain of the laminæ being of less extent than others.

DYNAMO ELECTRIC MACHINE. A. L. Parcelle, Boston, Mass., 563,940. Filed Jan. 7, 1896.
The combination, with an alternating current generator, of a synchronous rotary transformer, and a two-part commutator, which is connected to the secondary of the said transformer.

Electro-Metallurgy:—

COATING METALS BY ELECTROLYSIS. H. Alexander, Berlin, Germany, 563,723. Filed July 31, 1895.
Composed of a solution of from five to eight parts of commercial chloride of aluminum, containing free acid in 100 parts of water, and of so much of reguline coating metal as will dissolve therein, while the bath is heated to the boiling point, and from two-tenths to three-tenths of a part of chloride of the coating metal.

Lamps and Appurtenances:—

ELECTRIC ARC LAMP. J. C. Knight, Roselle, N. J., 563,773. Filed Nov. 21, 1895.
Shunt-controlled feed mechanism.

ELECTRIC LAMP STAND. W. D. Gridley, Brooklyn, N. Y., 563,922. Filed Feb. 19, 1896.
Details of construction.

ELECTRIC LIGHT FOR COLD STORAGE ROOMS. D. B. and R. H. Hawes, Springfield, Mass., 563,960. Filed May 22, 1896.
Lamp is lighted by opening door of room and extinguished by closing same.

ELECTRIC HEADLIGHT FOR STREET CARS. A. C. Thompson, St. Louis, Mo., 564,036. Filed Aug. 26, 1895.
Details of construction.

Measurement:—

INSTRUMENT FOR MEASUREMENT OF ELECTRIC RESISTANCES. S. Evershed, London, England, 563,917. Filed Feb. 6, 1896.
Consists of a cross-shaped magnetic needle system of soft iron, the lower vertical limb of which is adapted as a tube to receive an internal supporting pin, in combination with surrounding exciting coils, to form an astatic needle.

Miscellaneous:—

ELECTRIC HEATER. C. H. Minchew, Taunton, Mass., 563,780. Filed Nov. 19, 1895.
Embodies a series of parallel longitudinal heating coils embedded in non-conducting packing.

THERMOSTAT. L. G. Woolley, Grand Rapids, Mich., 563,831. Filed June 24, 1895.
Means for mechanically removing any corrosion from the point of contact of the electrodes.

METHOD OF AND APPARATUS FOR REGULATING TEMPERATURE OF ELECTROLYTES. R. Kroseberg and E. Straub, Berlin, Germany, 563,912. Filed July 13, 1893.
Consists in passing a continuous current of a regulating fluid in contact with a series of hollow electrodes connected with the opposite poles of the source of electricity, each electrode thus forming both anode and cathode.

PROTECTIVE APPLIANCE FOR ELECTRICAL APPARATUS. A. De Khotinsky, Boston, Mass., 564084. Filed May 5, 1896.
Consists of a rod of carbon forming a part of the circuit and held by a spring in tensile or longitudinal strain and means whereby the circuit is opened and grounded when the rod is volatilized.

PROCESS OF AND APPARATUS FOR AGING BEER, WINE, ETC. F. C. Wiedring, Chicago, Ill., 563,130. Filed June 11, 1894.
Employs a mass of small pieces of metal arranged in the bottom of the receptacle and in contact with each other, so as to form a closed electrical circuit, and a source of electricity electrically connected with said mass of metal.

HYDROCARBON BURNER. E. G. Mummery, Detroit, Mich., 563,398. Filed Jan. 25, 1896. Issued June 30, 1896.
Details of construction.

ELECTRICAL PROGRAM-CLOCK. Andrew J. Reams, Chicago, Ill., 563,883. Filed Nov. 20, 1895.
Details of construction.

ELECTRIC-GENERATOR ATTACHMENT FOR DENTAL ENGINES. Claude L. Woolley, Baltimore, Md., 563,995. Filed May 18, 1896.
The combination of the drive-pulley of a dental engine, the standard of said engine, and electric generator supported by said standard and having a revoluble armature, which is driven by contact with said drive-pulley.

Railways and Appliances:—

TROLLEY WHEEL. W. C. Cottrell, Asbury Park, N. J., 563,749. Filed Aug. 28, 1895.
Consists of a larger and a smaller wheel with ball bearings between the two.

TROLLEY FINDER. H. H. Blanchard, Augusta, Me., 563,998. Filed Sept. 24, 1894.
Flaring arms are fastened to the shaft on which the wheel revolves and are brought into an upright position by a suitable cord or pulley down the trolley below the wire.

ELECTRIC RAILWAY SYSTEM. D. M. De Witt, Morrillton, and W. K. Elliott, Little Rock, Ark., 564,054. Filed Jan. 29, 1896.
Conductors are laid in conduits along the track, normally insulated therefrom, and contact is made through devices operated by moving cars.

POWER GEARING FOR ELECTRIC CARS. E. A. Sperry, Cleveland, O., 563,425. Filed June 9, 1894. Issued June 30, 1896.
Comprises a motor, the running gear of the car, power-driving connection from the motor to the running gear, and inclosing housing for the connection, consisting of two independent casings, one only mounted upon the axle, and the other mounted upon the motor supporting bar.

BRAKE FOR ELECTRIC CARS. Walter V. Ash, Irvington, N. J., 563,725. Filed Aug. 5, 1895.
The combination with the car and brake operating means, of a connecting-rod and two shoe-sections, one to engage the track and other the wheel, said sections being pivoted to one another and to said connecting rod.

AERO-ELECTRIC AUTOMATIC BRAKE. Charles Luyers, Brussels, Belgium, 563,934. Filed Sept. 29, 1894.
Employs electric relief-valves.

Regulation:

SPEED REGULATOR FOR DYNAMOS. C. E. Scribner, Chicago, Ill., 563,317. Filed Dec. 10, 1888. Issued June 30, 1896.
Embodies a driving shaft for rotating the armature, a variable speed connection between said driving shaft and said armature and means operated by the variation of the pull upon the armature for automatically changing the speed with which said variable speed connection drives the armature.

Switches, Cut-Outs etc.:—

CIRCUIT-CONTROLLING DEVICE. J. H. Clark, Boston, Mass., 563,743. Filed Jan. 29, 1892.
Provides a single set of resistance contacts so connecting the regulating member thereof with the operating shaft that the said regulating member will be moved in the same direction over a single set of resistance contacts by movement of the operating shaft in opposite directions.

Telegraphs:—

PRINTING TELEGRAPHY. J. J. Reifgraber, St. Louis, Mo., 564,101. Filed July 30, 1895.
Details of system.

Telephones:—

TELEPHONE SYSTEM. W. R. Patterson, Chicago, Ill., 563,877. Filed Jan. 21, 1896.
In a substation telephone system means for sounding a signal when the subscriber hangs up his receiver and has neglected to return his plug to his individual spring jack.

TELEPHONE SYSTEM. A. Graham, London, England, 563,920. Filed May 3, 1894.
Obviates the use of call bells.

TELEPHONE TRANSMITTER. H. A. Martin, Hartford, Conn., 563,935. Filed Nov. 13, 1895.
Comprises a chambered body, a diaphragm, a movable member in the chamber of said body, and two non-mixable conducting fluids in said chamber, one of said fluids being supported by and resting on the other fluid.

TELEPHONE EXCHANGE APPARATUS. J. J. Carty, New York, 564,173. Filed Nov. 17, 1887.
Details of construction.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

MAGNETIC BLOW OUT CUT-OUT BOX.

The magnetic blow out principle with which we are familiar in the street car controllers, automatic circuit breakers and lightning arresters has been recently applied to the smaller currents. In the form "H" cut-out box, shown in the accompanying engravings, the General Electric Company has provided a cheap and simple means for the protection of direct current generators and other apparatus against the destructive effects of overload and short circuits, provided the current does not exceed 600 volts and 100 amperes. It may be fitted with fuses of any capacity from three amperes to 100 amperes, and any arc which may occur is instantly extinguished. Under test this cut-out box even handled a short circuit of 2,000 amperes at 500 volts, extinguishing the arc instantaneously.

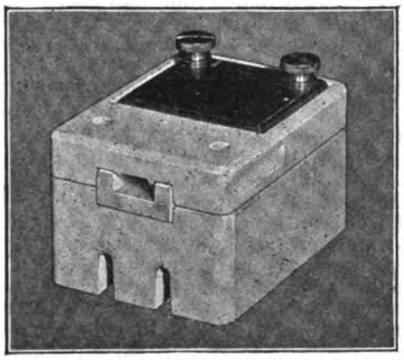

Fig. 1.—The G. E. Magnetic Blow-Out Cut-Out.

The box is of porcelain 5¾ inches by 4¼ inches by 4 inches thick. The fuse is secured in the cover and when the cover is in position rests in a closed chute. The base of the box contains a small electromagnet in circuit with the fuse having its magnetic circuit continued by the iron plate on the cover and by the iron screw posts. The magnetic lines are thus compelled to pass across the space containing the fuse, maintaining a strong magnetic field in the chute when the current is flowing. At the blowing of the fuse the arc which starts finds itself in a powerful field and is immediately extinguished.

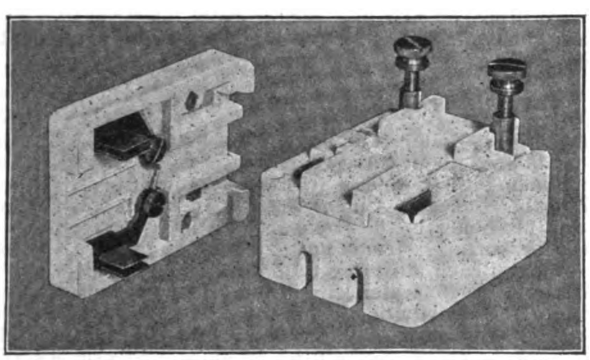

Fig. 2.—The G. E. Magnetic Blow-Out Cut-Out.

ELECTRIC VEHICLES AT CHICAGO.

ELECTRICALLY propelled carriages are being sold and rented by the American Electric Vehicle Company, of 447 Wabash avenue, Chicago. They are turning out handsomely finished vehicles, furnished with storage batteries and motors and especially devised braking and steering gears. Henry Potwin is president, F. S. Culver vice-president, C. E. Corrigan general manager and treasurer, and C. E. Woods secretary. They have completed for use an electric mail phaeton which has an equipment of two 2 horse-power motors at a normal working rate which can be momentarily run up to 6 or 7 horse-power. The motors are connected, one on either hind wheel, independently, and are run in series or parallel, giving variations of speed. The special feature of these motors is that they are dust and water proof, and are especially designed for this class of work. The battery equipment consists of thirty-two 180 ampere-hour cells, made by the Syracuse Storage Battery Company, which are grouped in series or parallel by a controller, and, working in conjunction with the motors, make possible five different speeds.

The vehicle is supplied with two brakes—one a band brake applied to the sheave on the shaft of the sprocket wheel, the other an emergency brake which operates directly on the tires. The arrangement of the mechanism in the latter brake is such that the act of putting it on not only cuts the current off from the motors, but automatically sets the controller back to the starting point. The maximum speed of the vehicle is 15 miles an hour. The batteries weigh 1000 pounds and will give a continuous 6 or 7 horse-power service.

THE CARBON ELECTRIC GENERATOR CO.

The Carbon Electric Generator Company, which has taken over Dr. Jacques' inventions for obtaining electricity directly from coal, has been organized, with a capital stock of $5,000,000. Mr. William H. Forbes, formerly president, and now a director and member of the executive committee of the American Bell Telephone Company, is president. The directors are Mr. Forbes, Mr. C. P. Bowditch (also a director and member of the executive committee of the American Bell Company), Messrs. F. G. Webster and Robert Winsor, of the banking house of Kidder, Peabody & Co.; Dr. W. W. Jacques, and Mr. Charles A. Stone. Mr. W. Cameron Forbes is treasurer. The executive offices are at 95 Milk street, Boston, and the engineering department, which is in charge of Dr. Jacques, is at 104 Milk street.

While the invention has been made and a broad patent for it granted, and while it is clear that the first cost of the generator is far less than that of equivalent steam boilers, engines and dynamos, and careful tests, show that the fuel consumption and attendance required are very small, there are still many details to be worked out before the generator can be put into commercial use in a large way. Extensive laboratories have been equipped and a corps of experts is now engaged in developing the invention so that it may meet the requirements of the various commercial purposes for which it is suitable to be used.

NEW FACTORY OF THE BEACON LAMP CO.

The Beacon Lamp Company, of Boston, are building, at New Brunswick, N. J., a new brick lamp factory, 200 x 100 feet, two and a half stories high. Their business has increased to such an extent that their present quarters are entirely too small. The reasons for moving to New Brunswick are the excellent shipping facilities which that place affords, and the company's increased export trade which is generally shipped from New York. They expect to be in their new building about September 1.

THE F. W. OLIVER CO.

The F. W. Oliver Co., of Niagara Falls, have just installed lighting plants in the plant of the Niagara Paper Company and also in the mill of the Traders' Paper Company, both of Lockport, N. Y.

The Oliver Company have received a contract for a 60 horse-power slow speed motor to be connected to the refrigerating apparatus of the Niagara Falls Brewing Company. This motor will be operated from the new generators of the Cliff Paper Company until such time as the new power plant of the Niagara Falls Hydraulic Power and Manufacturing Co. is in operation.

THE STANDARD UNDERGROUND CABLE COMPANY are determined to place themselves in a position where they can handle a contract for any character of installation with the least possible delay. For years they have been able to successfully undertake any contract for installing underground cables of high character, except conduits for rubber-covered wires and cables. Appreciating the importance of meeting every possible demand on the part of the electrical public, a large addition to their already extensive factories has been erected, and a complete modern plant for insulating wire and cables of all descriptions with rubber has been installed therein. This branch of their business has met with unexpected approval on the part of customers, and the high character of the product will undoubtedly steadily increase the output. The arrangements for testing the wires are particularly complete, and the care exercised in this department insures the production of absolutely perfect insulation, or the discovery of any faults before the wire leaves the factory.

NEW YORK NOTES.

WENDELL & MACDUFFIE, 26 Cortlandt street, New York, have just finished the installation of motors, wiring and lighting in V. Henry Rothschild & Co.'s shirt factory, at Trenton, N. J. This work consisted chiefly of the installing of a 60 kilowatt Thompson-Ryan dynamo, manufactured by the J. H. McEwen Manufacturing Company; eight E. G. Bernard Co.'s motors, wiring, etc.

THE NEW YORK ELECTRICAL COMPANY, 393 Pearl street, New York, are putting on the market a superior watch case receiver which they quote at 50 cents. It is very strong, made of the finest tool steel, and so highly magnetized that it will hold suspended its own weight. This company manufactures also medical batteries and other specialties in electrical supplies and will take pleasure in mailing catalogues to any address on application.

MR. CYRUS ROBINSON, who for years has occupied the position of manager and engineer of the Jeffrey Manufacturing Company, of Columbus, O., has resigned his position with that company, and has allied himself with the J. H. McEwen Manufacturing Company, in New York, as general manager of the sales department. Mr. Robinson is well known in the East, being well posted on electrical work, and will be welcomed by many electrical workers in this city.

THE GENERAL ELECTRIC COMPANY'S long burning arc lamp is meeting with considerable favor. Several extensive orders have been recently secured, 350 of both the 100 and 150 hour type having been shipped to Hartford, Conn., and nearly 200 to Warren, R. I. The company is also giving considerable attention to the question of mill lighting with these long burning arc lamps, and a large number have recently been purchased for the lighting of several large cotton mills in the South and elsewhere.

THE S. & B. ELECTRIC COMPANY, 72 and 74 Fulton street, New York, though a comparatively new firm in the electric line, are doing a very satisfactory business, owing to personal attention to all matters and prompt shipment of orders. This concern bought out the Mason Electric Exchange in 1895, which was run by Jas. H. Mason, the inventor and patentee of the well-known Mason battery. The S. & B. Electric Company are the sole manufacturers of these cells and also handle a great variety of electric supplies, novelties, etc.

THE "PIONEER" once more claims our attention by a quaint but striking illustration of the arc lamp trimmer on his ladder scattering dust from the old arc lamp. This is one thing which the "Pioneer" certainly spares its users, and it is quite a feather in the cap of the enclosed arc lamp that a pair of carbons will burn 150 hours without attention. This means time and money saved as well as great annoyance avoided.

We are advised that the original advertising of the Electric Arc Light Company has quickly brought the merits of the "Pioneer" to the eyes of electricians and lamp purchasers, and daily the show rooms at 687 and 689 Broadway are thronged with visitors. The genial manager, Mr. Joseph Bijur, assures a hearty welcome to all.

PATTERSON, GOTTFRIED & HUNTER, LTD., the largest general supply house for machinery, metals, hardware, tools, etc., in this country, are well located for their line of business at 146-150 Centre street, New York. This firm occupies four floors of about 23,000 square feet, which, withal, gives them hardly room to carry their enormous and varied stock, suitable for electric light plants, factories, machine shops, etc. Having a force of about seventy employés, they are well prepared and constantly busy filling the many orders, both large and small, for supplies of all kinds from all over the country. Messrs. Patterson, Gottfried & Hunter supply the largest electric plants, factories, etc., and it is safe to say that there is hardly a tool or supply in the market but what they have it in stock, ready to ship on order. This firm will mail price lists and catalogues on application.

WESTERN NOTES.

THE order for the two 40 kilowatt and one 20 kilowatt direct connected multipolar generators with panel switchboard for the Ohio State Hospital at Columbus, O., was awarded to the Triumph Electric Company, of Cincinnati, O., with Buffalo Forge Works engine. Alexander Schulmann, of the same place, secured the contract for wiring.

THE AMERICAN BATTERY COMPANY, 40 West Quincy street, Chicago, have received a handsome bronze medal and diploma, which was awarded to them by the World's Columbian Commission for excellence of design, efficiency, and indications of due ability in the storage batteries which they exhibited at the World's Fair, and was the only award given for exhibits of storage batteries made in this country.

THE ELECTRIC APPLIANCE COMPANY state that they are now in a position to quote specially low prices on Paranite cables of extra large carrying capacity up to a million circular mils. They are also able to make very prompt deliveries, as the nearness of the Indiana Company's factory precludes the possibility of delays in transit. Paranite telephone cables from ten to five hundred conductors are also in large demand, and the Electric Appliance Company have secured a number of good orders.

THE WESTERN TELEPHONE CONSTRUCTION COMPANY have contracted to furnish telephone systems for Sandersville, Ga., Maysville, Ky., Cobbleskill, N. Y., Hot Sprngs, S. D., Cape May, N. J., Auburn, Ind., La Crosse, Wis., and have practically arranged for exchanges at Minneapolis and St. Paul. The La Crosse Telephone Company have purchased a 900-switchboard equipment from the Western Telephone Construction Company. The Keelyn system of central office equipment will be used.

THE CHAS. E. GREGORY COMPANY, South Jefferson street, Chicago, in getting out their July Bargain Sheet, hit upon a novel and effective departure from their regular style. The sheet itself was gotten up in the usual way with the exception of having four alternate heavy red and blue diagonal lines printed across the front cover, which was in itself a sufficient means of attracting notice to it. A short piece of twine being slipped over one end of an inside page with the ends of the twine projecting a little from the other end of the page, the whole being rolled up and slipped inside of a roll composed of Chinese red paper, left to all outward appearances so good an imitation of a fire cracker as to deceive the average small boy until he found out that he was wasting matches in his efforts to get it to go off.

NEW ENGLAND NOTES.

MR. F. WILLIAM ERICKSON, who has for the last twelve years been engaged in electrical construction work with the Edison Company and the Electrical Equipment Company, of New York and in Boston, representing General Electric and Edison interests, is now connected with the Lord Electric Company in Boston. This is only a young construction company, but they have already attained considerable prominence, and in the past year have installed upward of fifty thousand lights. They are prepared to equip entire steam, electric and power plants and have facilities for the engineering and equipment of electric roads.

THE HOGAN BOILER CO.

The Hogan Boiler Company, Middletown, N. Y.., are now established about three years and have been very successful in placing their boilers with many concerns in different parts of the country. Among the many features which have brought this boiler to the front are: No scale accumulates on the heating surfaces, drums not exposed to the heat collecting all sediments; each steaming tube discharges directly into the steam space; each water circulating tube discharges downward into the distributing drums, where precipitation of the impurities takes place. Water flows into the heating tubes as rapidly as steam is produced in them and escapes from them. Steaming tubes are over the fire and are exposed to the direct action of the heat of the fire and of the gases. The water circulating tubes are not exposed to the heat so as to secure downward currents. Steam can be raised in twenty minutes without injury to any part.

Contractor John B. McDonald in ordering a second new 300 horse-power Hogan boiler for the Jerome Park reservoir, New York, summarizes in brief regarding the first in use: "That the 240 horse-power water tube boiler installed by this company at Jerome Park reservoir for an air compressor outfit, is doing excellent work driving a compound condensing Corliss engine, steam cylinder, 24 x 44 x 48; air cylinders 24¼ x 48. The compressor runs, daily, ten rock drills, fifteen hoisting engines and three pumps, with capacity of at least 25 per cent additional service in drills and hoists." Among the many other places these boilers have been installed, constantly in use and never cleaned for scale, etc., may be mentioned the Middletown State Homœpathic Hospital, Middletown, N. Y.; National Starch Works, Glen Cove, L. I.; Franklin Illuminating Company, Sea Cliff, L. I.; Geo. Monroe Publishing Company, 17 Vandewater street, New York City, and many other representative concerns in different parts of the country. The Hogan Boiler Company is a pushing concern and with the many orders to fill, its prospects for the future are exceedingly bright.

Electrical Engineer.

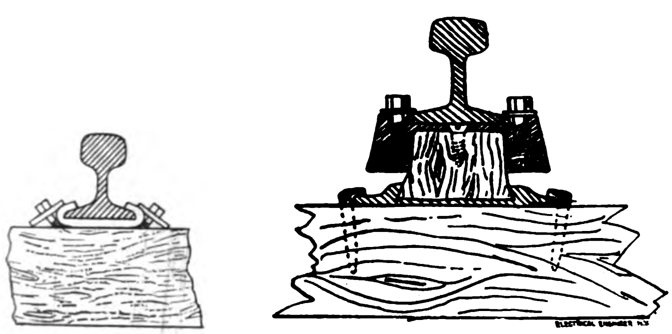
Vol. XXII. AUGUST 5, 1896. No. 431.

Electric Transportation.

THIRD RAIL CONDUCTORS.

BY LEO DAFT.

THE account in The Electrical Engineer of July 1, of the excellent performance of the cars on the Nantasket Beach electric road, recently equipped with a third rail, so vividly recalls the use of similar conducting devices in early electric railroad days, that I venture to relate a few experiences with



Figs. 1 and 2.—Daft Third-Rail Insulators.

third rails as conductors, in the hope that they may not prove entirely uninteresting at the present time.

In October, 1883, I equipped 1.25 miles of the main line of the Saratoga, Mount McGregor and Lake George steam railroad, for experimental purposes, with a 35-pound third rail, placed midway between the service rails of the track, and insulated by means of wood blocks which had been thoroughly baked and plunged into boiling pitch while hot from the baking. The foot of the rail was further protected by sheets of soft rubber curled back over the flange and held by square washers under the head of lags screwed to the block beneath, Fig. 1.

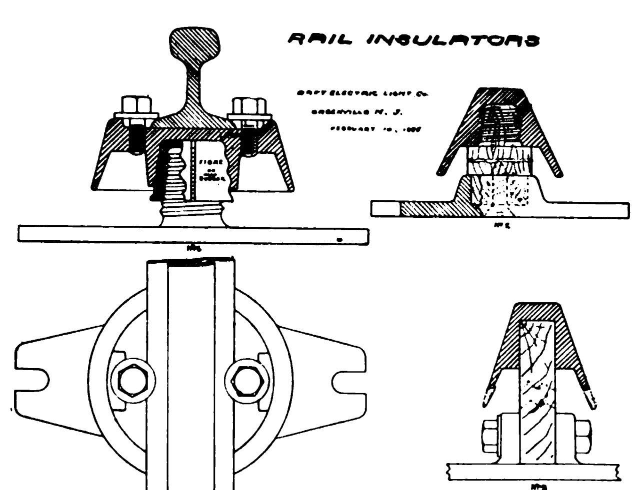
The joints were first prepared by thoroughly cleaning the plates and points of contact underneath, when thin sheets of tinned copper were interposed and the joint firmly made up. This did very well for the middle rail, but the service rails were in such bad condition that we found it necessary to adopt some other method, and I finally decided to drill the foot of each rail on one side of the track and run a continuous copper wire with a turn under the heads of special clamp bolts in the newly-tapped holes. From this ground wire and bond combined a few cross bonds were led to the other service and clamped under freshly cleaned joint plates. It only remained to get the deep rust off the third rail, which was done by hanging a heavy board to the motor so that one end would trail on the track, and after attaching a segment of coarse emery wheel to the under side it was duly weighted and towed back and forth until the desired result was attained. The "weight" at first consisted of a 160-pound man, but I regret to add that after a few trips at dead of night our friend failed to find the novelty of the situation a sufficient inducement to continue the exercise, and a resort to inanimate material became imperative. The "collector" consisted of two bronze wheels, mounted on an iron frame in the form of an X, and capable of independent contact with the rail.

The motor ran over the section so prepared nearly every night for two or three weeks with a pressure of 100 to 130 volts, and, contrary to general expectation, the insulation was not low enough at any time to permit of lighting a 75-volt incandescent lamp, in circuit to third rail with line open, except once, when a 10-inch snowstorm was followed by a quick thaw. This rough test of insulation was applied because the use of galvanometer and bridge was difficult on account of strong local disturbances, and the halcyon days of high resistance Weston voltmeters were yet in the dim future.

I think the next use of the third rail in this country was on the Baltimore and Hampden electric road, which was a trifle over two miles long, in 1885. As this was an example of commercial use, having been ordered and promptly paid for in the ordinary course of business, continuing in daily use for four years, practically on the original lines, it may perhaps be deemed worthy of passing notice. In the spring of 1885 we began placing the 25-pound rail midway between the outer rails of the track, which was situated at the side of the road clear of the ordinary traffic for the greater part of the distance, thus affording a good opportunity for the use of surface conductors; and as the railroad company had some rail in stock they were naturally anxious to use that rather than buy other material which would not be available for renewal, in case of the absolute failure, which nearly all our good friends, and especially one eminent professor of physics, confidently predicted. This latter consideration prevented the use of a special section, which I had previously designed and submitted to the railroad directors, and which bore a very close resemblance to the rail recently laid at Nantasket; in all essential particulars one may say they are identical.

Figs 3, 4 and 5 are exact copies of the original drawing, made by our draughtsman from my sketch, and dated by him Feb. 10, 1885. The specification called for insulation consisting of hard rubber or fibre for Fig. 3, and wood, prepared by baking and boiling in pitch, for Figs. 4 and 5. Fig. 3 was also designed for the Baltimore road, but Fig. 2 was adopted as being cheaper and involving less delay. The turned blocks of wood were subjected to the above described treatment, and were then driven into the dovetailed slot of the iron shoe.

The rail head was completely incrusted with scale and rust, so that some means of cleaning was necessary, and after a dismal failure to reach the desired end with a gang of men armed with new files, I rigged up a coarse emery wheel in a frame attached to free out-board journals on the armature shaft of a small motor, and ran it by belt from the motor. The emery wheel was thus free to describe a circle, of which the



Figs. 3, 4 and 5.—Daft Third-Rail Insulators.

frame and belts were radii, without changing the tension of the belt, and when placed on the front platform of one of the motors, with the emery wheel resting on the center rail and both supplied with current from the track, we found little difficulty in dressing the entire two miles in a few hours so as to afford almost perfect contact. Some fruitless efforts to make

good joints by other means were quickly followed by substantial bonding with tinned copper bonds rivetted into the feet of the rails. So laid, the center rail continued in uninterrupted use until the autumn of 1889, and during that four years two, and sometimes three motors, always with trailers in tow, made daily runs averaging 75 miles each.

It has been stated in one or two well-known books that the third rail on this road was abandoned in favor of an overhead conductor, but the latter was used only at crossings and through the village of Woodberry, in consequence of the frequent complaints of fastidious people who did not like to have their horses knocked down. The rail was protected throughout by a rough wooden guard, but the ingenuity of horses in getting down to it, despite the narrow slot, was past belief.

The potential used was 250 volts, from two compound machines in series. A few preliminary experiments with one of these machines, before the other arrived, occasioned the statement that only 125 volts was used, but save for a week or so, during the cleaning of the rail and other minor operations, the former pressure was employed from beginning to end.

That the insulation was imperfect, goes without saying, but it may perhaps be worthy of note that at no time was it low enough to appreciably increase the load, though occasions were by no means wanting when the hoods of several insulators were actually submerged during the sudden and violent storms peculiar to that region.

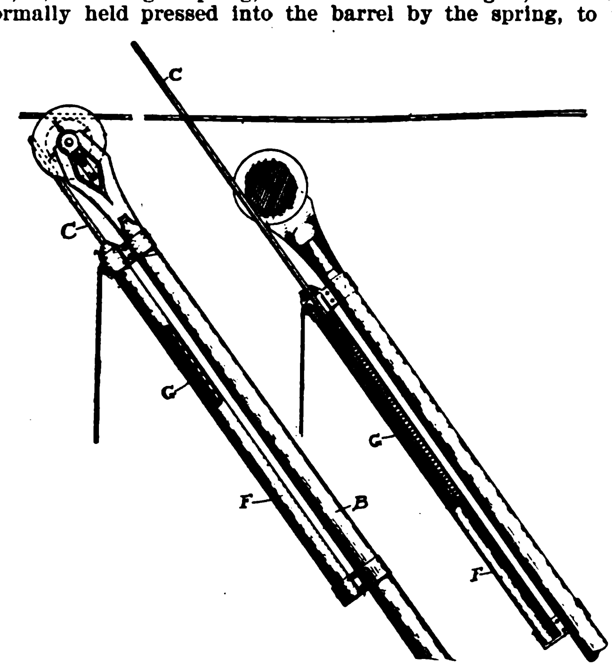
With a hooded rail and suitable wood blocks saturated with creosote by vacuum boiling, there was certainly no occasion to doubt the entire success of the Nantasket test, nor will there be serious trouble on sections of moderate length so insulated, unless much higher pressures than 500 volts be used or melting snow allowed to accumulate for considerable distances.

It now needs no prophet to read "the writing on the wall."

THE OGBORN TROLLEY FINDER.

ONE of the greatest annoyances of electric railroading is that caused by the trolley wheel leaving the trolley wire, and in not a few instances serious accidents have occurred as a consequence. A variety of trolley finders have been devised to rapidly replace the wheel on the wire, but one of the most effective which has come under our notice is that due to Mr. Harrison Ogborn, of Indianapolis, which is illustrated in the accompanying engravings.

As will be seen, it consists of a barrel, F, attached to a trolley pole of the ordinary pattern, which barrel contains a guiding rod, C, and a light spring, G. As shown in Fig. 1, the rod is normally held pressed into the barrel by the spring, to the



A Novel Trolley Finder.

lower end of which the trolley rope is fastened and thence it runs over a pulley at the upper end of the barrel. This guiding rod is projected beyond the trolley wheel by the trolley rope whenever it is drawn upon with sufficient force to draw the trolley wheel down below the overhead conductor. Should the trolley wheel jump the wire or be otherwise displaced, the trolley pole and trolley wheel will spring forward and upward and project the trolley wheel above the conductor wire. When the operator takes hold of the trolley rope to draw the pole and pulley down, the rope will first draw on the lug to which it is attached and by which the rod, C, is projected upward and outward close to and in the rear of the center of the trolley wheel. Then the trolley wheel being further drawn down by means of the trolley rope, until it is below the wire, the pole is swung toward the wire until the rod, C, comes in contact with it, by which the pulley is guided to its proper place, in contact with the trolley wire, as shown in Fig. 2. When the draft on the rope is slackened, the rod, C, is instantly withdrawn out of the way into the case, F, by the force of gravity and the spiral spring.

NEW GENERAL ELECTRIC COMPANY RAILWAY MOTOR, G. E. 1,000.

THE most prominent feature in the development of electric railway work during the past two seasons has been the remarkable increase in the number of suburban and interurban railways, the majority of them operated in conjunction with city lines. As the same cars are operated from the heart of the city into the suburban districts, a street railway motor of a capacity between that of the city and suburban car equip-

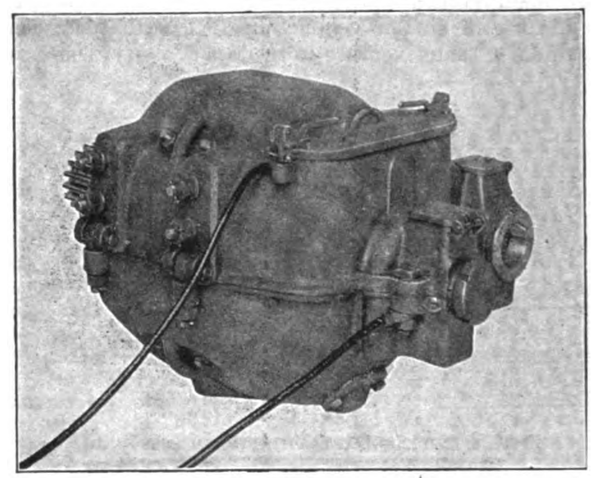


Fig. 1.—G. E. 1,000 Railway Motor.

ment became necessary, and to meet this demand the General Electric Company have designed a motor known as the G. E. 1,000, which possesses some improvements not embodied in the older types. The armature is of the usual iron-clad type with slotted core, consisting of discs of high grade annealed iron, built upon the shaft. The coils are similar in character to those on the G. E. 800 armature with the additional advantage,

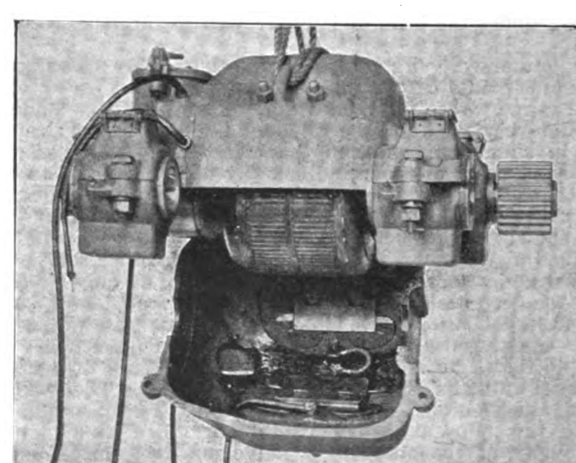

Fig. 2.—G. E. 1,000 Railway Motor.

however, of having the short commutator lead start from the center of the end of the coil to facilitate the removal of the coil in case of repair. With this change in position of the short lead, only half as many coils need be lifted when the armature is undergoing repairs. There are 93 coils in all, with four turns

per coil; the diameter of the armature is 14½ inches and its weight 570 lbs.

Two bowl-shaped castings hinged and bolted together form a strong water-tight frame of a type which has never been broken. The lower half can be lowered into the pit, being hinged at the front to the upper half suspended from the axle and a suspension yoke. A hand hole in the bottom of the frame, under the commutator allows any foreign matter to be easily removed. This opening has a cover suitably fitted so as in no way to impair the water tightness of the motor. The weight of the top field complete is 884 lbs., of the bottom field 495 lbs.

The field coils are interchangeable and four in number, secured by an extension of the pole piece secured in turn by two bolts passing through the frame. One particular advantage of having four coils is that any heating is distributed over a greater surface.

The commutator is constructed without bolts, the clamping ring being held in place by a ring nut and no chance given to oil or other substance to work itself underneath the segments. The surface of the commutator is grooved where the commutator leads are connected in such manner as to form an ear. The advantage of this in case of repair to the armature when removing the leads is obvious. Ninety-three bars of hard drawn copper, with one-inch allowed for wear are used. The diameter of the commutator is 8¼ inches.

The brush holder is a modified form of that used in the G. E. 800, the brushes being held radially, and the yoke being treated with a special insulating compound with enamel finish to insure cleanliness and freedom from leakage.

The gear reduction is 3.94 to 1 and consequently gives a low armature speed with its advantages.

The suspension of the G. E. 1,000 motor is somewhat similar to that used with the W. P. 50, but differs from it in that the bar is bolted to the nose of the motor and its ends carried backward toward the axle and attached to the truck frame at points in line with the armature shaft. As this axle is virtually the centre of weight of the motor, the suspension balances the motor, and gives an effect equivalent to the side bar suspension. This method is termed the "yoke" suspension. The yoke supporting an ordinary church bell is a comparison in kind, but not in degree since the church bell is only partially balanced while in the "yoke" suspension the same idea is carried out to a perfect balance. The axle bearings are relieved of the greater part of the weight, and the hammer blow on tracks reduced to a minimum. The motor practically rests upon springs. The total weight of the motor is 1,950 lbs.

The accompanying diagram illustrates graphically the performance of the motor, showing the speed, horizontal effort and efficiency. The efficiency curve is especially worthy of note indicating that the efficiency runs above 75 per cent. between 20 and 100 amperes. The horizontal effort is also shown to increase almost exactly in direct ratio to the current applied.

PENNSYLVANIA R. R. TO POSTPONE ELECTRICAL EXPERIMENTS.

It is stated by the Philadelphia "Press" that in all probability it will be some time before the Pennsylvania Railroad Company does anything further with electricity. It now has one line, that from Burlington to Mount Holly, in operation, but owing to a number of details which have not been supplied by the electrical apparatus manufacturers the test which was to have been made some time ago has been delayed. This road is giving satisfaction, as far as the service goes, but owing to there not being enough traffic to run the trains at more frequent intervals the cost of operating is greater than it would be if the service were greater.

There was considerable talk last year about the company

making the Camden and Atlantic Railway a trolley road, and the matter was so far discussed by the directors and officers of the company that an estimate was made of the cost of operating an electric road from Camden to Atlantic City. It was found that if the present system of electricity was adopted that the cost of operating would be greater than if the road were operated by the old steam locomotive, unless the trains were run at frequent intervals. It was also found that if the trains were run every half hour that the cost would be greater than it is now.

Electric Lighting.

THE KINCAID ARC LAMP REFLECTOR.

In street lighting it is required that the streets only be lighted, and the remainder of the light which shines upon the interiors of the blocks, or would, were it not for trees, houses, or other obstructions, and which represents the greater portion of the light, is practically lost. It is quite evident that if this wasted light could be directed upon the streets, the degree of illumination as well as the range would be greatly extended.

To accomplish this purpose Mr. W. H. Kincaid, of Santa Barbara, Cal., has invented a special arc lamp reflector, the nature of which will be readily understood by an inspection of the plan view, Fig. 1. This type is adapted to a lamp intended to light two streets intersecting at right angles. Should the streets intersect at any other angle the reflectors are set accordingly. In cases where a street branches, only three reflectors will be required.

The engravings, Figs. 2 and 3, show the reflector complete when closed and open, respectively. The reflecting wings are silvered or nickeled metal plates fastened to the curved supports. These supports are shaped to a parabolic curve, excepting about an inch of each end, which is curved in such a manner that the rays of light from those parts of the reflectors will be scattered. The object of this is to light the triangular shadows that would otherwise exist near the lamp; the distance not being great, a small amount of light will suffice. The reflectors with their curved supports are fastened to two semicircular curved arms hinged one at each end of a curved bar, which latter is clamped to the lamp frame.

To the back of each reflector is hinged a light metal frame holding a sheet of glass extending across to the reflecting face of the adjacent reflector. This is to protect the arc from the wind.

A suitably constructed ground glass half globe (not shown)

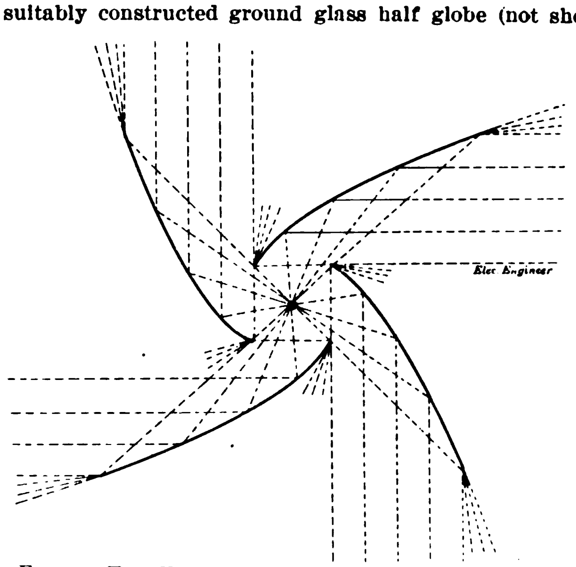

Fig. 1.—The Kincaid Street Arc Lamp Reflector.

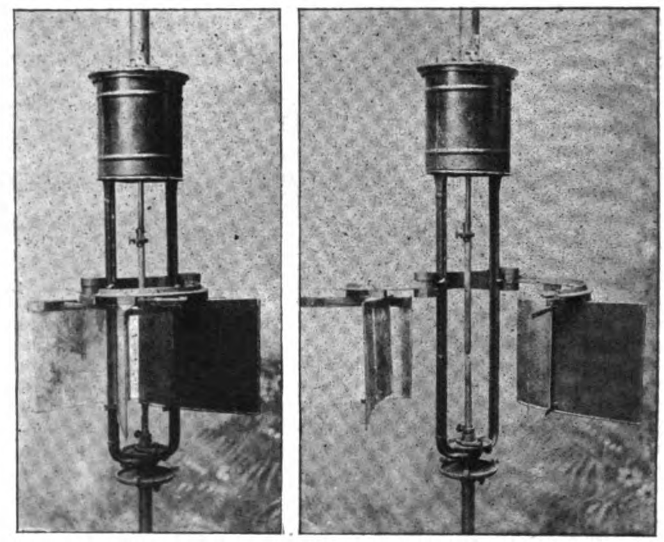
is held by the globe-holder close up under the reflectors, the object of which is to diffuse the light and to tone down the shadows under the lamp cast by the lower edges of the reflectors. These reflectors can easily be adapted to double carbon lamps.

The model which the inventor used was roughly constructed of wood and tin. The lamp to which it was attached was hung in the center of two intersecting streets at a height of about eighteen feet. Disinterested parties stated that they could tell the time with greater ease on a watch, at two blocks, with the reflectors than at one when the reflectors were opened out, letting the light shine out in the ordinary and natural way.

Its advantages are that it can be attached to any of the single or double carbon non-focusing arc lamp in use at present, and without making any alterations in the arc lamps or frames.

Alternating current arc lamps may be employed, using a re-



Figs. 2 and 3.—The Kincaid Street Arc Lamp Reflector.

flector above the arc to throw the light down. High candle power incandescent lamps, having straight filaments, may be used, in which case it will be unnecessary to open the reflectors, and the glass windows.

STEEL PIPE FOR INTERIOR CONDUITS.

BY REGINALD PELHAM BOLTON.

In an editorial in The Electrical Engineer of July 15, respecting the new rules of the New York Fire Department, reference is made to the use of plain iron pipe with lead covered conductors as being so expensive a method of construction, that doubt is expressed if any one will employ it.

I am now doing so upon the installation of the Bowling Green Office Building, in New York, and find the result very satisfactory, as well as economical. The net difference in cost between this construction and the interior conduit with ordinary insulated wire is considerably in favor of the former.

I wish to point out, however, that in making this, the first decision to employ the new construction in this city, I am very clear as to the necessity for strictly high-grade materials, especially in the piping. The term "plain iron" pipe is very misleading, inasmuch as butt-welded iron pipe is almost invariably found to have rough scaleing, and a fin inside at the joint. I specify steel pipe, which can now be obtained free of fins, and demand that it shall be practically free of scale, and furthermore, insist on the whole being dipped into paint, inside and out.

It happens that in steam practice, steel pipes are obnoxious, as upon application of steam pressure they throw down the scale and become clean inside, and the curious result follows that that feature which is objectionable for steam work is precisely what is best for the conduit work. It is, therefore, greatly to be hoped that electricians will not attempt the use of common iron gas or steam pipe on conduit work, or the whole system will again be brought into discredit and confusion.

I have for a long time pointed out the inherent difficulty connected with the interior conduit, of its "sweating" under steam temperatures, and have urged the adoption by the Board of a much higher temperature test than is even now adopted. I maintained that under their regulation the conduit may be kept away from actual contact with hot pipes, yet it is impossible to avoid the running of conduit in heated and close places, in which the long continued high temperatures will soften the insulation, and, besides this, there is no power, ex-

cept rigid inspection, to prevent steamfitters, who care for neither God nor man, from running their heat pipes onto conduit lines. Therefore, any temperature test less than 210 deg. F. will leave matters where they are.

The Interior Conduit and Insulation Company deserve every credit for their efforts in the direction of high class work in the past, and it is with much regret that I see their material passed over, but the difficulties I refer to are real. I trust it is not too late to hope for further improvement in interior lining of conduits, but if it should be so, we must look for the development of high standard work along the line of hard and incombustible insulation, coupled with the use of drawn steel tubing.

ROENTGEN RAYS.

THE SURVIVING HYPOTHESIS CONCERNING THE X-RAY.

A SUMMARY of the different hypotheses concerning X-rays is given by Dr. Lodge in the London "Electrician" of July 17, in which the most recent aspect of the matter is stated as it appears in view of the latest experimental progress. The discovery that salts of zinc, calcium and especially uranium when exposed to strong light acquire the power of emitting an invisible radiation which continues after the exposure to the light, and which can penetrate aluminum and act on a photographic plate, has greatly strengthened the theory that X-rays are of the nature of ultra-ultra violet light. The uranium rays are capable of some amount of polarization and are, therefore, certainly transverse disturbances; they can also be reflected and refracted to some extent, while the X-rays can neither be reflected or refracted to any appreciable extent. Neither kind can be deflected by a magnet, nor even in a vacuum, not even after their passage through a highly electrified plate. Looking at these things in the light of a notable dispersion theory of Von Helmholtz, it has become almost certain that the X-rays are simply an extraordinary extension of the spectrum, far beyond the ordinary ultra-violet, and that the Becquerel rays are a less extreme extension in the same direction.

The dispersion theory of Helmholtz is of special interest at the present time, as it proves to be a remarkable mathematical prediction of the behavior of X-rays three years and more before their discovery. This theory shows, on electromagnetic principles, that ethereal radiations of smaller and smaller wave lengths should become more and more refrangible by matter in the molecular form, up to a certain maximum, which is, of course, ordinary dispersion; but for waves that are shorter still the refrangibility should rapidly, in fact, almost suddenly, drop nearly, or quite, to zero, thus doubling the spectrum back upon itself and giving an anomalous dispersion so great that the rays might be bent by a prism in the wrong direction for a certain size of wave. This state of things would be accompanied by extreme opacity, or absorption of the vibrations by the material molecules. If, however, waves existed of a kind still smaller, then the opacity would become less obtrusive; the refractivity would likewise remain very small—either positive or negative, perhaps—but probably negative; and ultimately, for extremely small waves of atomic dimensions, the refractivity would become nothing and the opacity very small.

In a general way it may be said that material atoms act as if they loaded the ether, so that coarse ether waves large enough to affect some dozens or some hundreds of molecules in a row, such as are the waves of visible light, would by reason of this loading be retarded, and therefore both reflected and refracted. All very coarse waves would be refracted about the same amount, but for smaller waves a new phenomenon would appear; as they got smaller the period of the waves might synchronize with some of the periods of atomic vibration, such vibration as enables atoms to emit light, and whenever that occurred a violent absorption might be expected, owing to the syntonic response or sympathetic resonance between the matter and the ether. This would have the effect at first of retarding the waves rather more, and of giving the well-known effects of ordinary dispersion, or the sorting out of waves roughly according to size, which we get in the prismatic spectrum. Or if the syntony is strongly marked, fluorescent and phosphorescent effects are to be expected from the jangled atoms; and if for this or any other reason absorption is rapid, the dispersion will be what is called "anomalous," which in this connection—indeed in all possible connections—only means unexpectedly complicated.

Push the matter further, however; assume the existence of waves smaller still, so small that they cease to evoke any vibratory response from the material atoms among which they now make their way; the ether of the interstices can hardly be appreciably loaded by the great blocks of immovable substance which now represent the appearance of the atoms, and accordingly retardation and refraction abruptly disappear together, and true absorption also nearly ceases.

To waves penetrating ethereal interstices, matter, even conducting matter, is fairly transparent; for ordinary notions of conductivity do not apply to these intermolecular spaces; electric displacements no longer excite necessary conduction currents, even in bodies which in the gross are conductors, and accordingly there is little or no dissipation of energy, and any obstruction that exists to the passage of light of this kind is of the ground-glass or turbid-medium type, a certain percentage of the energy being scattered at each obstacle in all directions, instead of being able to excite the material vibrations which we know as heat.

This is a very bare account of the matter, but it may suffice to indicate the sort of view which is now coming to be almost universally held regarding the nature of these no longer quite X-rays. The proof is not complete, and will not be till their length has been measured, but in all probability they are ordinary transverse ethereal waves, moving with the customary velocity of light, of various grades of wave length down to 10^{-8} m. in length, vibrating therefore some trillions of times in a second (a trillion being 10^{18}); and by the aid of this highest type of X-ray we may hope in the future to gain some diffractional insight into the actual structure and appearance of the material molecules among which they go.

There is not lacking indirect evidence to show that what we call atomic weight is approximately proportional to atomic bulk, i. e., that the heaviest atoms are the biggest atoms, and that the actual substance of all matter may be much more nearly of one uniform density than is commonly supposed. Grant this hypothesis, and it is plain why platinum or other dense material appears to be the easiest substance in which to excite the necessary electric atomic oscillations, by the impact of charged and excessively rapidly moving gaseous particles. It also suggests that the gas with the most rapidly moving atoms, viz., hydrogen, may be the best substance for the vacuum bulbs to contain; for these would impart their charges to the large platinum atoms in the most sudden manner. It would also be plain why dense bodies should be more turbid than rare ones, and it is not unnatural for the turbidity to be largely a matter of atomic weight, i. e., bulk, than anything else, because the ethereal interstices required for the passage of the waves would in such substances be considerably filld up.

HOW ROENTGEN DISCOVERED THE X-RAY.

An account of the manner in which Professor Röntgen made his famous discovery of the X-rays is told by Dr. Chas. Nootnagle, of Minneapolis, who was studying at the University of Würtzburg, where Professor Röntgen occupies the chair of physics, at the time the discovery was announced. Dr. Nootnagle was present at the first lecture concerning X-rays which was delivered before but a few persons. It was then that Professor Röntgen told how he had chanced to ascertain the peculiar faculty of the cathode ray of passing through substances that are opaque to what we know as light. Of course the peculiarities of the light emitted by the cathode pole of the Crookes tube have long been a subject of study and investigation by many scientists. One night Professor Röntgen was working in his laboratory with a Crookes tube, trying to fathom the mystery of the cathode rays. By chance he happened to note that a little piece of paper lying on his work table was sparkling as though a single ray of bright sunshine had fallen upon it lying in the darkness. At first he thought it was merely the reflection from the electric spark, but the reflection was too bright to allow that explanation. Finally he picked up the piece of paper and, examining it, found that the reflected light was given out by a letter "A" which some student had written on the paper with a platinum cyanide solution. Then he concluded that the invisible cathode rays must have caused the illumination of the paper. Naturally enough he next endeavored to intercept the rays, first with a book, and, afterwards, with several solid substances. He found that nothing except a lead plate had any appreciable effect upon the rays. It was then but a step further for a scientist to see if these rays to which the eye is not sensitive would affect a photographer's sensitive plate. He found that they would, thus showing that the retina of the human eye is not so sensitive as a prepared photographic plate. The shadowgraph was simply the result of the use of the sensitive plate in conjunction with rays which had passed through a solid body.

X-RAYS IN MEDICAL DIAGNOSIS.

THE GENERAL ELECTRIC COMPANY, of Berlin, has recently perfected some apparatus for X-ray work, especially the vacuum tube, so that it is possible to examine a number of peculiarities of the interior of the human body by direct inspection with the fluorescent screen. The London "Lancet" describes the results which were demonstrated before medical men representing the chief European capitals at the recent Twenty-fifth Surgical Congress at Berlin.

The screen employed measured about ten inches by eighteen inches, and consisted of small crystals of platinocyanide of barium dusted on to an adherent surface. Although the results obtained are probably capable of further improvement, still they were sufficiently good to indicate the probable value in the very near future of the X-rays in diagnosing certain conditions. They were, at any rate, far in advance of anything that has yet been achieved. By means of this new tube, which appears to afford the maximum production of X-rays, the labor and trouble of photography may be dispensed with, and a direct vision of certain abnormalities of the heart and in the chest may, as was shown in this demonstration, be gained.

The following were among the results shown: When the head was placed between the tube and the screen the thickness of the scalp was easily visible, the hair not appearing. The light penetrates the cartilages of the nose which are only visible in slight shadows. The frontal cavity and the antrum of Highmore are to be seen as distinctly lighter areas. In the neck are to be seen the shadows of the œsophagus, of the hyoid bone, and the cartilages of the larynx (the last not as distinctly as the hyoid bone), which both in rest and in movement are easily detected. If the light be thrown through the thorax from behind, the screen gives the following picture: In the middle occurs a dark broad stripe, the sternum; on both sides are to be seen horizontal shadows crossing each other, which are plainly the ribs; the lower margin of the thorax is represented by a shadow, the left side of which is pale and thin, but the right side is intensely dark. The picture is still better if the rays be thrown from the front and the screen placed behind, only in this case the vertebræ are seen, and not the sternum. The shadow line, which is constantly moved on inspiration and expiration for about three inches, is the diaphragm, and the darker shadow on the right side is the liver and the lighter on the left is the stomach.

This picture shows, further, that the diaphragm and the ribs are situated at a very acute angle with one another. Another big shadow is seen immediately above the diaphragm and in the middle of the thorax. This shadow (that of the heart) consists of an intensely dark central part with a light periphery. This movement of the heart is distinctly visible, principally at the apex, but on close examination the movement of the aorta may be noticed also. The heart shadow and movement are emphasized after a deep inspiration has been taken. If now the tube and screen be moved downward, the light is thrown through the stomach. The limits of this organ may be well seen, but the definition is far better after it has been distended by the administration of an effervescing mixture.

These results demonstrate pretty conclusively the possibility in the near future of the X-rays becoming a powerful aid in diagnosis coupled with the employment of a fluorescent screen. Already it has been fruitful in not only confirming previous methods of diagnosis, but in affording means of ascertaining with some precision certain symptoms which by methods now employed would not be indicated. The movements of a complex joint, such as the carpus, were clearly seen, and will throw a new light upon surgical anatomy.

PHYSIOLOGICAL EFFECT OF X-RAYS.

The following dispatch from Berlin was recently printed in the New York "Journal":

"Dr. Markuse, whose 'interior' has been photographed thirty times within the past twenty days by the Röntgen process, has lost all of his hair as a result and his face has assumed a brownish color. The skin has peeled off his breast where the Hittorff instrument nearly touched it, and on his back what was first a sore finally developed into a bleeding wound, surrounded by burnt looking cuticle. The victim is exhausted."

MR. CHARLES R. BARNES, of Rochester, has been appointed by the New York State Railroad Commission as consulting electrical engineer and expert to the commission. This position was created by an act of the last Legislature and the salary is fixed at $3,000, with traveling expenses.

MISCELLANEOUS.

THE THERMO-TROPIC BATTERY AND A NEW METHOD OF DEVELOPING ELECTRICAL ENERGY.

BY C. J. REED.

THE Jacques "carbon consuming primary battery," as described in The Electrical Engineer of May 13, 1896, and other journals, did not seem to the writer to be a galvanic cell. A series of experiments with this cell and modification of it indicated clearly that the electromotive force was due to thermo-electric instead of galvanic action. These experiments were repeated at a joint meeting of the Chemical and Electrical sections of the Franklin Institute on May 26. A detailed account of the results obtained was published in The Electrical Engineer of July 22.

Another series of experiments undertaken by the writer simultaneously, pointed as strongly to an entirely different conclusion and to the discovery of an entirely new method of transforming heat into electrical energy. Realizing the possible commercial value of this new process the writer was not prepared to make it public at that time. For this reason no reference either to these experiments or the conclusions to which they point was made in any of the communications heretofore published.

The new process of transforming heat into electrical energy is an exceedingly simple one and requires for its exhibition only a piece of wire, a galvanometer and a Bunsen burner. A piece of copper wire two feet long and one-eighth of an inch in diameter is well adapted for this purpose. The arrangement is shown in Fig. 1.

The wire is bent into a nearly circular loop and the ends connected to the terminals of a galvanometer or voltmeter, G. Two blocks of wood, W, held together by screws, form a suitable clamp to hold the ends of the wire firmly in position. After being rigidly clamped the wire is cut or sawed in two at the point, C. The ends are bent so as to spring together and fit as closely as possible.

The ends are then separated and heated to a red heat while exposed to the air. In this manner a thin film of oxides of copper is formed over the ends of the wires. The oxidized ends are then allowed to press together and the flame of a Bunsen burner or blow-pipe is applied to one of the wires at B, as close to the junction as possible. The other wire is kept cool. A strong electric current flows through the circuit in a particular direction. If the flame be transferred from B to A, the direction of the current reverses.

The thin film of cupric oxide may be replaced by a film of any conducting oxide or salt not decomposed by the flame. Fused caustic alkalies serve the purpose well. With the arrangement shown in Fig. 1, using copper wires, an electromotive force of from 0.2 to 0.4 volt may be obtained.

With brass, iron and other metals similar results may also be obtained. The electromotive force obtained by two copper wires is at least 100 times as great as could be obtained from a thermo-electric junction composed of any two of the abovenamed metals.

When copper wires or plates are used the hot wire acts as the zinc plate and the cold wire as the copper plate of the Daniell cell. With iron wires the hot wire acts as the copper plate and the cold wire as the zinc plate of the Daniell cell.

It is not necessary that both wires should be of the same metal. Any two pieces of metal may be used and even carbon and a metal. The best results are apparently obtained from the best electric conductors, and it seems evident that the development of electric potential in this apparatus is due only to the flow of heat across the surface of contact and across the film of metallic oxide or metallic salt intervening between the adjacent pieces of metal. To distinguish this process of transformation from the thermo-electric process, the term "thermotropic" suggests itself as a suitable name.

Fig. 2 shows a more efficient form of apparatus. It consists of a strip of sheet copper held in a horizontal plane in the flame of a Bunsen burner and heated to a red heat. Against the upper surface of this sheet is firmly pressed one end of a stout copper wire, the wire and sheet being both connected by suitable wires to a galvanometer. Care must be taken to allow no other heated metallic junctions in the circuit unless they are soldered or welded junctions.

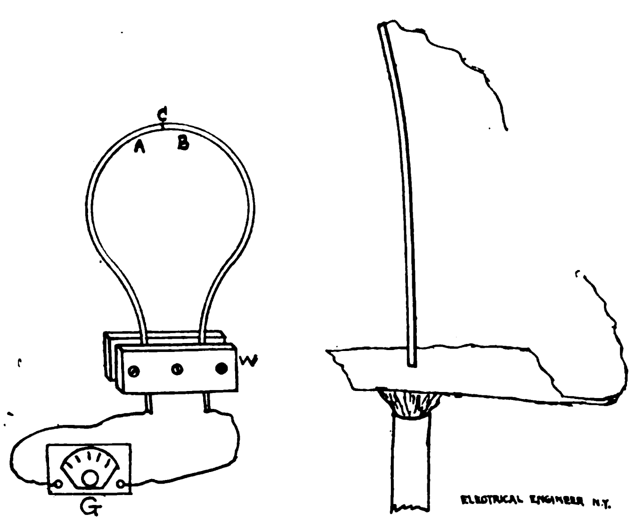
The development of electrical potential by the passage of heat from one conductor to another through an intervening electrolyte is a process more nearly resembling galvanic action than thermo-electric. While the efficiency of this method is undoubtedly limited by the second law of thermodynamics, it has not the other limitations of the thermo-electric method, and has the advantage of enormously greater electromotive force

and of being favored instead of retarded by great heat-conducting power in the metals used.

The very high electromotive force, the reversibility of direction and the development of electrical potential from a junction of two pieces of the same metal, all prove that the transformation is not thermo-electric in the sense in which that term has always been used. The reversibility, the development of electrical potential from two pieces of the same metal and the opposite effects given by copper and iron, all show conclusively that the electrical energy does not originate in chemical action. There is, therefore, only one inference left, namely, that the transformation results in some way from the flow of heat across the thermo-tropic junction.

It is generally recognized that conducting compounds are conductors only as electrolytes. We should, therefore, expect the current in this apparatus to have an oxidizing effect on one of the copper wires and a reducing action on the film of oxide, that is, at one surface there will be oxidation and at the other reduction in an equal amount. The amount of this oxidation and reduction will be the electro-chemical equivalent of the current. This chemical action does not evolve energy and does not produce electric current, but is the result of the electric current passing through the electrolyte. In the experiment with copper wires described above, the evidence of this electrolytic action is very marked. That the same electrolytic action takes place in the Jacques battery, there can be little doubt, as suggested by the writer in The Electrical Engineer of May 27, it having been found in the tests made by Messrs. Stone and Webster that an amount of carbon consumed was practically equivalent to the current.

In discussing the nature of the action that takes place in galvanic and electrolytic cells, it is to be regretted that there is a careless tendency at the present time to confuse the galvanic



FIGS. 1 AND 2.—THE REED THERMO-TROPIC ELEMENT.

cell and the electrolytic cell. The two are very much alike, but also very different. In both there are always two simultaneous chemical reactions, one of which takes place at each terminal of the electrolyte. In all cases these two reactions are each electro-chemically equivalent to the current, both in the galvanic and in the electrolytic cell. In either case a metallic substance may pass into the electrolyte, or be deposited from the electrolyte, or be deposited from the electrolyte, or both may occur simultaneously.

There is one respect, however, in which a galvanic cell always differs from an electrolytic cell. The galvanic cell always evolves energy and is spontaneous in its action, that is, the sum of its chemical reactions is exothermic. The electrolytic cell always absorbs energy and is never spontaneous; that is, the sum of its chemical reactions is either endothermic or athermal.

If an electric current be passed through a solution of cupric sulphate between copper electrodes, an electro-chemical equivalent of copper will be deposited from the electrolyte on the cathode and an equal amount of copper will pass from the anode into the solution. The oxidation and reduction of equal amounts of copper cannot either evolve or absorb energy, unless we admit that energy may be either created or destroyed. The quantity of copper oxidized or reduced in this case can only measure the current that has passed through the electrolyte. Energy has been transferred from one copper plate to another, but none of it has been evolved from the cell. The only energy transformed in such an action is the amount expended (absorbed from without) in forcing the current through the resisting medium (electrolyte), and is, of course, measured by the product of the current and electromotive force between the copper electrodes. As this reaction is not exothermic, but absorbs energy from without, it is electrolytic and cannot take place spontaneously. In other words, two chemically pure copper plates placed in a solution of a copper salt could not evolve electrical energy or constitute a galvanic cell. Similarly two zinc plates in a solution of zinc salt could not constitute a galvanic cell.

If, on the other hand, a copper plate be immersed in copper sulphate and a zinc plate in zinc sulphate, the two solutions being separated by a porous partition through which they may slowly mingle, we have a cell which may be made to either absorb or evolve electrical energy. It may act as an electrolytic or a galvanic cell. If an electric current be passed through the cell, the zinc plate acting as cathode, an electro-chemical equivalent of zinc will be added to the zinc plate and an equal electro-chemical equivalent of copper will go into solution from the copper plate. The sum of these reactions is endothermic and the energy absorbed is equal to the difference between the formation heats of equivalent amounts of copper and zinc sulphates. This amount of electrical energy is transformed into chemical energy and the action of the cell is electrolytic. The electromotive force required to do this work will be added to that required to drive the current through the resisting medium.

If we remove the external source of current and connect the copper and zinc plates by a conductor, these reactions spontaneously reverse. The zinc passes into solution and an equivalent amount of copper is deposited on the copper plate, both being electro-chemically equivalent to the current that flows through the circuit. Here an amount of energy is evolved as electrical energy, exactly equal to the difference between the formation heats of the copper and zinc sulphates. The action of the cell is exothermic and spontaneous, that is, galvanic.

In the thermo-tropic junction described above we have two pieces of copper joined by an intervening film of copper oxide acting as an electrolyte. Copper is reduced on one surface. An equal amount of copper is oxidized on the other surface. But no energy is evolved by these reactions and, therefore, the transformation is not galvanic.

The same argument applies with the same force to the Jacques battery. Dr. Jacques did not state the direction in which the current flows in his cell. Assuming that the carbon acts as the zinc plate of a Daniell cell, it will be oxidized by an amount equivalent to the current flowing, whether the action is electrolytic or galvanic. The only constituents of the electrolyte (sodic hydrate) that can be reduced are sodium and hydrogen. We may determine the energy of this cell, therefore, on either of two suppositions, (1) that hydrogen is liberated; (2) that sodium is liberated. But the liberation of an amount of either hydrogen or sodium that would be electro-chemically equivalent to the carbon oxidized would require the absorption of much more energy than the combustion of the carbon would evolve. The action of the Jacques cell is, therefore, highly endothermic and electrolytic instead of galvanic. The chemical reactions of this form of cell are necessarily very wasteful of energy and are opposed to the electric current. All the energy evolved from the oxidation of the carbon and the additional amount absorbed which is necessary to reduce either the hydrogen or the sodium, is wasted, since the reduced hydrogen or sodium, on which this work has been expended, is all lost.

The possibility of a galvanic or electrolytic cell in which oxidation may take place without equivalent reduction, is not worthy of discussion. We might as well expect to find in mechanics a shaft with only one end.

ELECTRICAL DEFENCES AT BULUWAYO.

The work of the electrical engineer is very much in evidence in Buluwayo, which owes its present safety to the efficiency of the electrical devices adopted for its defense against the Matabeles.

Within four days after it was decided to "go into laager," telephone lines were run from the main laager to the various outposts, namely, observatory, hospital, and headquarters' office, and were in perfect working order. Circuits had also to be rapidly laid for the dynamite mines. These mines were necessary for the protection of the northeast and east sides of the laager, which were considered very weak on account of the formation of the ground, and the protection afforded to the enemy by the houses. The ten mines were laid from 200 to 400 yards from the center of the laager, at an angle which, while calculated to do the greatest damage to the enemy, would be the least likely to throw stones or rubbish into the laager. The mines average about 150 feet long by 3 feet wide and 2 feet deep. The dynamite was laid in canvas along

the bottoms of the trenches and the wire connected with the top of the Market Hill building, where the local electrical engineer is stationed at night.

A searchlight has been put in the crow's nest on the building, and, by its aid, the engineer can command a good view of every bit of land around the town. The Matabeles nearly always choose the hour before dawn for their attack, but at Buluwayo, thanks to the searchlight and the telephone, a night surprise is impossible.

CONTACT RESISTANCE.

BY CHARLES WIRT.

REFERRING to the results given under the heading, "Phenomena of Commutator Resistance," in The Electrical Engineer of July 8, I think it worth while to direct attention to the great difference existing in the case of contact resistance between surfaces at rest and in motion. Contact resistance is an important subject on which very little information has been published. The article quoted asserts that in the case under consideration (contact between surfaces in motion), pressure has but a slight effect on the contact resistance.

The writer carried out a set of rather crude experiments relating to contact resistance between surfaces at rest in the Edison Laboratory a few years since. The apparatus consisted merely of a pair of circular contact blocks of red brass, 2 in. diameter by 1 in. thick, with means for measuring the contact resistance and pressure. The potential difference at the contact was measured by a Kelvin galvanometer previously calibrated and connected from block to block, using measured currents of a few amperes sufficient to give a suitable deflection. The facts deduced were as follows:

1.—With pressures between 25 and 250 pounds per square inch resistance varies nearly inversely as the pressure.

2.—The total pressure remaining constant, reduction of area does not alter resistance within wide limits.

3.—Pressure and area remaining constant, variations in the perfection of fit between the surfaces produces slight, if any, change in the resistance.

4.—Clean petroleum oil placed between the contact surfaces does not greatly alter the resistance.

5.—Clean petroleum oil mixed with pure graphite to the consistency of cream does not greatly alter the resistance.

6.—A washer of thick tinfoil (pure tin) interposed between the contact surfaces, gave a total resistance for the double contact not greater than the single contact of the blocks with each other, except with the lighter pressures.

No time tests were made. During the experiment, the two surfaces were fitted until the lower block could be lifted by the upper block by suction. Ordinary care was taken to exclude dust. The slight effect of oil on the resistance is surprising, as with well-fitted surfaces and only moderate pressure, it might be expected that a continuous film of oil would interpose between the plates. It would appear that actual contact between the surfaces with moderate pressure, even with well-fitted surfaces, is at a few points only; that increase of pressure brings more points into contact in proportion to the pressure; also that the actual points of contact are able to displace the liquid film.

A careful quantitative study of this subject would be of great interest and practical value. In all electrical connections not soldered, it should be remembered as a useful rule of thumb that conductivity depends within wide limits not on area of contact, but on pressure. This is at variance with practice, but is undoubtedly true.

Large surface of contact is of value, in switches for instance, for giving increased radiating surface and proper conductivity without undue pressure per unit of surface area; that is to say, in switches while conductivity might be secured with less surface than is now the usual practice, under sliding motion such pressure would give increased tendency to cut. In bus-bar joints, and similar cases of joints carrying large currents, where the conductors are ample, if a heavy pressure can be secured and maintained, the area of contact may safely be reduced to the amount required by mechanical considerations. It is also probably true that in such joints the interposition of a washer of pure tin, not too thick, is of advantage in protecting joints from the effects of corrosion.

BORIDE OF IRON FROM THE ELECTRIC FURNACE.

Moissan has announced a new product from his experiments with the electric furnace. He has prepared a considerable quantity of it, and has examined its properties. Those who are interested in these experiments will find them in the "Bulletin de la Société Chimique de Paris," 1895, p. 956. He says that in the electric furnace a current of 300 amperes and 65 volts may be made to produce a large quantity of the compound within the space of five or six minutes, if fragments of iron be placed in a boron-brasqued crucible; but the temperature must not be excessive, as crystalline boride of carbon will also be formed.

ELECTRIC REPULSION.

BY PROF. I. THORNTON OSMOND.

ALL text books on electricity state, as a law, that "like charges repel!" But is there any such thing as electric repulsion in the sense of a mutual force action of separation? It is true that two bodies bearing like charges move apart, if free to do so. Naturally, the first explanation was to conceive a repulsion, and this important idea immediately crystallized into a law that has endured and has permeated all electrical literature, and now adds to the difficulties of electrical studies a needless complication of error.

Will not the next author who writes, or who thoroughly revises, a work on electricity omit the false doctrine? Let him follow some such method of treatment as here outlined:

(1) In any operation of electrifying there are always two (or more) bodies having electrification of different kinds.

(2) Whenever an electrified body is brought near other bodies, the latter have the opposite kind of electrification on the parts toward the former.

(3) Between bodies of unlike electrification there are lines of force that tend to shorten and so draw the bodies together, if one or both be free to move.

(4) Two bodies of like electrification and near together are drawn apart because each has lines of force drawing it to other bodies of unlike electrification, but has no lines drawing it in the direction of the other body of like electrification.

By thus bringing to the front, or second place, the fact that every charged body is connected by lines of force (that tend to shorten) to others having unlike charge, all need for a repelling action between like charges vanishes; electric force, like gravitation force, acts only attractively. Gravitation was formerly thought to act as repulsion on certain states or conditions of matter, to account for the moving apart of the earth and bodies that rise in fluids, as smoke in air, wood in water, etc. An advance in physical knowledge has caused this false doctrine of gravitation to pass out of science. Let "like charges repel" so pass.

Is it true that "like magnetic poles repel?"

RUBBER TREES IN FLORIDA.

Those familar with the southern portion of Florida are aware of the fact that the rubber tree is indigenous here, and grows in greatest profusion on both coasts south of a line drawn west from New Smyrna. Many large trees grow on the east coast.

To the natives countless numbers of immense rubber trees are known, but, as their usefulness has not yet been developed here, they are very little noticed.

On the west coast the trees are abundantly prominent, and are an open bid for the people of Florida to investigate their value. At this time, when the people are looking for new avenues in natural products of the soil to replace the orange culture, it would be reasonable to suppose that they would utilize the wild rubber tree. On any of the keys along the coast one could find a rubber plantation or estate in an advanced state of growth.

At Anna Maria Key, says the "Daily Florida Citizen," at the entrance to the harbor, Col. John R. Jones has a place upon which is one of these trees, with five separate trunks, similar to a banyan tree. The largest trunk is eleven feet in circumference; the others measure twenty-eight, twenty-seven and eighteen and fifteen inches, respectively. When the tops of these trees become too spreading, they send down a sucker, which takes root and assists in the support of the branches. Such a tree as mentioned above covers a large area, and would afford a good revenue were its great flow of sap utilized.

Colonel Jones, on April 14 last, planted a little rubber nursling eighteen inches in height. On the 14th ult. that tree stood five feet ten inches high, showing with what rapidity they grow in their wild state without cultivation.

A NEW TYPE OF THREE-PHASE ARMATURE.

At a recent meeting of the Elektrotechnischer Verein, of Berlin, Herr Dolivo-Dobrowolsky showed a new type armature for three-phase motors. The armature resembles a compact and massive drum, the surface of which is provided with a large number of small radially cut grooves parallel to the axis. Into these grooves are pressed copper strips, which extend at both ends over the edge of the drum, and are there connected to copper rings. Herr Dobrowolsky states that this construc-

tion is electrically equal to the old one of the Allgemeine Elektricitäts Gesellschaft, which consisted of laminated iron, through which insulated copper bars are led.

ELECTRICAL SOAP.

A battery has been patented by Mr. Herbert E. Rider, of New York, consisting of a source of electrical energy placed inside a cake of toilet soap. The device is intended for curative applications of electricity to the human body. To use the language of the inventor, the invention is based on the fact that the chemical decomposition of soap is such that when dissolved in water it produces a liquid having an exciting effect upon certain metallic electrodes placed in proximity to form an electric battery. The arrangement of the electrodes is such that they may be reached by the solution formed in the use of the same, and provided with terminals on the exterior of the soap through which the electric current is transmitted to the person of the user. The elements of a simple galvanic battery are used and the effect of the current is intensified by the addition of an induction coil. Next!

THE DIELECTRIC CONSTANT.

A research published in the "Zeitschrift für Physikalische Chemie," has recently been conducted by F. Ratz upon the dependence of the dielectric constant on temperature and pressure. He appears to have followed the well-known method of Nernst which was first published in 1894. The constant was determined at various temperatures and pressures in the case of benzene, toluene, carbon bisulphide, ethylic ether, chloroform, aniline, amylic alcohol, ethylic alcohol, and water. The value $(D - 1) / (D + 2)d$ is a function of both temperature and pressure, the temperature coefficient increasing with the dielectric constant. The variation between the values of the constant obtained from the formula and the actual number is, for a temperature of 30 degrees, below 10 per cent., and the value of the above expression within 40 degrees changes by less than 5 per cent. The temperature coefficient is small, and in all cases negative, decreasing slightly as the temperature rises. No maximum for D is found at 4 in the case of water, and if such exists at all, it must be between 0 degree and 1 degree. In all cases the value of D is greater than A^2 obtained from refraction observations. The pressure coefficient is small and positive, so that it follows that the influence of temperature is greater, and that of pressure less, than the calculated effect.

THE MEASUREMENT OF VERY LARGE AND OF VERY SMALL ALTERNATING CURRENTS.

At a recent meeting of the Physical Society, London, a paper on the above subject was read by Mr. Campbell, who advocates the use of air-core transformers for measuring voltages and currents which are either above or below the range of the instruments available.

If an attempt is made to measure the current in the primary of an air-core transformer by observing the voltage on an open circuit secondary, it is found that the readings depend on the frequency. In order to overcome this difficulty the author uses a closed secondary with a very high inductance. In this case the primary current is proportional to the secondary current, which latter may be measured by an ammeter. The author has also investigated the case of transformers with iron cores, and of which the inductance of the secondary is large. In the case of a ring transformer with a closed magnetic circuit, if the load on the secondary consists solely of a Kelvin 100 ampere balance of very low resistance, the ratio between the primary and secondary currents is practically constant. With an open magnetic circuit transformer, however, this is not found to be so, as the ratio between the primary and secondary currents varies considerably with the frequency.

GRIFFITHS' RESISTANCE BOX.

A novel resistance box has been exhibited before the London Physical Society by its inventor, Mr. Griffiths, which embodies the following features: (1) It permits of all the coils being compared with one another without the use of standard coils, and with great ease and rapidity. Hence it is sufficient at any time to compare any one of the coils with a standard to obtain the correction to be applied to all the coils. (2) The bridge wire can be calibrated by means of the box itself. (3) The temperature of the coils can be accurately determined, since they consist of bare platinum-silver wire wound on mica and immersed in an oil bath, which bath is kept stirred. (4) The resistance of the leads from the box to the object being tested is eliminated, as well as any error due to a change in this resistance with temperature. (5) The coils are arranged according to a binary scale, and the author claims that it is possible to measure resistances up to 105 ohms to within 0.000001 ohm. (6) All the coils, after being adjusted, have been heated to redness and allowed to cool slowly, so that all strain has been removed from the wire. (7) By having a separate pair of blocks for each plug, it is impossible for the insertion of one plug to affect the fit of a neighboring plug. The plugs themselves are so made that no part of the plug is wider than the top of the hole, and so it is impossible to wear a "shoulder" on the plug.

ELECTROLYTIC MOLYBDENUM BRONZES.

Stavenhagen and Engels describe in the "Berichte der Deutschen Chemischen Gesellschaft" some molybdenum bronzes which they have recently succeeded in preparing. Amongst these, there is one which bears a great resemblance to tungsten bronze, and is formed by electrolyzing fused acid, sodium molybdate. The fusion is performed in a platinum crucible, with a current of 8.5 amperes and generated by three accumulators (4.9 volts) placed in series. The bronze separated quickly at the cathode in crystals, which have to be washed with boiling water and dilute hydrochloric acid. It is soluble in alkalies, in nitric acid, and aqua regia, but not in hydrochloric or sulphuric acids; its composition is found by analysis to correspond to the formula $N_2Mo_5O_{15}$.

CONDUCTIVITY OF SALTS DISSOLVED IN GLYCEROL.

Carlo Cattaneo has, during the last two or three years, devoted a considerable amount of attention to the investigation of electrical conductivity of salts dissolved in various solvents, for example, water, alcohol, and ether. He has now turned his attention to the conductivities of solutions of ammonium, sodium, zinc, barium, and ferric chlorides, and potassium bromide, and iodide in glycerol containing 25 per cent. of water at various temperatures between 0 degree and 24 degrees Centigrade. The conductivity of the various salts is, in general, greater than that of the corresponding ethereal solutions, but less than that of the alcoholic ones; the conductivity of the aqueous, alcoholic, and glycerol solutions increases more rapidly than the concentration. As the concentration decreases, the molecular conductivity of the salts in aqueous solution increases, and in ethereal solution decreases; that of the chlorides increases, whilst that of the bromides and iodides decreases, in alcohol solution, and in glycerol, the molecular conductivity of the chlorides increases, whilst the concentration decreases. The temperature coefficients are usually greater for aqueous than for alcoholic solutions; in ether, they are of approximately the same order as in water, but are negative in sign, whilst, in glycerol, the temperature coefficients have very high values. In his paper in the "Real. Accad. Lincei," 2, page 112, Cattaneo gives a table of the conductivities of the glycerol used at various temperatures, showing that it obeys the rule enunciated by Bartoli, which states that those carbon compounds which become most viscous on cooling, are those whose conductivity increases most rapidly as the temperature rises. At 18 degrees, the conductivity of the glycerol was found to be of the order of 10^{-12}.

DISCHARGE OF ATMOSPHERIC ELECTRICITY.

At a recent meeting of the Berlin Meteorological Society Dr. Schwalke spoke on the investigation of some important theories of atmospheric electricity, and added an account of experiments he had made on the dissipation of electricity by vapor. A metal plate insulated, charged to ten volts, and connected with a Thomson quadrant electrometer, discharged itself in exactly the same time when dry as when wetted with water or other easily vaporized fluid. Sprinkling with finely-pulverized quartz greatly hastened the discharge.

LETTERS TO THE EDITOR.

THE JACQUES CARBON BATTERY.—A CORRECTION.

In The Electrical Engineer of July 22, which has just reached me, I notice in my article on "The Jacques Carbon Battery" that the engraver has, in reducing Figs. 2, 4 and 5, not reduced the scale of temperature in the same proportion as the curves and time scale, thus introducing a number of apparent inconsistencies.

In Fig. 2 the temperature 238 degrees, as stated in the text, corresponds to 18 minutes, instead of 32 minutes, as shown by the engraver.

In Figs. 4 and 5 the temperature of 343 degrees corresponds, as stated in the text, to 38 minutes, instead of 65 minutes, as shown by the engraver. C. J. REED.

CONTENTS.

THE TROLLEY BASE DECISION.

NOT only those operating electric railways, but the entire electrical fraternity, is directly affected by, and will be interested in, the decision just rendered by the Circuit Clurt of Appeals in New York, involving the manufacture and use of trolley bases. Following the decision of Judge Townsend in the suit of the Thomson-Houston Electric Company vs. The Winchester Avenue Railroad Co., sustaining the Van Depoele under-running trolley patent, the Thomson-Houston Electric Company applied for a preliminary injunction against the Kelsey Electric Railway Specialty Company, of New Haven, to restrain the manufacture and selling of an improved trolley stand made by that company. It was contended by the defendant in that case that the trolley stand made by it was a decided improvement upon the trolley stands made by the General Electric Company, and that the sales made by it had been made to replace General Electric stands, which, on account of their greater height were less effective and less efficient than those made by the defendant. Judge Townsend, however, granted the injunction, holding that such a use was unlawful as being a reconstruction of the patented combination. The Circuit Court of Appeals now holds that such sales are lawful. It may be noticed that in its opinion, printed in full on another page, the court takes very strong ground against what, by implication, it believes to be a bar to all further improvement. Thus, in commenting on the character of the trolley made by the defendant company which possessed qualities not pertaining to the apparatus made by the General Electric Company, it says that a refusal to permit the substitution of the improved apparatus is equivalent to a declaration that no street railway company can be permitted to improve its stands except by the consent of the General Electric Company. The court, on the contrary, holds, in just so many words, that if a purchaser chooses, the day after his purchase, to substitute a stand which is better made and better adapted to his peculiar needs he has the right to do so.

An interesting feature of the arguments in this case was that brought forward by the complainant, the General Electric Company, who referred to the suit brought by the General Electric Company against the Davis Electrical Works, which resulted in the latter company being enjoined from repairing worn out incandescent lamps by the insertion of a new filament, but the court held this case to be irrelevant and the conditions not analogous. What the result of litigation of this kind in the future will be likely to result in may be gathered from the dissenting opinion of Judge Wallace, who goes even further than his colleagues on the bench, and who believes that the Van Depoele under-running trolley patent consists "in various combinations of parts of which a trolley stand in some form is one." If these trolley stands were originally bought from the General Electric Company, Judge Wallace believes that "they (the railway companies) have a right to repair their trolley stands, to substitute new ones for those old or worn out or to substitute a better and improved kind for those originally bought of the complainant," and any one, according to Judge Wallace, ought to have the right to make and sell the stanas to electric railways. As to the necessity for the manufacturer to inquire for what purpose the trolley base is to be used he considers the case analogous to that of a man who sells a gun or a knife who would be deemed guilty of an impertinence if he

should inquire of the purchaser whether he intended to use it legitimately. We believe that this decision will be hailed with satisfaction by all railway operators and railway supply manufacturers, and hope that it may put a salutary restraint upon the coercive methods of the Electrical Trust. It may be well also to repeat the fact that the litigation under discussion comes under the broad Van Depoele trolley patent, which had been previously sustained, the trolley base constituting merely a detail under that patent, or one of the elements of the combination. One or more such decisions on details of the underrunning trolley patent may cause this patent to go the way of many before it, that have been used for similar purposes.

THE ADVANCE IN THE PRICE OF INCANDESCENT LAMPS.

WE understand that the long-discussed agreement among the manufacturers of incandescent lamps for the purpose of arranging a schedule of prices has at last assumed definite shape, and that almost all of the lamp manufacturing companies in the country are represented in the combination. While little of the detail of this agreement has been made public it is understood that the first move of the companies will be to return to the 20-cent price for 16 candle-power lamps, which was generally in vogue about a year and one-half ago. Such an agreement, if it is not abused, must be considered a wise step for both the manufacturers and the consumers, as no one familiar with this branch of the electrical business can question the fact that for some time the price of lamps has been below a figure at which manufacturers can realize a reasonable profit, if sufficient time and skill are expended by them to make first-class lamps. About two years ago, when the fundamental Edison lamp patent expired a war of extermination was declared between the General Electric Company and all the other lamp manufacturers in the country, and from the prices of 30 to 35 cents, then current for 16 candle-power lamps, a reduction was soon made to about 18 cents, and in some cases large orders have been quoted at from 12 to 15 cents. Although these prices come very close to the actual cost of manufacture only a very few of the weakest concerns have been forced out of the business, though probably not a single concern is earning a profit. The strenous competition has had the effect, of course, of keeping the quality of lamps up to a fair standard, but there is much room for improvement, and if the quality of lamps is improved commensurately with the prices, the advance will be an actual saving in the pockets of lamp consumers. It is recognized that without some agreement between manufacturers it would be almost impossible to advance prices to where they belong, and it will be of great advantage to the consumers to have a standard price for lamps and have the competition between the companies carried on along the line of quality.

It is not generally appreciated by consumers, except central station men, that the first cost of an incandescent lamp is almost a negligible quantity in comparison with its total cost. A specific example makes this point very evident. Take the case of a moderate size isolated plant in which the cost of producing current will be about 15 cents per kilowatt hour. If a 16 candle-power lamp is burned here for 500 hours and its average efficiency is 70 watts, its operating cost will be $5.25 and its first cost, say, 20 cents, will bring its total cost up to $5.45. Another lamp of an average efficiency of 60 watts for 500 hours would cost to operate $4.50 and at the same first cost would make a total of $4.70, which would leave a saving of 75 cents to the consumer in favor of the second lamp. This is sufficient to show the great importance of quality and the relative insignificance of the first cost of incandescent lamps, and any reasonable advance should be highly satisfactory to consumers as long as the advances in price are accompanied by corresponding improvements in the average efficiency of the lamps.

Apropos of this action of the lamp manufacturers is the increased demand by consumers for a 2½ watt lamp, and of a "constant economy lamp" of 20 candle-power instead of the time-honored 16 candle-power lamp. Our readers will also recall Mr. Beggs' lamp specification which gave the lamp manufacturer a bonus for exceeding the standard laid down. All these factors point to the imperative necessity of an increase in the price of lamps for the benefit of all concerned and while combinations in restraint of trade are the bane of modern industry, the present combination is one which, we believe, will work to the advantage of both producer and consumer.

THE NIAGARA-BUFFALO TRANSMISSION.

WHAT must be considered one of the most important developments of the present year is the actual letting of the contract for the building of the power transmission line between Niagara Falls and Buffalo. This project has been so much talked of, and its practicability so often denied, that the perusal of some articles, written but a short while ago, must appear somewhat ridiculous to their authors. That this epochal undertaking involves many new questions of engineering goes without saying. The mode of transmission itself was in doubt for a long time. Underground conductors were seriously discussed in the early stages of the undertaking, but overhead conductors have been finally adopted. The description and illustrations which we give of the new line in this issue show that extraordinary care has been taken to forestall all possible elements of disturbance and we see no reason why the line should not, with ordinary care and supervision, remain in practical working order for an indefinite period. Aside from the methods of construction themselves, not the least interesting point in connection with this transmission is the nature of the first contract for the supply of power to Buffalo. This contract is made with the Buffalo Railway Company, whose steam power plant has been looked upon as one of the most economical in the country, and yet the company apparently finds it advantageous to contract for one thousand horse-power at $40 per annum, with a reduction to $36, for all power in excess of that amount. If, with a plant such as the Buffalo Railway Company possesses, containing boilers with mechanical stokers, compound engines, etc., $40 per horse-power per annum is an inducement to make a change, what may we not expect in the case of the hundreds of other plants not so fortunately situated in the way of improved steam plant? The contract with the power company calls for the erection initially of a circuit of 5,000 horse-power capacity from the falls, but we shall be greatly mistaken if the full capacity of the line is not called for sooner than even the promoters of the scheme contemplate.

A CONCEPTION OF ELECTRIC REPULSION.

ELSEWHERE we print a short note by Prof. I. Thornton Osmond, which offers a new conception of the idea of electric and magnetic repulsion. The writer objects to the law that "like poles repel" on the ground that there is absolutely no repulsive force exerted between two poles of similar polarity, and that the idea of repulsion is an unscientific view of the phenomenon which is noticed on the approach of two similar poles. We must admit the justice of his conception, however, that two poles which apparently repel each other only separate when free to move, for the reason that each is more powerfully attracted to neighboring bodies of opposite polarity than it is to the similar neighboring pole. But even accepting this theory of the behavior of charged bodies, the apparent repulsion of like charges, which is perhaps as unscientific as the old conception of negative gravitation, is so convenient that it will probably remain a "law" for the majority of electrical text books.

"THERMO-TROPIC" GENERATION OF ELECTRICITY.

WE print elsewhere in this issue an interesting contribution from the pen of Mr. C. J. Reed, in which he points out an apparently new method of generating electrical energy, to which he has given the name "thermo-tropic." In this process the electric current is developed merely by the passage of heat from one conductor to another separated by an electrolyte, which in the present case was a film of oxide formed at the junction of two pieces of metal. There are several notable points in connection with this method of generation which distinguish it radically from the action of the thermo-electric battery and from that of the electrolytic cell, all of which are clearly pointed out in Mr. Reed's paper. A feature of this new method is the remarkably high electromotive force produced by it. The fact that from .2 to .4 of a volt is obtained, which is many times that of a thermo-electric battery, suggests that this method may find some practical application, although its efficiency would, of course, be but small. It would also have been interesting to know what the internal resistance of such a couple is.

Power Transmission.

THE NIAGARA-BUFFALO TRANSMISSION LINE.

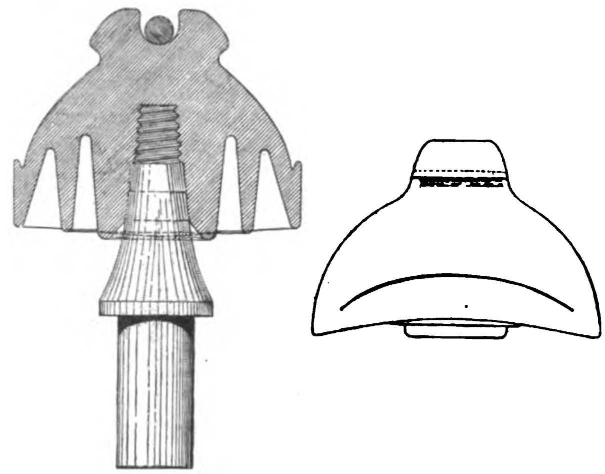
THE Buffalo Power and Conduit Company, which was organized to distribute Niagara power in Buffalo, has awarded the contract for the construction of its power transmission line between Niagara Falls and Buffalo to the White-Crosby Company, of New York. This transmission line will run from the power house at Niagara Falls along what is known as the Two-mile-line road, near the tracks of the New York Central and Erie railroads, crossing the creek at Division street, and from Tonawanda to Buffalo city line it will follow the canal banks.

The transmission line embodies a number of special features of construction, in view of the fact that it will carry very heavy wires, and will be subject to the high winds and storms of snow and sleet which the region in the vicinity of Niagara is subject to. The poles will vary from 35 to 65 feet in height, depending upon the contour of the ground, so as to maintain the wires as level as possible. Depending upon the height they will vary from 14 to 28 inches in diameter at the butt, and will not be less than eight inches in diameter at the top. They will be set into the ground to a depth of from 7 to 8½ feet, depending upon the height. All poles will be of white cedar, selected, shaved and painted.

The pole line is intended to transmit 20,000 horse-power over four circuits, of three wires each, the three-phase system having been adopted. These circuits will be erected on two cross arms, each side of the cross arms carrying three wires, as shown in the accompanying illustration, Fig. 1. Each of these three wire sections is thus intended for 5,000 horse-power transmission.

In order to make the construction as strong as possible a special form of brace has been employed, which, it will be seen, consits of a 2½x2-inch angle iron, bent in one piece. These angle irons will be secured to the cross arms by two lag screws, so as to insure a tight bearing without play, a feature which could not be secured if through bolts had been used, which, in addition, would have weakened the pole to some extent. The angle iron, it will be evident, constitutes as good a strut as it does a tie, and in this respect is much superior to the usual form of straight iron brace.

As the potentials carried on this line will be very high, a special form of insulator has been designed, capable of withstanding 40,000 volts. These insulators will be of porcelain, with triple petticiats, as shown in section in Fig. 2, and will be of the helmet form, as shown in Fig. 3. The base of the helmet measures seven inches in one direction and nine inches in the other, and the insulator will be placed with the greater length



Figs. 2 and 3.—Insulator for Niagara-Buffalo Transmission.

parallel with the line of the wires. It will thus be seen that any water falling on the insulator will run into the grooves or brim of the helmet and drop down clear of the cross arms. Icicles which may be formed will also fall clear of the cross arms.

The insulators will be mounted on 2-inch pins, and in order to increase their strength a construction has been adopted such that the body of the insulator bears for a considerable distance below the thread of the pin. This prevents the revolving of the insulator and the stripping of the thread, even with a full lateral load on the wire.

The conductors, three-quarter inch in diameter, 350,000 circular mils section, will lie in the groove in the top of the insulator, and will be tied. It will be noted that the insulator is so designed as to have the same thickness of body between the top of the pin and the main conductor, as between the pin and the tie wire when in place.

Special precautions have been taken to guard against light-

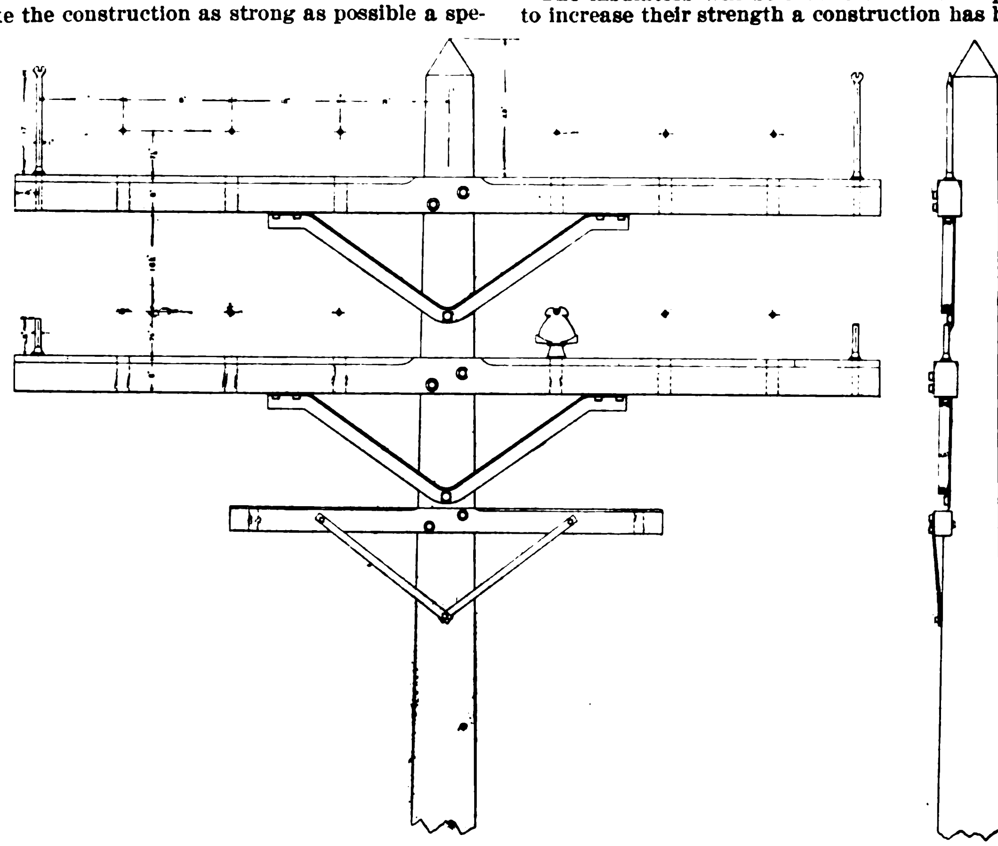


Fig. 1.—The Niagara Falls-Buffalo 20,000 H.-P. Three-Phase Transmission Line.

ning, and for this purpose the top cross arm on each pole is provided with a one-inch rod of double refined iron, forked at the top with a three-eighths-inch groove. In this groove, or channel, barbed galvanized iron wire will be run, and tied for safety. A line of barbed wire will also be run along the tops of the poles thus affording a complete protecting mantle. At every fifth pole one of the lightning arrester bolts is prolonged through the cross arm, and to this prolongation a ground wire will be attached. The ground will consist of a coil of tinned No. 6 copper wire, buried in the ground and brought up a foot above the surface, where it will be attached to the iron wire leading down from the lightning arrester pin. Iron has been adopted to lead down the poles to the grounds, as it is less likely to fall a prey to copper wire thieves.

These lightning arrester pins will also act as a guard to prevent the upper wires from falling to the ground in case the insulator should break. On the lower cross arms special iron guard pins, six inches high, will be placed, which will act in the same way to catch the wire in case of a fracture of the insulator.

Below the two main cross arms a third cross arm, six feet in length, and carrying six pins will be run, which will carry three circuits of No. 12 copper telephone wires.

The main conductors will be transposed at five points between Niagara and Buffalo, so as to avoid the effects of induction between the circuits. The contract calls for the erection of the pole line complete with three wires by November 15.

NIAGARA POWER TO RUN THE BUFFALO STREET RAILWAY.

SIMULTANEOUSLY with the letting of the contracts for the Niagara-Buffalo transmission pole line, another important contract was made. The parties to this second contract are the Cataract Construction Company, the Buffalo Power and Conduit Company, the Buffalo Street Railway Company, and the General Electric Company.

The contract which has been closed between these four companies provides for all of the apparatus and machinery necessary for the transmission, transformation and delivery of 1,000 horse-power to the lines of the Buffalo Street Railway Company for the operation of the electric cars on the various lines in Buffalo, by November 4.

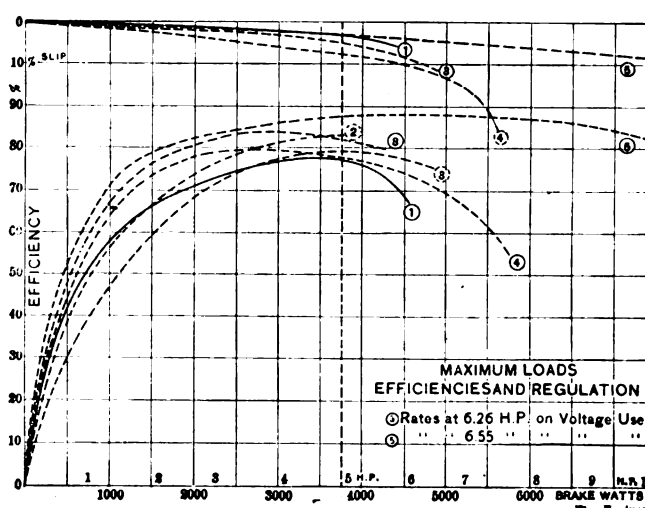
It is not the intention of the railway company to wholly supersede its present Niagara street power plant with this Niagara power, although they hope in time to do so. The Buffalo Street Railway Company produces the steam power which it is now using to run its machinery for the development of electrical power, at a remarkably low cost, and the adoption, even partially, of Niagara Falls power in the face of this fact indicates the belief of the company in the successful and cheap transmission of this power to that city. At first they will use it entirely for running the night car service of the city, and during the day they will use it in addition to the power developed in the Niagara street plant. It will be taken from the city line along the Erie Canal to a point in the rear of the Niagara street power house. The cost of the machinery which the General Electric Company is to furnish will be but a portion of the entire first cost of the undertaking. Yet this cost of machinery shows how comparatively cheap it is to get the power plant in operation after the transmission line is in operation. The contracts just closed are for about $50,000 worth of apparatus and machinery.

The contract entered into with the Cataract Construction Co., of Niagara Falls covers three transformers, which will be the largest ones ever built. These transformers will "step up" the alternating current of 2,200 volts generated by the dynamos in the Niagara Construction Company's power house, to either 10,000 volts or 20,000, as may be thought desirable. The power may be transmitted to Buffalo at either of these voltages. The transformers which the General Electric Company have contracted to furnish to the Buffalo Power and Conduit Company will reduce this voltage or pressure again to 400 volts and at this voltage the electric current will enter two 500 horse-power rotary converters which will be erected in the Niagara street power house of the Buffalo Street Railway Company. In these rotary converters the alternating current will be transformed into a direct current of 550 volts, which will be the same voltage as that generated by the large generators now used for the creation of electric power in the railway company's power house. The rotary transformers will be used in parallel with the direct current generators in the railway power house.

Considering the cheapness of the power developed by the Buffalo Street Railway Company, it is highly interesting to know exactly what this Niagara power is to cost the Buffalo users. The contract calls for the delivery in Buffalo of the first 1,000 horse-power at $40 per horse-power per annum. Should the Buffalo Street Railway Company want more than this 1,000 horse-power the price will be $36 per horse-power for the additional amount used.

EFFICIENCY AND POWER FACTORS OF ALTERNATING CURRENT MOTORS.

IN his excellent paper on alternating current motors, read before the Northwestern Electrical Association, Prof. D. C. Jackson gave the results of a series of tests carried out on eight machines of different make. The table and curves embodying these results reached us too late for publication in our last issue, but in view of their importance we print them this week.



CURVES OF EFFICIENCY OF ALTERNATING MOTORS.

Five horse-power, alternating current motors of the following American makers were available for the purposes of the tests: Fort Wayne Electric Corporation, single-phase; Stanley Electric Manufacturing Company, two-phase; Westinghouse Electric and Manufacturing Company, two-phase; General Electric Company, three-phase. A 5 horse-power three-phase made by the Allgemeine Electricitäts Gesellschaft of Germany, was also

included in the tests, and results of tests on machines made by the Oerlikon works and by C. E. L. Brown, of Switzerland, were obtained. A 10 horse-power Westinghouse two-phase was also tested. A capacity of 5 horse-power in the motors to be tested was chosen, as that may be considered to be near the average capacity of motors used in the service of ordinary central stations. The results of the tests may, therefore, be accepted as representing, for the central stations, comparative results between the average motors which they may use on alternating current systems, and the results may also serve as a basis for comparison between average conditions of operating with continuous current and alternating current motors. According to Professor Jackson, four out of the six motors tested affected the incandescent service disastrously, and showed the absurdity of attempting with them a combined service on the same circuits as the incandescent lighting in those plants where regulation and the satisfaction of the customers is considered of importance. The tests show that the alternating current motors give equally satisfactory regulation and efficiency as is given by continuous current motors, but the power factors of most of the machines are small for part load, the starting currents excessive, and the starting torques with the present arrangement of starting resistances are unduly small. The best performance of the American 5 horse-power machines lies between No. 3 and No. 5 of the tables. These machines will stand well above the others. They are about even in starting torque, but No. 5 will carry considerably the higher before dropping out of its pace; No. 5 also regulates the better and has the higher efficiency. On the other hand, No. 3 has a power factor incomparably better than any of the other machines.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST MILLENNIUM EXHIBITION.—III.

BY ALFRED O. DUBSKY,

THE larger single-phase induction motors, such as the motor shown in Fig. 13, start with a greater torque. There is only one double-width pulley and the motor starts with the belt on the loose pulley on the countershaft. The induced part —either revolving or not—has a polyphase winding; as during

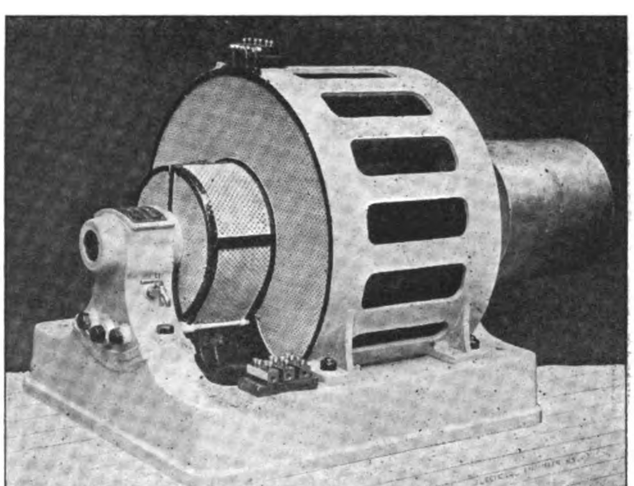

FIG. 13.—20 H.-P. SINGLE-PHASE INDUCTION MOTOR.

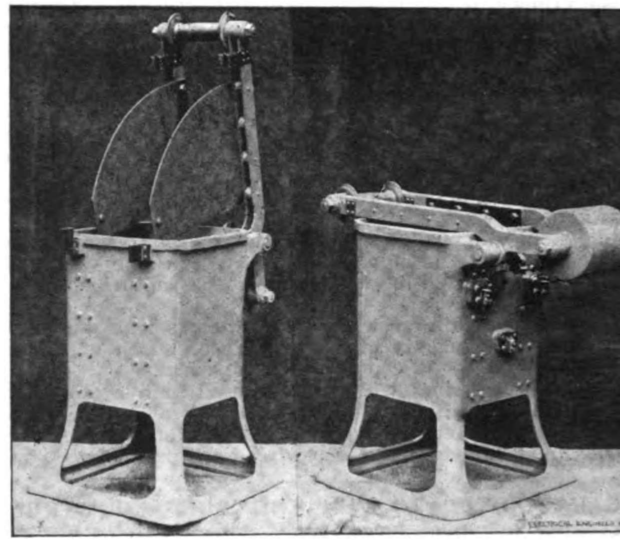
the start the primary works as a diphase winding, the secondary induced winding is preferably a three-phase one, as it gives a nearly equal starting torque in every position. The induced current is carried to a water rheostat, Figs. 14 and 15; by dipping the iron plates at first very little into the water, a large resistance is inserted in the secondary, which greatly increases the starting torque.

The starting current is never as large as the current during ordinary work. This is of great importance, for the reaction of the starting of a motor on the central station is of importance. The author has employed a simple way to start an induction motor of this construction, if any other motor of the same kind near at hand is already running. Referring again to Fig. 10, we see that at full speed the current flows from I. to II. In the mean time, it is quite natural that with the winding drawn in the figure the tension between I. and III. has a difference of phase of just 90 degrees from the tension between II. and III. In reality III. is the middle of the winding between I. and II.; but at full speed a voltmeter applied to the terminals between I.-III. and II.-III. will show nearly 70 volts, if the main tension between I. and II. is 100 volts. By connecting the three terminals of any induction motor of suitable size to the terminals I., II. and III. of a motor already running, the former will start under full load, as an ordinary polyphase motor.

This method is a modification and concrete application of the



FIGS. 14 AND 15.—WATER RHEOSTAT.

phase shifting transformer of Messrs. Ferraris and Arno[1]; it has the advantage that by connecting the three terminals of all motors situated near at hand, only one motor need be started with the device mentioned above; all the other motors can start with two phases. In case of a large overload an ordinary induction motor would stop; by using these connections the phase-shifting action of the running motors does not permit the overloaded apparatus to come to rest. When the slip of one motor is larger than the slip of the other motors, there is always an equalizing current flowing between the middle terminals (III., of Fig. 10), of the motors; the larger the difference of load, the larger is the intensity of this current.

Fig. 16 shows an external view of the starting apparatus of a 3 horse-power single-phase induction motor. In its interior are the ohmic resistance and the choking coil. There are three positions of the handle: "Off," "Start," and "On."

A special arrangement for the starting of induction motors is the method proposed by Mr. de Kando. It is well known that the self-induction of toothed armatures depends to some extent on the number of the teeth. The primary winding of any polyphase motor can be divided into two different parts, so that the number of the teeth would be different for the

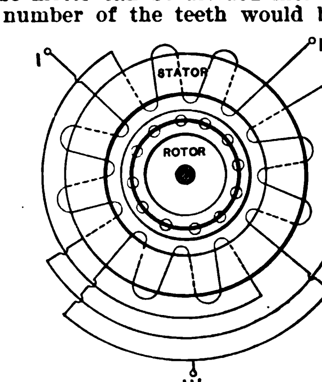


FIG. 10.

unit of length; the value of the self-induction would be different in the two windings. By sending a current in both coils the phase of the current will be split and it would be possible to produce a rotary field in this way. Nevertheless, it would not be advisable to employ an armature with different teeth. It is much better to remove from the circuit one part of the winding located in certain notches, for only the teeth magnetized by the current can have any influence on the value of self-induction. If between such two notches there is one slot the winding of which has no current, this part of the armature acts—as regards self-induction—as a winding located in teeth of double thickness.

[1] See The Electrical Engineer, June 3, 1896.

Referring to Fig. 17, if the switch is in the position shown by the dotted lines, the windings drawn dotted are removed from the circuit. Therefore in two quarters of the primary

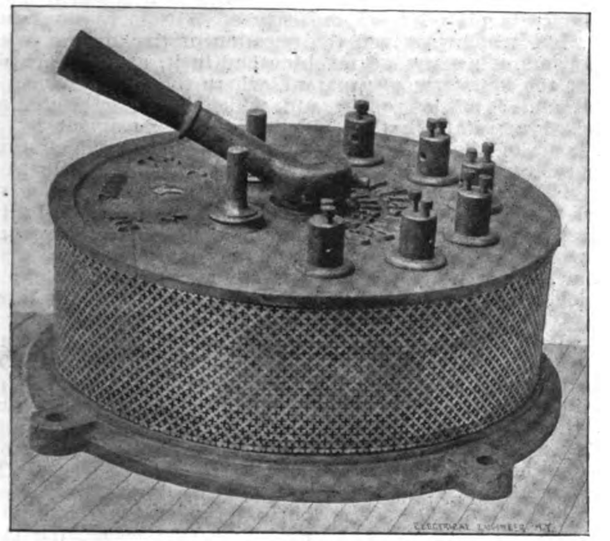

FIG. 16.—STARTING BOX FOR INDUCTION MOTORS.

the winding is located in teeth of double thickness. The motor will start nearly as a diphase motor, for the phase of the main current will be split into two different phases in both windings. At full speed the switch is thrown to the other position, and current flows through every notch. In this way we change during the starting the number of teeth which influence the

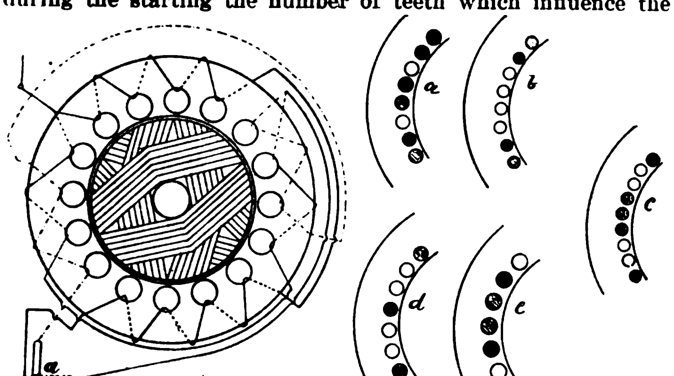

FIG. 17.—KANDO STARTING DEVICE FOR INDUCTION MOTORS.

self-induction. The figures a to e are different ways of proceeding; the windings in the black or in the shaded holes can be removed from the circuit.

An alternating fan motor starts in the way just described. A special small switch permits the change of connections at full speed.

POLYPHASE TRANSMISSION IN BELGIUM.

The Soignies Quarries in Belgium are equipped with an electrical plant which is of interest not only from its extent, but also from the fact of the use of three-phase alternating currents. The territory covered has an extent of 52 hectares and the former method of operation by a central steam plant required a fuel consumption of from 4 to 5 kg. of coal per horse-power hour. The fuel consumption with electrical transmission and distribution is less than 1 kg. Three Cornwall-Galloway boilers are used and a 350 horse-power compound slow-speed engine. Two dynamos are used, one for lighting, furnishing 300 amperes at 125 volts, and a three-phase alternator of the Oerlikon type, furnishing about 200 horse-power for the power work. The power house is centrally located and three lines are run from it, the length of each being 200 m., 310 m. and 700 m., respectively. At present four 24 horse-power motors, one 18 horse-power motor and one 9 horse-power motor, are operated for running sand saws and diamond saws. About 57 horse-power of the alternating current is used for illuminating purposes. The Soignies Quarries are the first industrial institutions in Belgium to use alternating current for power purposes and the results reached seem to fully justify the innovation.

LEGAL NOTES.

THE TROLLEY BASE SUIT.—JUDGE TOWNSEND'S ORDER GREATLY MODIFIED.—TROLLEY BASES MAY BE SOLD AND USED UNDER CERTAIN CONDITIONS.—GENERAL ELECTRIC CO., VS. THE KELSEY CO.—OPINION OF THE U. S. CIRCUIT COURT OF APPEALS.

On July 29 the United States Circuit Court of Appeals, sitting at New York, handed down an opinion in the suit of the General Electric Company against the Kelsey Electric Railway Specialty Company, of New Haven. Its decision, which is final, greatly modifies the stringent prohibition against the manufacture and sale of trolley stands or bases as contained in Judge Townsend's injunction order granted by him in March last against the Kelsey Company. The result is that it is now possible for electric railway companies to replace broken or worn-out trolleys purchased from the General Electric Company, or to replace them entirely by other improved trolley bases purchased in the open market.

Judge Wallace in a dissenting minority opinion, goes even farther and holds that the injunction ought never to have issued and that there ought to be no bar whatever to the free manufacture and sale of trolley bases. In view of the importance of the case we give below both opinions in full:

SHIPMAN, C. J.

The Circuit Court of the United States for the District of Connecticut, after an exhaustive investigation of the validity and alleged infringement of letters patent No. 495,443, dated April 11, 1893, and issued to the administrators of Charles J. Van Depoele, decreed that the Winchester avenue Railroad Company had infringed claims 6, 7, 8, 12, and 16 of the patent. The complainant in the suit was the Thomson-Houston Electric Company, the assignee of the patentees. The combination covered by these claims and now used generally by the electric railroads of the country, consisted "generally in an electric railway having an overhead conductor and a car for said railway provided with a contact device carried by the car so as to form a unitary structure therewith and consisting of a trailing arm, hinged and pivoted to the car so as to bridge the space between it and the conductor and move freely both laterally and vertically, and said arm carrying at its outer end a contact device capable of being pressed upward by a suitable tension device into engagement with the under side of the conductor."

The important and distinctive part of the invention was the trailing arm hinged and pivoted to the car, and moving laterally and vertically, with a contact device at its outer end capable of being pressed upward by a suitable tension device into engagement with the under side of the conductor. The novel element of "the overhead, underrunning, spring pressed, laterally swinging contact arm" was of great utility and has superseded pre-existing attempts at trolley road equipment. The trolley stand, so called, is the means by which the traveling arm is hinged and pivoted to the car with a capacity for lateral and vertical movement, and is pressed upward by some suitable spring. No particular form of a stand was included in the Van Depeole invention, for any one of a number of forms would answer the purpose.

The defendant, the Kelsey Electric Railway Specialty Company, manufactures a particular form of trolley stand, for which letters patent have been issued, which it has advertised for sale, and has also in its advertisements represented itself as a dealer in trolley poles and overhead trolley equipments. Its trolley stand consisted in the main of a base secured to the car roof, a frame revolubly mounted upon the frame so as to receive the end of a trolley arm, and springs by which tension upon the arm is produced. The Thomson-Houston Electric Company having brought suit against the Kelsey Company for infringement of this Van Depeole patent, the Circuit Court for the District of Connecticut granted a motion for an injunction pendente lite against its making or selling any apparatus embodying the subject matter of, or any trolley bases devised or intended to be used in infringement of those claims of said patent which were found to have been infringed in the Winchester case. The present appeal is from this order.

The question, as presented in the affidavit and briefs, relates particularly to the manufacture and sale of trolley stands. As evidence of an intention to infringe, the complainant relied upon the language of the defendants advertisement, which offered for sale the stands and overhead trolley equipment generally.

The defendant admits that he has sold trolley stands directly or indirectly to electric companies which purchased their equipment originally from the .complainant's licensees,

either by way of repair or because the purchasers wanted an improved stand. It denies that it has knowingly sold to an infringer of the patent in suit or to be used for the purpose of infringement. The circuit judge was of opinion that the defendant was selling stands capable of and designed for an unlawful use, and that inasmuch as they are useful only for the purpose of performing functions involved in the operation of the patent, there was a presumption of an intention that these stands should be so used, which was not dispelled by the affidavits.

The question being one of contributory infringement, the appellant urges that there was no sufficient evidence that the defendant had concerted or was concerting, or intended to concert with any person for the infringement of the complainant's patent, and that consequently the injunction order either ought not to have been issued or was too sweeping in its terms.

What contributory infringement is, and why it should be enjoined, was clearly shown in Wallace v. Holmes (9 Blatchf. 65), the earliest case in this country upon the subject, and upon which the subsequent cases if contributory infringement rest. The complainant's patent in that case was for an improved lamp, which consisted of an improved burner or metallic portion and a glass chimney. The defendant made and sold the improved burner, which must be used with a chimney, and in order to make sales, exhibited the burners with chimneys to customers and the circuit judge thought that a concert with others to use the patented article as a whole was a certain inference from the obvious facts in the case, and the efforts of the defendant to solicit sales by showing the operation of the whole patented article.

The willingness of the defendant in this case to aid other persons in any attempts which they may be disposed to make towards infringement, is also apparent. Its trolley stands are designed to be used in the patented system and to be the means of enabling the trailing pole to perform its distinctive and novel part in the combination. It sufficiently appears from the defendant's adverstisements and affidavits, that it was ready to sell to any and all purchasers, irrespective of their character as infringers. A proposed concert of action with infringers, if they presented themselves, is fairly to be inferred from the obvious facts of the case, and an injunction order is the proper remedy against wrongful acts which are proposed or are justly to be anticipated.

But the defendant says also, that the order which was granted, is capable of too sweeping an interpretation, because it has a right to supply purchasers who have acquired the right to use the patented combination, with its trolley stands, either by way of repair, or because the stands which were furnished to them were not adapted to the needs of the cars upon which they were placed, and it invokes the principle which was stated in Chaffee v. Boston Belting Company, 22 How. 217, as follows: "If a person legally acquires a title to that which is the subject of letters patent, he may continue to use it until it is worn out, or he may repair it or improve upon it, as he pleases, in the same manner as if dealing with property of any other kind." The complainant, which is utilizing its patent rights by the manufacture and sale of trolley railroad equipments, and desires to compel purchasers to continue to supply themselves with its form of stands, replies that the defendant's sales are not for the purpose of repair, but are for the reconstruction of the patented combination; and that a reconstruction of a destroyed or worn out combination is an infringement. This proposition is true, and examples of the cases to which it is applicable are found in Cotton Tie Compnay v. Simmons, 106 U. S., 89, and Davis Electrical Works v. Edison Electric Light Company, 60 Fed. Rep. 276. In the Cotton Tie case, the continued use of patented ties, which consist of a band and buckle, was purposely destroyed by the purchaser, by cutting the band after he had received the bale around which the tie was placed, and the parts were sold as waste material. A new purchaser bought the several parts, mended the bands, replaced the buckles, sold them to be used as ties, and was held to be an infringer.

In the Edison case, the reconstruction was equally extensive; the infringer made a hole in the bulb of an Edison incondescent electric lamp, in which the carbon filament had been worn out, put in a new filament having its ends cemented in platinum sleeves, fused a tube of glass into the open end of the bulb, exhausted the air and sealed the bulb. Inasmuch as "the filament duly charged is the light giving thing," the work of the infringer was the manufacture of a new lamp.

The complainant, recognizing that the facts in these cases are not analogous to those in the record now before us, urges that in order to constitute reconstruction of a patented device it is not necessary that the structure should have been destroyed intentionally, or that the vital and peculiar element of the invention should have been worn out by use, but that the substitution of an important member of a patented combination, which was intended to be permanent, in place of the corresponding member which had been accidentally broken or had been worn out, is reconstruction, and that there is a recognized distinction between such a substitution and the replacing of fragile members whose life is necessarily short.

Reliance is placed upon the case of Wilson v. Simpson, 9 How. 108, which involved the question of the interest which the owners of a patented machine had in it, after the expiration of the first term of a patent, where there had been a renewal and extension of it, and which has been sometimes supposed to establish the rule that the replacement by the purchaser of the parts of a patented machine which must, from their nature, be temporary, is permissible while in no event is the replacement permissible of a part which it was hoped would be permanent. The case related to the right of a purchaser of a Woodworth planing machine to replace cutters which ordinarily had a life of only sixty or ninety days, and, as a necessity, the opinion dwells upon that fact, but the decision did not make it a sine qua non, and did not intend to say that temporary cutters can be replaced, and that an element intended to be permanent, but accidentally broken in thirty days after it was purchased, cannot be replaced. The distinction which the court was endeavoring to point out and which it thought was well illustrated in the Woodworth planer, was the difference between the repair or replacement of a single element of a combination and the manufacture of a new machine in place of one which had become useless. The court says: "We admit, for such is the rule in Wilson v. Rousseau, 4 Howard, that when the material of the combination ceases to exist, in whatever way that may occur, the right to renew it depends upon the right to make the invention. If the right to make does not exist, there is no right to rebuild the combination.

"But it does not follow, when one of the elements of the combination has become so much worn as to be inoperative, or has been broken, that the machine no longer exists, for restoration to its original use, by the owner who has bought its use. When the wearing or injury is partial, then repair is restoration, and not reconstruction.

"Illustrations of this will occur to any one, from the frequent repairs of many machines for agricultural purposes. Also from the repair and replacement of broken or worn out parts of larger and more complex combinations for manufactures. In either case, repairing partial injuries, whether they occur from accident or from wear and tear, is only refitting a machine for use. And it is no more than that, though it shall be a replacement of an essential part of a combination. It is the use of the whole of that which a purchaser buys, when the patentee sells to him a machine; and when he repairs the damages which may be done to it, it is no more than the exercise of that right of care which every one may use to give duration to that which he owns, or has a right to use as a whole."

This distinction is both natural and founded upon right reason and gives to the patentee all the benefits to which he is entitled by the grant of the patent. While it is not intended that a trolley stand should be broken, or should lose its useful capacity, either calamity may befall it, and the right to replace the injured part by a new stand from any person who can supply the article, should be conceded by the owners of the patent.

It is not intended to permit the unauthorized substitution of the vital and distinctively new part of an invention in place of one worn out by use, as the substitution of a new filament in an Edison incandescent lamp, or the substitution of a new for an old burner in the Wallace case (supra), but the trolley stand is not the vital element of the invention, though a portion of it is an element of the combination; it is the means, and in most cases the non-patented means, for there are numerous forms of these bases by which the pole is permitted to perform its functions.

The defendant also says that in order to obtain the use of an improved trolley stand, purchasers from the complainant are sometimes willing to discard its stands and substitute another form which has its own advantages. For example, the trolley stand which is sold by the defendant, is said to be less elevated above the top of the car than the stand of the complainant, and, therefore, it is said that the Norwalk Street Railway Company found it necessary to change the stands which were furnished by the complainants, because of the low bridges constructed by a steam railroad company over the tracks of the street electric road. A refusal to permit such a substitution is equivalent to a declaration that the Street Railway Company cannot be permitted to improve its stands, except by the consent of the complainant. If a purchaser of the complainant chooses, the day after his purchase, to substitute a stand which is better made and better adapted to his peculiar needs, he has the right to do so. But it will be urged that such a permission opens the door to infringement and permits a spoliation of the conceded rights of the com-

plainant. It does throw upon the defendant the duty of careful investigation into the objects of the purchasers of its stands and of an abandonment of indifference as to whether they are seeking to trench upon the rights of the owners of the patent or else a liability to suffer the consequences of a violation of the injunction order.

The order is directed to be modified, without costs of this Court by adding the words: It is not intended to enjoin the defendant against the sale of trolley stands by way of replacement of broken stands or stands worn by use, or of substitution for trolley stands previously sold by the complainant to purchasers from it, but this permission does not give authority to reconstruct or rebuild a combination which has been sold by the complainant.

Mr. Frederic H. Betts, for the complainant. Mr. Edward H. Rogers, for the defendant.

The following is the opinion of Judge Wallace:

WALLACE, C. J.

This case presents in my view an utterly unwarranted attempt on the part of the complainant to enlarge the monopoly which it had acquired as the owner of the patents in suit and to dominate exclusively the manufacture and sale of articles which its patents do not cover and which others have a legal and moral right to make and sell. The preliminary injunction by which the defendants are restrained from making or vending their trolley stands was granted without a particle of evidence that they had ever infringed any of the claims of the complainant's patents, and, as I think, without the slightest evidence that they threaten to do so. They are as much entitled to make and sell their trolley stands as they are to make and sell the rails, the poles, the wires, the screws, the paint or any other article which may be required for use by those who own and operate electric railways in which the improvements covered by the patents of the complainant are utilized. The country is crowded with electric railways which utilize these improvements, but the improvements do not consist in the trolley stand; they consist in various combinations of parts of which a trolley stand in some form is one. These railways are generally owned and operated by corporations, a great number of which buy their outfit from the complainant and thereby acquire the right to use the patented combinations during the life of the organized parts. Concededly they have a right to repair their trolley stands, to substitute new ones for those old or worn out, or to substitute a better and improved kind for those originally bought of the complainant. The defendants have an equal right to make and sell the stands to such owners for that purpose.

The injunction was granted upon the theory that a case of contributory infringement had been shown. The only evidence of contributory infringement consists in the fact that the defendants are making, advertising and selling their trolley stands to the public. That they are concerting with infringers with a view to assist them in appropriating without compensation the inventions patented by the complainant there is not a particle of evidence. Being entitled to sell their article they are under no obligation before selling it to inquire whether the purchaser intends to make an illegal use of it. Privity with a wrong-doer is not to be inferred from the exercise of a legal right. The man who sells a gun or a knife would be guilty of an impertinence if he should inquire of the purchaser whether he intends to use it legitimately, and is under no duty to do so. The same rule applies to one who makes or sells an article which is not patented, but which may be used by the purchaser to work an infringement of a patent if he so chooses. One who assists another to infringe a patent is of course a tort-feaser, and whether he is called a contributory infringer, or merely an infringer, is only a matter of nomenclature. But he does not assist or concert with another to infringe merely because he sells him an article which may be used to effect an infringement. In other words, participation in a wrong is not established by doing a lawful act without evidence of an unlawful intention.

I think the order granting the preliminary injunction should be reversed.

A RECEIVER FOR THE U. S. ELECTRIC COMPANY OF BALTIMORE.

ON July 14 application was made for an accounting and for the appointing of a receiver for the United States Electric Power and Light Company, of Baltimore. The petition is directed against the Brush Electric Company and sixteen others, comprising the stockholders of the United States Company. The question is raised that the charter of the United States Company is ineffective because the law does not allow the chartering of an electric company in Baltimore, save for telegraph or telephone purposes. Other electric companies, it is claimed, have amendments to the charters granted by special act of Legislature.

The petitioner charges that the United States Company was formerly operated at a profit, but under the control of the Brush Company, and since last fall has come to be operated at a loss, as the absorbing company took all the profitable contracts to itself. On account of the ineffectiveness of the charter, it is claimed that the stockholders are simply copartners, and for that reason could be made individually liable for the debts of the company. For fear outside creditors would step in and compel the stockholders to pay the deficiency in receipts of the company the receiver is asked.

INJUNCTION AGAINST THE CHICAGO GENEREL ELECTRIC RAILWAY COMPANY DISSOLVED.

Judge Neely last week dissolved the injunction recently obtained by Charles Austin Bates against the Chicago General Electric Railway Company.

Some months ago Bates filed a bill claiming the ownership of $2,000,000 of stock and alleging that he had given it to Pres. Clark escrow. Clark, he said, wanted it simply to make it appear that one man owned a controlling interest in the stock of the company, which would the more readily induce purchasers to invest. The court held that Bates had no valid claim to the $2,000,000 worth of General Electric stock, which he said President Clark was illegally withholding from him.

WESTINGHOUSE AIR BRAKE CO. SUES H. S. PARK ON HIS ELECTRO MAGNETIC CAR BRAKE.

The Westinghouse Air-Brake Company has filed a bill in the United States Court charging Harvey S. Park with wrongfully withholding three patents for improvements on Park's electromagnetic car brake. The company asserts that the purchase of the patents included the subsequent improvements which Park now seems to use for the benefit of himself and A. N. Loeb.

IN conversation with Mr. Louis B. Marks, of the Electric Arc Light Company, who first delivered his lecture on the theory of the inclosed arc at the World's Fair Electrical Congress, in 1895, we learn that many of those who at that time pooh-poohed the practicability of his scheme now admit their error.

Mr. Marks states that he has succeeded in interesting the proper backing, which now represents a capital of $2,000,000, with offers of $7,000,000 to $8,000,000 more when needed. He intends to invoke the full protection of the law for his patents. The long-hour lamp has evidently come to stay, judging by the preference it is receiving in all large orders now being placed.

REPORTS OF COMPANIES.

THE NEW YORK EDISON CO.

We give below the New York Edison Illuminating Company's earnings for June:

	1896.	1895.	Iucrease.
Gross	$ 159,068.02	$ 147,637.40	$11,430.62
Net	67,412.39	72,273.72	5,861.33 dec.
Gross, 6 months ..	$1,105,904.64	$1,015,948.19	$89,956.45
Net, 6 months	544,532.99	491,002.32	53,530.67

EDUCATIONAL.

MECHANIC ARTS AT THE UNIVERSITY OF NEBRASKA.

The University of Nebraska, recognizing the need of secondary technical instruction in that State, has established a School of Mechanical Arts, with the object of giving an impetus to industrial pursuits in Nebraska. Among the faculty we note the name of Professor R. B. Owens, E. E., professor of electrical engineering. This school is intended for those young men who expect to enter some one of the mechanical trades, and who desire a scientific basis for their work. All the scientific and technical instruction is planned to be of practical value in any line of mechanical work that may be taken up. The school year will coincide with the university year, beginning Sept. 15, and closing June 10.

INTERNATIONAL TELEGRAPHIC CONFERENCE.

The conference at Buda-Pesth was opened by a speech from the Minister of Commerce, His Excellency, Ernst Dániel, who presided. Representatives from Chili, San Salvador, and Venezuela, which countries have hitherto stood outside the International Convention, were present, in addition to the accredited representatives of the States subscribing to the convention, and the principal cable and telegraph companies.

SOCIETY AND CLUB NOTES.

MEETING OF THE ASSOCIATION OF EDISON ILLUMINATING COMPANIES.

The next meeting of the Association of Edison Illuminating Companies will be held on August 11, 12 and 13, at Manhattan Beach, Brooklyn. The Oriental Hotel has been selected as the headquarters of the convention during its Brooklyn session, although the Manhattan Beach Hotel is also available, and within easy walking distance.

The first two days of the convention will be devoted to the reading and discussion of papers, and on the third day the General Electric Company invite the delegates to Schenectady to inspect their works and will return the party to New York on the same day.

VERBAND DEUTSCHER ELEKTROTECHNIKER.

The fourth annual meeting of this society of German electrical engineers was held at Berlin recently, and was, according to the "Elektrotechnische Zeitschrift," a great success. Among the guests at the grand dinner was Li Hung Chang, the viceroy of China. The annual report of the Verband shows an increase in the membership of 102, bringing the total up to 1,645. The finances are in a satisfactory condition, and in the technical department several successes have been obtained. The Verband has been consulted by the Imperial Government with regard to the proposed law relating to the standardizing of electricity meters. Several municipalities have also consulted the Verband in electrical matters. The committee on low-pressure wiring rules reports the completion of the same, and has now been charged with the drawing up of similar rules relating to high-pressure installations. The $75 prize offered by the Verband for the best design of an un-interchangeable fuse was won by Mr. A. Rittershaussen, of Amsterdam. The incandescent lamp question was also under discussion at the Berlin meeting, and a committee consisting of manufacturers, supply station engineers and others, has been appointed to investigate the matter. The election of officers for the ensuing year resulted as follows: President, Herr Stübben, of Cologne; members of council, Herren Budde, Slaby, Naglo, Jordan, of Bremen, and Jordan, of Berlin. Eisenach has been selected for next year's meeting.

ANNUAL CONVENTION OF THE NEW JERSEY STATE DENTAL ASSOCIATION.

ELECTRICITY was very much in evidence in the papers, clinics, and exhibits at the twenty-sixth annual convention at Asbury Park, on July 29-31, of the New Jersey State Dental Association. For a scientific body, this association has a great deal of vigor and enterprise, and at all their meetings the pervading idea seems to be that it will not be long before electrical developments dominate practically the whole field of both diagnostic and operative work in dentistry. This is evidenced in the titles of many of the papers at Asbury Park.

It will be remembered that at the last convention of the association at the same place, quite a sensation was created by Dr. Gillett's paper on "Cataphoresis in the Obtunding of Sensitive Dentine." The principle of the electrical anæsthetizing of the tooth, so as to enable dental operations to be carried out painlessly had long been discussed, but the time occupied in creating the anæsthesia was so long as to be virtually prohibitive. A patient might sit in the chair half an hour, and still not be sure that his tooth was so obtunded that it could be operated upon without pain. The loss of time was serious, the nerves of the patient were disorganized, and not improbably those of the operator also. Dr. Gillette showed that the cataphoric method could be brought down to an operative duration of, on the average, seven or eight minutes. This meant that really painless dentistry was at last within reach, and further investigations in cataphoresis were actively pushed.

This activity has borne somewhat remarkable fruit. Foremost among those who have taken up the subject is Dr. G. Carleton Brown, the results of whose work may be said to have formed the principal feature of this year's convention. Cocaine, which is the standard drug used by dentists for anæsthetizing, is a non-conductor, and to be effective in cataphoresis it had to be blended with an electrolyte. Upon the effectiveness of this combination hung the whole time question of anæsthetic operations. Dr. Brown has discovered that by making a 15 per cent. solution of hydrochloride of cocaine and electrozone, and saturating the electrode cotton with it, perfect anæsthesia can be secured within a minute and a half. A singular point in the production of the obtunder is that after the component parts are placed in the graduated tube, even in carefully gauged proportions, there is no certainty that the product will come out all right. It should have a yellowish precipitate; if the color is white, the product is of no use.

In view of this supreme interest in cataphoresis in the world of dentistry, it is but natural that a leading feature of the electro-dental exhibits is the instrument with which cataphoric work is to be performed. For this instrument no adequate name has yet been originated, and as a makeshift the term volt selector is being used. The Edison Manufacturing Company showed a "fractional volt selector and regulator for cataphoresis," which they claim meets the demand of the dentist for a device that shall actually regulate both the voltage and the amperage used by the operator, when applying either the battery of the street current, for cataphoresis, both for obtunding and bleaching purposes. Their instrument runs up to 100 volts, and the regulator will graduate from 20 volts by one-hundredths of a volt, which gives a perfectly even regulation, and obviates the possibility of unpleasant shock. This question of shock is the bugbear of all the instrument makers. The Edison Manufacturing Company's instrument is provided with a Kennelly volt-milli-ammeter, reading from 0 to 15 milli-amperes, and 0 to 150 volts. By turning a switch to the right, the volt meter is thrown into the circuit, and on moving it to the left the milli-ammeter is brought into service, so that the operator can ascertain at any instant the exact current and voltage he is using. The instrument is equipped with a graduated scale along which moves a pointer for indicating the amount of resistance employed at any time. It can be used equally well for battery and for electric light current.

Another new dental apparatus for cataphoric treatment exhibited by Waite & Bartlett, was the Van Woert rheostat, made after suggestions by Dr. Van Woert, who pins his faith on the intelligent and successful use of cataphoresis to a reliable battery, the cells of which can be thrown on, one or more at a time, in order that the result may be accomplished with as low a voltage as possible. Dr. Van Woert may be looked upon as the apostle of the homeopathic dosage of electricity. His argument that it is of no use to take an electrical sledge hammer when a tack hammer will do is unanswerable. In this instrument a reliable rheostat controls the current evenly and smoothly, so that the patient is distressed by no sudden shocks or jumps. One of the important features of the instrument is a milli-ampere-meter, which is graduated to indicate fifths or tenths of a milli-ampere. The amount of current actually used for ordinary operations rarely exceeds from three-fifths to one milli-ampere. In the Van Woert apparatus, on the contrary, all parts are contained in one small, portable case, to which they are permanently fixed. This apparatus is for dental cataphoresis only.

The very latest candidate for current controlling honors as applied to cataphoresis is the instrument shown for the first time in public in the exhibit of the S. S. White Dental Manufacturing Company. This is one of the most beautiful instruments for surgical and dental work that has ever been constructed. In it the use of the Carpenter enamel rheostat is admirably combined with that of the Weston milli-ammeter, and the result is an appliance which can be used either with battery or street circuit, and which appears to meet all the requirements of cataphoric work.

A very complete electrical dental outfit was also shown by the S. S. White Dental Company. The motor is enclosed in a glass vase to protect it from dust. It has an extra pair of brushes, and collecting rings for use with a transformer for operating the electric mallet, hot-air syringe, etc. The entire control of the running of the engine with this apparatus is in the treadle, which starts, stops, or reverses according to the direction and degree of foot pressure exerted.

The Wheeler fractional volt-selector was also shown at the exhibit of the Electrotherapeutic Company.

The X-ray naturally found an important place in the list of papers. Dr. Houston's paper on this subject, as well as that of Dr. Van Woert, was supplemented by the taking of radiographs by the static machine. Dentists recognize that the X-ray is already invaluable to them for both diagnostic and operative purposes. One picture showed a darkening in the bottom of a tooth the trouble of which it had been impossible to diagnose by ordinary methods. Another showed how the position of children's teeth within the gum can be ascertained, and thus many incipient troubles can be detected and remedied in good time. Dentists are on the lookout for an X-ray outfit of simple design that can be used in their offices, and are already wondering how they have been able to do so long without what now appears an indispensable adjunct to their equipment. In practice, the first thing a dentist will do with a new patient will be to make an X-ray picture of his mouth and jaw. Not only will all irregularities of formation be at once made apparent, but also the metallic filling in every tooth that has been already stopped.

After dwelling on the immense advantage of the new photography to dentistry, Dr. Van Woert proceeded to show the improvements that had been made in electrical dental supplies during the past twelve months. He said that the use of electrolysis for the treatment of abscesses, and certain diseases of the tooth was rapidly extending, and that the electric furnace had become standard in dental laboratories. In the glazing of the teeth and the baking of the investment or mold it saved all cracking and distortion, and the certainty of its results was a pleasant change to men who had had a long experience of the disappointment and vexation of the old dental furnaces.

Interesting additions to the records of new work in the bleaching of teeth by cataphoresis were given by Dr. C. A. Meeker. Dr. Meeker finds the best results with pyrozone, of which he uses a 25 per cent. aqueous solution for cataphoric work. When using hot or dry air, he employs a 75 per cent. ethereal solution. In this way badly discolored teeth can be effectively bleached in 25 to 30 minutes. Beyond these applications of electricity, the extirpation of nerve pulp, extraction, implantation and many other dental operations, as well as new special uses for different kinds of current, came up for discussion.

PERSONAL.

MR. T. C. MARTIN is now en route for New York, having left Southampton August 1, on the American liner "St. Louis."

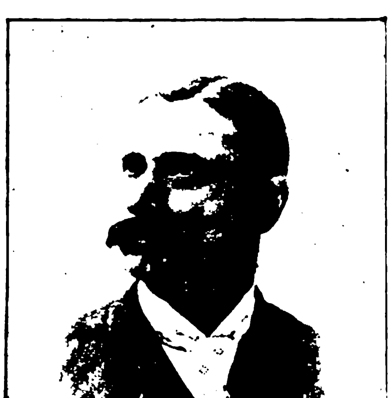
MR. THOMAS G. GRIER, formerly with the Bryant Electric Company, from which he resigned on June 1, has accepted a position with the Western Electric Company, and is now installed in the supply department of that concern.

MR. NIKOLA TESLA has just visited Niagara, where he inspected the great power house, in company with a party consisting of Mr. E. D. Adams, Mr. W. B. Rankine, Mr. Theo. N. Ely, chief of motive power of the Pennsylvania Railroad, and Chief Engineer Geo. W. Melville, U. S. N. This was Mr. Tesla's first visit to Niagara since the great work there was begun.

MR. THOS. J. FAY has been appointed general manager of the C. & C. Electric Company, of New York. Mr. Fay has been associated with the company for a number of years, both in a practical and a business capacity, and his extensive experience in the electrical business undoubtedly qualifies him to take entire charge of the large and growing business of the C. & C. Company.

OBITUARY.

EDWARD A. ECKERT, whose sudden death on July 26 was mentioned in these columns last week, was prominently identified with the invention of important telephonic apparatus. To-day there are few exchanges licensed by the American Bell Telephone Company which do not contain his inventions.



Edward A. Eckert.

He was co-patentee with J. O. Shiras, of the multiple switchboard, and it was under his direction that the first multiple switchboard ever operated was put into service. This was in the Covington (Ky.) exchange of the Bell Telephone Co., of Cincinnati, in 1881.

The monitor desk, with which all large Bell exchanges are equipped, is another of his inventions. By means of this device the manager of the exchange is connected with the receiver and transmitter of each operator and can watch the service without the knowledge of the operator. The patent covering this, as well as the switchboard, were acquired by the American Bell Telephone Company, through its sale to the Western Electric Company, some years ago.

It will be readily seen that Mr. Eckert's inventions are of great importance in the operation of telephone exchanges. First, he improved the switchboard, thus permitting of rapid and reliable service, and then he invented apparatus which brought the discipline of the operating force to the highest standard, and to these two inventions much of the high grade service of to-day may be attributed.

Mr. Eckert was born in 1841, at Wooster, O., and served through the late war in the Military Telegraph Corps.

JOHN J. HOGAN, the inventor of the Hogan boiler, died in Middletown, N. Y., last week, of Bright's disease. He was born in Ireland and was educated in Dublin and Belgium. His mechanical genius led Sir William Fairchild to apprentice him to the Reading Iron Works, near London, paying a fee of £300 therefor. He lived for a time in New York and St. Louis before building the boiler works in Middletown.

NEWS AND NOTES.

FIFTIETH ANNIVERSARY OF THE "SCIENTIFIC AMERICAN."

We congratulate our esteemed contemporary, the "Scientific American," which has just signalized its 50th anniversary by the publication of a very handsome 72-page special number, which consists of a review of the development of science and the industrial arts in the United States during the past fifty years. It was an ambitious undertaking, and the work has been well done. The many articles are thoroughly technical, and they are written in a racy and popular style, which makes the whole volume—it is nothing less, being equal to a book of 442 ordinary pages—thoroughly readable. It is inclosed for preservation in a handsome cover, and is sold at the price of 10 cents.

THE MESSAGE AROUND THE WORLD.

The Western Union Telegraph Company and the Postal Telegraph Cable Company, and the Commercial Cable Co. have filed their official reports of the transmission of the historic message of Dr. Chauncey M. Depew around the world from the National Electrical Exposition on May 10. These reports, together with the original messages in the handwriting of Dr. Depew and Edward D. Adams, will be filed at the Smithsonian Institute, in Washington, together with all of the telegraphic instruments used upon that occasion. The transcription of the messages by Thomas A. Edison, acting as the receiving operator, will also be placed in the institution.

DISTURBANCE OF TELEGRAPH AND TELEPHONE CIRCUITS BY LIGHT AND POWER CURRENT.

Some interesting statistics with regard to disturbances of telegraph and telephone circuits by lighting and power currents have been compiled by the German Imperial Postoffice, and were communicated to the "Elektrotechnischer Verein" of Berlin by Dr. Strecker, a little time ago. The statistics cover the period 1891—1896, and give 76 cases of damage to circuits and apparatus. In 1891 there were five cases, in 1892 four cases, in 1893 two cases, in 1894 fifteen cases, in 1895 thirty-one cases, and in 1896, for the first four months, nineteen cases. The increase in the number of disturbances is explained by the increase of electric tramways. In almost all cases it was telephone circuits that suffered, and only two cases of damage to telegraph lines are reported. In 61 cases electric railways caused the disturbance, and in 15 cases electric lighting plants. In 59 cases the safety devices, such as wooden strips, guard wires, etc., failed to act. In 40 of the 76 cases the telephone or telegraph wire broke, and had been in contact with the live circuit. Many disturbances were caused during the stringing of the telegraph or telephone wire, and also by broken guard wires themselves. The damage caused, however, was mostly small, on an average of about $3.50. There were, however, two fires in 1894 at Dortmund and Barmen, and the damage amounted to $1,350 and $7,750. To protect instruments from currents of too high pressure the German postoffice puts fuses into the circuits. These fuses consist of a wire 0.07 mm. in diameter, and made of a non-oxidizable alloy. They are inclosed in glass tubes 5 cm. to 6 cm. long, sealed up at both ends, and fitted with metal contact pieces. In this way the formation of an arc at 500 volts pressure is avoided. The fusing current of the wire is 0.8 ampere. The whole fuse is kept in position between contact springs, and is easily interchangeable. Another type of fuse used by the Imperial postoffice consists of a porcelain block, about 5 cm. high, the fuse wire running through a hole across the block. Both types have given great satisfaction.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES—III.

BY J. A. FLEMING, M. A., D. SC., F. R. S., M. R. I.

We carried on a long struggle with bismuth in the endeavor to unravel some of the electrical peculiarities of that metal at low temperatures. Chemists are aware of the extreme difficulty of preparing bismuth in a state of perfect chemical purity by purely chemical means. From several different sources we procured bismuth which had been carefully prepared by the reduction of the oxychloride, or nitrate, after careful reprecipitations. This bismuth was then pressed into wire, and its resistance curves taken down to the lowest attainable temperatures. We found some very extraordinary results. Although sensibly agreeing in resistivity at ordinary temperatures, in two cases the resistance curves had a minimum point, and after reaching this at about —80 deg. tended upward again, showing that the resistance was increasing as the metal was further cooled. These curves could be repeated as often as necessary with these samples. Another specimen gave a curve with a double bend (see Fig. 8). These results convinced us

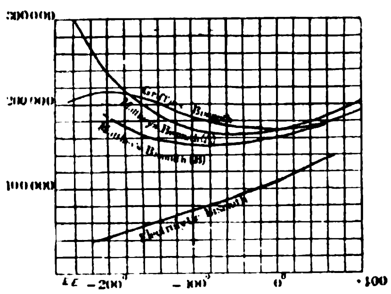


FIG. 8.

that it would be necessary to prepare bismuth electrolytically, and with the assistance of Messrs. Hartmann and Braun, of Frankfort, who have made a special study of the preparation of electrolytic bismuth, we were provided with a quantity of metal, which examination showed to be chemically pure. On taking the resistance curve of a sample of the electrolytic bismuth when pressed into uniform wire under great pressure, we found that its behavior was perfectly normal, and that the resistance line tended downward, as in the case of all other pure metals, to the absolute zero. Also we found that the specific resistance of this last was very much less than that of the chemically-prepared samples, and less even than that employed by Matthiessen. Hence, pure bismuth is no exception to the law enunciated above. Bismuth is characterized especially by many peculiarities. It has been known for some time that the resistance of a bismuth wire is increased when it is placed in a magnetic field so that the lines of the field are perpendicular to the direction of the current flow. This is easily shown by means of one of Hartmann and Braun's spirals, manufactured now purposely for measuring magnetic fields.

We have, however, discovered that if bismuth is cooled to the temperature of liquid air, the effect of any given magnetic field in changing its resistance is increased many times. Thus, for example, a certain bismuth wire we used had a resistance of 1.690 ohms at 20 deg. C. Placed in a magnetic field of strength

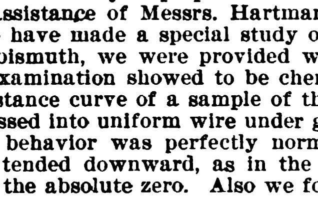

FIG. 9.

2,750 C. G. S. units, its resistance was increased to 1.792 ohms, or by 6 per cent. The wire was then cooled in liquid air, and its resistance lowered to 0.572 ohm. On putting it then into the magnetic field of strength 2,750 C. G. S. units, its resistance became 2.68 ohms. Hence, it had increased 368 per cent. This magnetic field can then actually reverse the effect of the cooling and cause the bismuth, when cooled and magnetized, to have a greater resistance than when at ordinary temperatures and unmagnetized. We are at present engaged in further unraveling the problems presented by this new discovery with regard to bismuth. It is certainly very startling to find that a magnetic field which increases the resistance only 5 per cent. at ordinary temperatures increases it five times at —186 deg. C. It will be seen that this process of taking the resistance of a conductor in liquid air is one which affords us a very critical means of discrimination as to the chemical purity of a metal. It ranks almost with the spectroscope as an analytical method.

Time will only permit one brief reference to the behavior of carbon in regard to electrical conductivity when cooled to low temperatures. We have found that carbon in the form of carbon filaments taken from various incandescent lamps continued to increase in resistance as it was lowered in temperature. The resistivity at various temperatures of the carbon from an Edison-Swan lamp at various temperatures is as follows:

C. G. S. Units.		Temperature.
$3,911 \times 10^3$	at	18° C.
$3,835 \times 10^3$	"	99° C.
3.911×10^3	"	18° .9 C.
$3,953 \times 10^3$	"	1° C.
$4,054 \times 10^3$	"	— 78° C.
$4,079 \times 10^3$	"	—100° C.
$4,180 \times 10^3$	"	—182° C.

These values when represented on a chart give almost a straight line, and show that the resistivity of carbon continually increases as it is cooled, but at a very slow rate. The temperature coefficient is therefore negative, and of about the same absolute magnitude as many alloys of high resistivity. The resistivity of this form of carbon is about three thousand times that of silver. Adamantine carbon taken from a Woodhouse and Rawson lamp had a resistivity 50 per cent. greater.

All the so-called insulators—e. g., glass, gutta percha, ebonite, paraffin—have resistivities enormously greater than that of carbon, but, like it, their resistance increases as the temperature is lowered. For the sake of comparison we have placed upon this chart of lines of metallic resistivity the resistance line of carbon, with ordinates drawn to a scale of one-hundredth part of those of the metals. To properly represent to the full scale the line of carbon, this chart, which is fifteen feet long, would have to be made one-third of a mile long. If we desired to represent on the same scale the resistivity of gutta percha, the length of the chart would have to be billions of miles; in fact, so long that light would take 5,000 years to traverse it from one end to the other. Even then, to represent to the same scale the resistance lines of paraffin and ebonite, it would have to be thirty or forty times longer[1].

We must next pass on to consider some problems in thermo-electricity which have engaged our attention. If we construct a thermo-electric couple of two metals in the form shown in the diagram (see Fig. 9), and connect this with a galvanometer, and if one junction is kept at a constant temperature—say, 0 deg. C.—whilst the other junction is heated or cooled to various temperatures, we shall in general, but not always, find an e. m. f. acting on this circuit when the junctions are at different temperatures. This e. m. f. depends on three things—the nature of the metals, the temperatures of the junctions, and on a certain temperature called the neutral temperature of the metals. An important matter in the experimental theory study of thermo-electric action is to discover the position of these neutral temperatures when different metals are tested with lead as the standard of comparison, and when one junction is kept at 0 deg. C. Elaborate experiments made by Professor Tait many years ago furnished full information on this matter for temperatures lying above 0 deg. C., and we especially desired to extend this knowledge to ranges of temperature between 0 deg. C. and —200 deg. C. Accordingly a number of thermo-electric junctions were prepared of various pure metals and alloys, the comparison metal being always pure lead. These couples were grouped together, and one set of junctions always kept at 0 deg. C. in melting ice. The other sets were cooled to various low temperatures by means of liquid air. The experimental process then consisted in measuring the e. m. f. set up in each length respectively, and at the same instant measuring the temperature of the low-temperature junction.

Two general conclusions are arrived at from a study of the thermo-electric lines as laid down in our chart, Fig. 7. The first of these is that the thermo-electric lines of many metals are by no means straight lines over extreme ranges of temperature. Hence the thermo-electric power is not simply a linear function of the absolute temperature. The second important fact is, that in the thermo-electric lines of certain metals at low temperatures there are sudden changes of direction, which indicate a change in the sign of the Thomson effect in that metal, and probably, therefore, some important molecular change at the corresponding temperature.

[1] The resistivities of platinoid, carbon and gutta percha at 0 deg. C. are nearly in the ratio of the numbers 4×10^4, 4×10^6, and 4×10^{23}.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Alternating Currents:

ALTERNATING CURRENTS IN CONDENSER RUSHES.—By Bernard P. Scattergood, M. A., Oxon. Some phenomena observed and explained in detail.—Lond. "Elec. Rev.," July 17, '96.

Central Stations:

CENTRAL STATIO NWORKING.—By W. L. Gethins. The eighteenth of a series of papers on this subject deals with system and forms in central station management.—"Elec. World," July 18, '96.

DETROIT MUNICIPAL LIGHTING PLANT.—General description of plant with an account of the costs of construction and operation.—"Elec. Eng'r.," July 29, '96.

MUNICIPAL CONTROL.—By W. Worth Bean. An account presented to the citizens of St. Joseph, Mich., showing the mistakes of municipal control.—"Elec. Eng'r," July 29, '96.

CENTRAL STATION INSURANCE.—By C. C. Paige. Read before the Northw. Elec. Assoc. Author suggests that underwriter rules should be modified.—"Elec. Eng'r.," July 29, '96.

SELECTION OF A DYNAMO.—By Cecil P. Poole. Author considers insulation, armature windings, commutator, brushes and holders, field magnet, sub-base, bearings and pulley. An outline of the salient points.—"Am. Elec.," July, '96.

Dynamos and Motors:

ON A WINDING FOR MOTOR GENERATORS.—By P. M. Heldt. A method for obtaining alternating current.—"Elec. World," July 18, '96.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST EXHIBITION.—By Alfred O. Dubsky. A description of the Ganz & Co. alternator with a view of elevation and section.—"Elec. Eng'r.," July 22, '96.

SINGLE-PHASE ALTERNATING CURRENT MOTOR.—By Gordon J. Scott. A brief outline of the Scott and Janney motor.—"Elec. Eng'r.," July 22, '96.

DISSIPATION OF ENERGY BY ARMATURE CURRENT.—By Otto T. Bláthy. Author claims to have discovered a loss of energy thus far unobserved, but editorially this is looked upon rather sceptically.—Lond. "Elec.," July 17, '96.

ARMATURES OF MASSIVE IRON IN ROTARY CURRENT MOTORS.—By V. Dolivo-Dobrowolsky. The rotary current motor constructed by the author about 1889, which was of the squirrel cage type, consisted of laminated iron sheets and paper insulated conductors. He has shown lately that a solid iron coil and no paper wrapping around the conductors makes the machine practically of the same efficiency.—"Elektrot. Zeitschr.," July 9, '96.

HOW IS MOTION GIVEN TO THE ARMATURE OF A DIRECT CURRENT MOTOR?—By Townsend Wolcott. A popular description in "Am. Elec.," July, '96.

MODERN COMMUTATOR CONSTRUCTION.—A large number of types described and illustrated in "Am. Elec.," July, '96.

Insolated Plants:

THE POWER PLANT AT THE NEW YORK CUSTOM HOUSE.—Power and lighting is done from the same type of units, at a pressure of 220 volts. Three units are employed. Detailed description of generating plant and distribution system.—"Elec. World," July 18, '96.

Lighting:

USE OF HIGH-VOLTAGE LAMPS.—By W. N. Stewart.—Gives a list of central stations which use the 220 volt lamp, and dwells on the simplicity attached to a high voltage system.—"Elec. World," July 18, '96.

SAHULKA DIRECT-CURRENT EFFECT IN ALTERNATING CURRENT ARC IRON-CARBON.—By Franz Gold. A peculiar effect was studied according to which a strong direct current flows in the direction from iron to carbon electrodes. The author repeated Sahulka's experiments and explains in detail his method of experimenting in "Zeitschr. f. Elektrot.," July 15, '96.

ELECTRIC ARC EFFICIENCY.—By A. Blondel. Paper read at the Congress of the French Asso. for the Adv. of Science. By means of the lumenmeter, careful tests were performed.—"L' Eclairage Elec.," July 4, '96.

Magnetism:

EFFECTS OF HYSTERESIS AND FOUCAULT CURRENT ON POLAR DIAGRAMS.—By F. Bedell and James E. Boyd. Mathematical treatment of certain effects.—"Elec. World," July 18, '96.

Measurements:

INSULATION MEASUREMENTS OF SYSTEMS AT WORK.—By E. J. Houston, Ph. D., and A. E. Kennelly, Sc. D. Methods for determining insulation resistance of continuous current three wire systems, while at work. It is shown how the individual leakage conductances may be approximately determined by varying the working pressure on one side of the system and observing the corresponding variation of potential to ground on the other; also how the resistance in and up to the ground of a grounded conductor under load may be measured from the central station.—"Elec. World," July 25, '96.

THE CAPILLARY ELECTROMETER IN THEORY AND PRACTICE.—By Geo. J. Burch, M. A. Author describes minutely how to make the instrument. He discusses the law of the capillary electrometer, gives full directions for producing photographic records, and concludes by giving some applications of his apparatus.—Lond. "Elec.," July 17, '96.

MEASURING OF SELF-INDUCTION.—By Hugo Andriessen.—Description of a new method for measuring self-induction, where the resistance of the circuit is arranged so as to cancel.—"Elektrot. Zeitschr.," July 9, '96.

Miscellaneous:

LIGHTNING ARRESTERS.—By W. R. Garton. Paper read before the Northw. Elec. Assoc. Same general points regarding lightning arresters and a description of the Garton type.—"Elec. Eng'r.," July 29, '96.

ELECTRICITY IN PAPER MAKING AT NIAGARA FALLS.—By Orrin E. Dunlap. Description of plant with a view of turbine and one generator in the Cliff Company's new power house.—"West. Elec.," July 25, '96.

Railways:

SERIES PARALLEL CONTROLLER.—By Wm. Baxter, Jr. A description with illustrating diagrams of the General Electric controller for four motor equipments.—"Elec. World," July 18, '96.

TESTS OF HEAVY MOTOR CARS.—By H. P. Curtiss and H. O. Pond. Graduating thesis at Cornell University. Some results of tests on four-motor equipments, friction, traction, acceleration curves, distribution between motors.—"Str. R'way Rev.," July 15, '96.

ELECTRICALLY BRAZING RAIL BONDS.—A method of brazing the copper bond directly to the rail by means of electric current. The inventor is D. W. Payne, of Elmira, N. Y.—"Str. R'way Rev.," July 15, '96.

WASHINGTON, ALEXANDRIA AND MOUNT VERNON ELECTRIC RAILWAY.—Description of devices for automatic changing from underground to overhead trolley.—"Str. R'way Rev.," July 15, '96.

Telegraphy:

GOVERNMENT TELEGRAPHY.—By Patrick B. Delany. Abstract of argument before the U. S. Senate Committee; states the advantages of Government Ownership and urges the adoption of more rapid systems.—"Elec. Eng'r.," July 22, '96.

Roentgen Rays:

THE SURVIVING HYPOTHESIS CONCERNING THE X-RAY.—By Dr. Oliver J. Lodge, F. R. S. The article is mainly devoted to a lucid exposition of the meaning and bearing of a marvelous piece of mathematical prediction, due to Helmholtz and dating back to the early part of 1893. Taking for a basis the electromagnetic theory of light, Helmholtz worked out the properties of electromagnetic waves of various lengths, with the result that before even the peculiar properties of Lenard rays were known, Helmholtz accurately described, as regards reflection and refraction, the behavior of the numerous varieties of X-rays.—Lond. "Elec.," July 17; Elec. Engr., Aug. 5, '96.

SOME EXPERIMENTS WITH ROENTGEN RAYS.—By John Burke, M. A. Deals principally with measurements of radiation.—"Lond. Elec.," July 17, '96.

ROENTGEN RADIATIONS.—Some remarks by Sir G. Stokes, according to which this scientist strongly believes in their being transverse vibrations.—Lond. "Elec. Eng'r.," July 17, '96.

Electro-Chemistry:

ELECTRO METALLURGY OF ALUMINUM.—By Dr. J. W. Richards. Author considered electrolysis of aqueous solutions and of fused compounds and finally electrothermal processes. Abstracted from the May issue of the "Journ. of the Frank. Inst.," in Lond. "Elec. Rev.," July 17, '96.

Transformers:

ALTERNATE CURRENT TRANSFORMERS.—By Dr. J. A.

Fleming, F. R. S. Cantor lectures delivered before the Soc. of Arts. The first lecture deals with the action of a transformer. —Lond. "Elec. Eng'r.," July 17, '96. Lond. "Elec. Rev.," July 17, '96.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JULY 28, 896.

Alarms and Signals:—

ELECTRIC RAILWAY SIGNAL. W. Daves, Jersey City, N. J., 564,683. Filed April 22, 1896.
Comprises automatic time circuit-controlling mechanism whereby the motor circuit will be opened or closed after a certain length of time.

SIGNALING APPARATUS. P. Lupke, Trenton, N. J., 564,706. Filed May 9, 1895.
A circuit-closing device adapted to be operated by a pivoted hanger when the latter is struck by a traveling obstruction.

ANNUNCIATOR. C. C. Gould, Buffalo, N. Y., 564,746. Filed Sept. 28, 1891.
Specially adapted for telephone switchboard use.

Secondary Batteries:—

PASTE-CARRYING PLATE FOR ELECTRIC ACCUMULATORS. F. W. Schneider, Triberg, Germany, 564,652. Filed May 2, 1896.
Consists of parallel bars, the sides of which are perpendicular to the faces of the plate and are connected each to the next by bridges.

Distribution:—

ELECTRIC TRANSFORMER. F. L. Sessions, Fort Wayne, Ind., 564,944. Filed Sept. 28, 1895.
Designed for use in triphase or polyphase systems.

Dynamos and Motors:—

ALTERNATING CURRENT GENERATOR. B. G. Lamme, Pittsburg, Pa., 564,702. Filed April 30, 1894.
A multipolar polyphase alternating current generator, a field magnet and an armature having two more poles than said field magnet, and a closed coil carried by said armature.

ALTERNATING CURRENT GENERATOR. B. G. Lamme, Pittsburg, Pa., 564,703. Filed June 30, 1894.
A closed coil radial pole armature having all its poles wound in the same direction, the wire being wound so as to skip alternate poles.

DYNAMO ELECTRIC MACHINE AND ELECTRIC MOTOR. W. B. Elliott and J. W. Eskholme, Westfield, N. J., 564,743. Filed Aug. 26, 1895.
The armature coils are provided with supporting frames, and independent cores that are adapted for insertion in, and removal from, the coils and frames.

Electro Metallurgy:—

PROCESS OF NICKEL PLATING. H. L. Haas, New York, 564,748. Filed Nov. 27, 1895.
Consists in employing, in a neutral solution, a continuous solid anode having a corrugated surface, and then passing an electric current through the anode and solution, balancing the solution of the anode and the deposit at the cathode, whereby the metallic strength of the solution is maintained substantially uniform.

ELECTRIC METAL SEPARATOR. H. H. Whitacre and A. C. Wolfe, Wellsville, O., 564,858. Filed Nov. 8, 1895.
A conducting pipe, a series of magnets radiating from the exterior thereof, and a supporting ring for said magnets, of two series of converging fingers of different lengths, respectively, within the pipe, the fingers of each series being arranged alternately and constituting multiform polar extremities of the magnets.

Lamps and Appurtenances:—

INCANDESCENT ELECTRIC LAMP FITTING. E. F. A. Soleau, Paris, France, 564,723. Filed March 19, 1896.
Means for reducing the size of holder to a minimum for electroller uses.

CUT-OUT FOR ARC LAMPS. A. H. Lucas, Pittsburg, Pa., 564,757. Filed April 4, 1896.
Provides automatically operative means when the lamp is lowered, to close the shunt circuit through the lamp.

ELECTRIC ARC LAMP. W. C. Armstrong, New York, 564,771. Filed Aug. 29, 1895.
Consists of a chimney of reduced diameter located above the works, a cover to inclose the works, fitted to slide up and down along the chimney.

ELECTRIC ARC LAMP. W. C. Armstrong, New York, 564,772. Filed Aug. 29, 1895.
Similar to above.

ELECTRIC ARC LAMP. B. B. Ward, New York, 564,907. Filed Feb. 15, 1893.
Device for protecting the shunt coil of the lamp.

Metal Working:—

ELECTRICAL METAL WORKING APPARATUS. H. Lemp, Lynn, Mass., 564,792. Filed Nov. 25, 1892.
The combination with clamps for the work, of a transformer, and means for freely moving the terminals thereof into and out of electrical circuit with the work.

ELECTRIC METAL SEPARATOR. H. H. Whitacre and A. C. Wolfe, Wellsville, O., 564,859. Filed Nov. 8, 1895.
Similar to above.

Miscellaneous:—

MOTOR VEHICLE. C. H. Barrows, Willimantic, Conn., 564,584. Filed July 6, 1895.
Comprises a rotary twin electric motor mounted on a spindle to have its weight equally distributed on opposite sides thereof, and direct gear connections between the motor-shaft and driving-wheel.

ELECTRICAL PROPULSION OF CANAL BOATS. A. C. Mather, Chicago, Ill., 564,629. Filed Dec. 1, 1893.
A flexible line extending from the trolley to a canal boat, and means for taking up the slack in the line.

ELECTRICAL SOAP. H. E. Rider, New York, 564,717. Filed Oct. 8, 1895.
Inserts a galvanic element in the soap. See page 129.

SECONDARY ELECTRIC CLOCK. J. H. Wilson, Rockwood, Tenn., 564,811. Filed Jan. 9, 1896.
Details of construction.

METHOD OF PURIFYING WATER. G. H. Sellers, Wilmington, Del., 564,940. Filed Sept. 6, 1895.
Consists in agitating therein pieces of another metal with which the iron can form a galvanic couple so as to facilitate the formation of an iron salt, soluble in the water.

Railway Appliances:—

ELECTRIC CAR BRAKE. A. W. Mitchell, Winthrop, Mass., 564,632. Filed Sept. 19, 1895.
Consists of a brake rod, a gear on said rod, a rack bar arranged to move back and forth in suitable guideways and engaging with the gear, and a spring secured to a suitable support bearing on said rack bar.

TROLLEY FINDER. H. Ogborn, Indianapolis, Ind., 564,638. Filed Jan. 13, 1896.
For description see page 122.

TROLLEY. D. Lippy, I. E. Finfrock, G. A. Rhinehart and D. R. Francis, Mansfield O., 564,793. Filed Sept. 24, 1895.
Comprises a frame, a pivoted masthead, a coiled spring, a block connected to said head and with the spring and means for adjusting said block, to change the tension of the spring.

TROLLEY. D. Lippy, I. E. Finfrock, G. A. Rhinehart and D. R. Francis, Mansfield, O., 564,794. Filed Sept. 24, 1895.
Similar to above.

TROLLEY. D. Lippy, I. E. Finfrock, G. A. Rhinehart and D. R. Francis, Mansfield, O., 564,795. Filed Sept. 24, 1895.
Similar to above.

ELECTRIC RACK-LOCOMOTIVE. David L. Barnes, Chicago, Ill., 564,861. Filed March 19, 1896.
A motor having a frame supported by the axle and also having a bearing on the frame of the locomotive and gearing between the armature shaft of the motor and the axle, one of the elements of said gearing being the rack-shaft.

ELECTRIC-MOTOR SUPPORT. Sidney H. Short, Cleveland, O., 564,902. Filed Oct. 3, 1889.
A frame mounted on the axles independently of the yielding support for the car body, said frame having a support at two points upon one axle, and suspended at a single point at its other end, from the other axle.

YIELDING AND SELF-ADJUSTING SUPPORT FOR TROLLEY WHEELS. A. M. Brunswick and G. E. Johnson, Los Angeles, Cal., 564,955. Filed Oct. 7, 1895.
Comprises an inner and an outer frame, a trolley wheel journaled in the inner frame, and suitable means connecting the inner and the outer frames and arranged to allow the inner frame to partially rotate with relation to the outer frame.

Switches, Cut-Outs etc.:—

BACK CONNECTION FOR SWITCHBOARDS. A. J. Wurts, Pittsburg, Pa., 564,679. Filed Nov. 7, 1895.
The combination with a switchboard back terminal stud, of a plurality of separable coupling devices independently clamped thereon, each of said coupling devices having a socket for the reception of the end of the conductor.

ELECTRIC CURRENT REGULATOR AND DISTRIBUTOR. A. H. Washburn, Brockton, Mass., 564,951. Filed May 22, 1896.
A device by which a number of lights in groups or singly and of different colors may be put in or cut of circuit by groups or singly and the amount of current may be varied.

Telephones:—

TELEPHONE SYSTEM. C. C. Gould, Philadelphia, Pa., 564,745. Filed June 5, 1895.
A supporting frame, a switch plunger guided thereon, an electromagnet having an armature, a catch engaging with said plunger, and a locking slide operated by the armature of the electromagnet and interlocking directly with the catch.

ELECTRICITY AT THE VIRGINIUS MINES, COLO.

Our readers may recall the interesting description published by The Electrical Engineer of the electric power transmission installation at the Virginius Mines of the Caroline Mining Company, at Ouray, Colo. This was one of the first power transmission plants installed in this country and its operation since its installation in 1891 has been continuous.

The Virginius Mines are situated near the summit of Mount Sneffles, in a region of perpetual snow, some 12,700 feet above the level of the sea, or 5,000 ft. above the timber line. They consist of some mines rich enough to repay mining under the most adverse circumstances and of others containing a low grade of ore, which could not be mined profitably without cheap power. This power is derived from water of Red Canyon Creek, which is brought through a pipe line 4,000 feet long to Pelton wheels which drive G. E. bipolar dynamos. The transmission line passes first through dense timber, then over rocks and chasms and heavy snowdrifts until it reaches the mine four miles away from the power house. The current is direct and the voltage 800 volts. The motors drive hoists, pumps, blowers, stamping mills, drills and an order has recently been given the General Electric Company, which put in the original plant, for an 800-volt two motor mining locomotive for hauling the silver ore laden wagons in the mine.

Access to the mines in winter is impossible and in summer extremely difficult and before the adoption of electricity the Caroline Mining Company were paying $18 a ton for their fuel, the expense of this item amounting to over $100 a day. The amount of power now used is double that formerly supplied by the superseded steam plant, and the saving probably more than repays the cost of the plant every year.

Trade Notes and Novelties

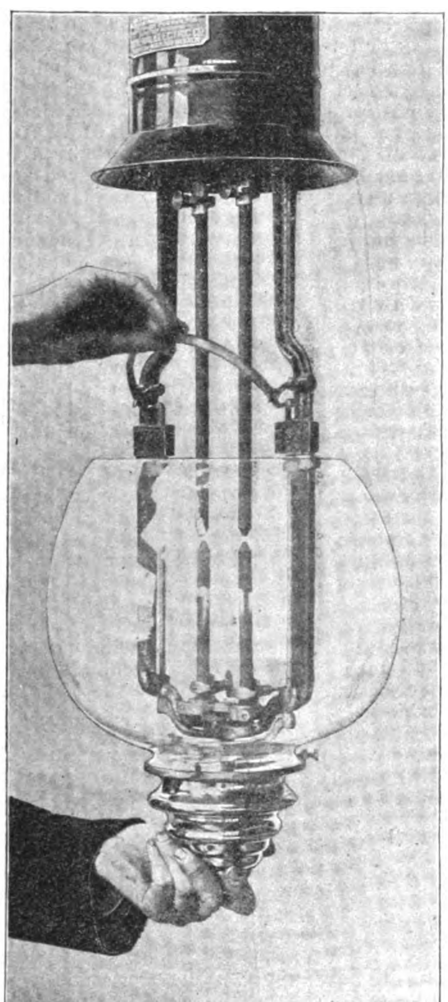
AND MECHANICAL DEPARTMENT.

BIDS WANTED FOR AN ELECTRIC LIGHT PLANT.

The electric light plant at the city of Salisbury, Chariton County, Missouri, was recently burned. At a meeting of the City Council, held July 28, 1896, an order was made and a committee appointed to advertise for bids on a franchise for putting up the electric light plant for the city. In compliance with that order the committee solicits bids of any person, corporation, company or syndicate. All bids or communication should be addressed to chairman of committeee, W. A. Thomas, or Secretary T. F. Trammell.

G. E. GLOBE LOWERING DEVICE.

To satisfy the need of a device for lowering an arc lamp globe in the shortest possible time without danger of breakage the General Electric Company has designed its new globe-lowering apparatus. The holder proper is hung from the vertical rods sliding along the sides of the lower frame. When in normal position these are held from above by a latch positive and certain in action, and locked by the weight of rods and holder. To lower the globe it is first lifted slightly to unlock

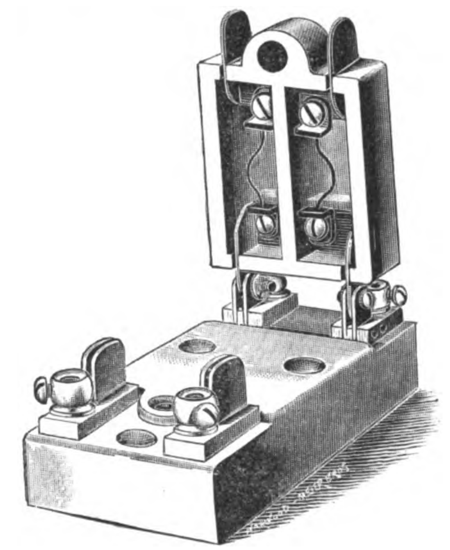


G. E. GLOBE LOWERING DEVICE.

the latch which may then be raised, releasing the rods and permitting the globe to be lowered several inches farther than in the old style lamps. This gives better access for trimming and cleaning. The fact that the globe must be lifted slightly before lowering insures a support from below and prevents its dropping accidentally. Every class of the many forms of arc lamps manufactured by the General Electric Company is now equipped with the new globe-lowering device.

THE FAGAN CUT-OUT.

The Electric Engineering and Supply Company, of Syracuse, are manufacturing a very ingenious device, known as the "Fagan" cut-out. It is a combination of a cut-out and switch. The illustration shows it as a double pole main block with a cover hinge on one end. Fuses are placed in the cover and can be easily replaced and the circuit is always broken when the cover is open. It is designed especially for an entrance switch, and

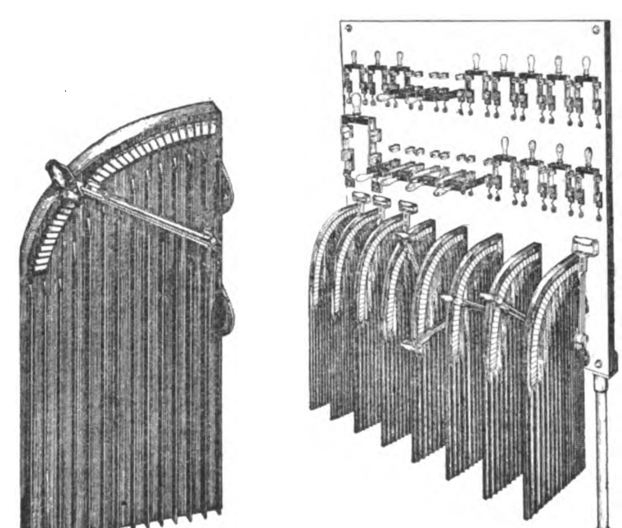


THE FAGAN CUT-OUT BOX.

answers the double purpose of a fuse block and switch. It is designed to be operated with a cord which is fastened in the hole at the lower end of the cover, passing through a hole in the base between the two contact terminals and then running along the channel in the back of the base and hanging down from the ceiling within easy reach of the hand. Or, if desired, it may be operated with a hook fixed on the end of a pole. This device takes very readily with practical men and the company report large sales of it.

IRON CLAD THEATRE DIMMERS.

The Iron Clad Rheostat Company, of Westfield, N. J., are putting upon the market a new line of theatre dimmers, one of which is illustrated in the engraving, Fig. 1. These dimmers are intended to supply the demand for dimmers which have more steps than the standard 21-step dimmer manufactured by



FIGS. 1 AND 2.—IRON CLAD THEATRE DIMMERS.

this company, and they are supplied with handles which move through an arc of 90 degrees, giving their maximum effect with the least possible movement of the handle. Fig. 2 illustrates the manner in which these dimmers are mounted on theatre switchboards.

They are made entirely of cast iron, inside of which, her-

metically embedded and sealed in solid insulating material, are the resistance wires. The iron shell acts as a radiator which quickly dissipates the heat of the coils, and being very compact, these machines are particularly adapted to the limited space in the wings of a theatre. The switch is so designed that where several dimmers are installed any or all of them may be thrown in simultaneously by means of an interlocking arrangement.

It is expected that these dimmers will fill a long-felt want for a low-priced dimmer with a large number of steps. The company is prepared to furnish them with 51 steps in all sizes and in any combinations.

NEW YORK NOTES.

THE WHITLOCK COIL PIPE COMPANY, Elmwood, Conn., are running busy at their Newark factory welding pipes by electricity. Aside from steam use these pipes are largely used in the ice and refrigerating trade.

FRANCIS KEIL & SON, 163d street, New York, manufacturers of builders' and miscellaneous hardware, are also the patentees and makers of the "Reliance" electric door spring opener. Their factory is one of the finest above the Harlem.

USERS OF SILK for insulating wire and for all electrical purposes will find it to their advantage to write for prices and samples to Charles N. Martin, silk manufacturer, 348 Canal street, New York. Mr. Martin carries a large and varieu stock of silk for every requirement in the electrical line.

C. A. ECK, 116 Wooster street, New York, reports large orders on his improved fan motor, which keep his factory busy full time. Mr. Eck contemplates moving shortly into a larger factory out of town, owing to increased business and to secure better facilities, especially for the manufacture of his power motors and ⅛ to 10 horse-power dynamos.

A DISASTROUS fire destroyed the major part of the factory of Messrs. Hamerschlag & Co., Thursday, July 23. We regret to hear of their misfortune, but from information gathered the two energetic members of this firm will have their factory in running order very shortly, turning out motor brushes and other electrical specialties manufactured by them.

THE ENTERPRISE COMPANY, New York, have been running busy night and day since May 1 on fan motors and electrical specialties which they manufacture for the trade only on contract. This firm is doing a prosperous business, due chiefly to the fact that the members of the firm, Messrs. W. B. Elliott, J. W. Eckholm and H. J. Linder, are all practical electricians.

THE C & C ELECTRIC COMPANY, of New York, have instituted a new departure in the manufacture of switchboards and will be glad to hear from electrical engineers and contractors, and furnish them with estimates on all classes of switchboard work. At present they are quite busy on their regular line of dynamos and motors, and with this new department are better equipped than ever to contract for complete installations.

THE LEONARD ENAMEL RHEOSTAT, in which a metal ribbon is attached edgewise by enamel to an iron plate, is proving to be a boon to the electric traveling crane and elevator trade to whom the rheostat problem has always been a most troublesome one. The capacity of this rheostat for absorbing overload currents without visible effect is most surprising to those familiar with the way the old coiled wire rheostats used to perform.

EUGENE MUNSELL & CO., miners and importers of mica, 218 Water street, New York, and 153 Lake street, Chicago, are enjoying an excellent trade in India mica, of which they make a specialty, being direct importers from the mines, and employing a large force in selecting the mica. They are in a position to furnish it cut to size and stamped to any shape or pattern for electrical insulation. They have just issued a neat price list, which is being mailed to the trade, and offer to send samples and quotations to the electrical trade on application.

AMONG the many exhibits which attracted attention in the Edison collection at the National Electrical Exposition was a large and striking copyrighted photograph of Mr. Edison seated outside his office at the Ogden Mines. This has been pronounced one of the finest pictures of the inventor ever taken. In view of the numerous inquiries that have been made as to where copies can be had, it may be stated that the photograph was taken by Kreidler & Crider, Easton, Pa., who will send it direct postpaid to any address on receiving a remittance of $2.

THE BABCOCK AND WILCOX COMPANY announce that they have consolidated their Canadian Sales Department with the General Sales Department at New York, and request that after this date, all correspondence be addressed to the Babcock and Wilcox Company, 29 Cortlandt street New York City. No change will be made in the Manufacturing Department, and all boilers for the Canadian trade will be built at the Belleville shops as heretofore. Mr. W. T. Bonnel, the company's former Canadian agent, has been appointed manager of the Babcock and Wilcox Company's business in the Cincinnati district, with headquarters at 969 Neave building, Cincinnati, O.

MR. CHARLES E. JENKINS, of the Belding Electric Alarm Mail Box Co.,of Chicago, is in the city at present for the purpose of placing the box on the Eastern market. Mr. Jenkins desires to make arrangements with some one well acquainted in the electrical business, and familiar with architects, to represent the Belding Company, and to push the box in this territory. In Chicago the box has had a big success, and as the company has done all its experimenting, it is ready to guarantee a perfect article. The mail box is intended to be put in apartment and office buildings, and gives an alarm as soon as mail is dropped in. It will alarm whenever any outsider tampers with it, and is also equipped with a visitor's call bell. The boxes are finished in thirty different styles, and are extremely handsome in appearance. Any one desirous of adding a specialty to his line should call on Mr. Jenkins, at 247 Canal street, New York, where he has a sample set in working order.

WESTERN NOTES.

THE ELECTRIC APPLIANCE COMPANY have remodeled their American telephone switchboard, introducing a number of important improvements, which they claim will make their board the most desirable on the market. They will be pleased to give full particulars on application.

THE SUNBEAM INCANDESCENT LAMP COMPANY, of Chicago, have discontinued manufacturing in their old factory and in a week or ten days will be able to start manufacturing in the new one located at Desplaines, a few miles out of Chicago. The new factory has been fitted up with the very latest modern devices for the manufacture of incandescent lamps.

THE BROWN HOISTING AND CONVEYING MACHINE COMPANY, of Cleveland, O., general Eastern office, Havemeyer Building, New York, have just received an order from Fried. Krupp, at Essen, Germany, for a complete hoisting and conveying plant for their blast furnace at Rheinhausen. This plant consists of three standard Brown overhead bridge tramways, to be operated by electricity, each machine having independent winding drums and electric motors. The Brown Hoisting and Conveying Machine Company are to furnish all the working parts, including the sheaves, engines, motors, hoisting and conveying machines, etc., in fact, everything but the bridges proper, which will be built in Germany, the Brown Company sending a man abroad for that purpose. There will be three Elwell-Parker motors used of about 60 horse-power each. The entire plant is to be in operation during the early part of 1897.

THE BELDING ELECTRIC ALARM MAIL BOX COMPANY, of 1038 Unity Building, Chicago, have just issued a new catalogue of their well-known electric alarm mail boxes. It is very attractive in appearance and is also most descriptive, as it contains 32 pages of cuts and reading matter. It goes very minutely into all details, regarding every style and size of box manufactured by this concern and also gives several cuts and diagrams of the interior and electrical parts in connection with them, so as to enable purchasers who are not technical to easily understand how they are operated. Amongst the many fine half-tone cuts are shown some of the buildings and residences in which they have already been placed. Architects, contractors, and others contemplating the erection of office or other buildings will find this catalogue very useful, as a good style of mail box forms a most important adjunct to every up-to-date building and dwelling.

NEW ENGLAND NOTES.

THE ELECTRIC STORAGE BATTERY COMPANY have removed their Boston office to 92 State street. Mr. Arthur E. Childs, their New England manager, will be glad to welcome his friends at the new quarters.

THE CROWN WOVEN WIRE BRUSH COMPANY, of Salem, Mass., are now supplying their customers with phosphor-bronze and brass brushes at the same price as copper brushes. This company have built up a large trade in their woven wire brushes and are now supplying nearly all the large builders of electrical machinery.

Their brushes are acknowledged as standard in all parts of the United States, Mexico and Canada. One of the many advantages of buying of this company is that they are prepared to furnish any shape, style or size in woven wire brushes for any purpose and of any metal.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

Vol. XXII. JULY 29, 1896. No. 430.

Electric Lighting.

THE DETROIT MUNICIPAL LIGHTING PLANT.

THE Detroit municipal lighting plant has been used to a great extent as the text for numerous arguments pro and con city ownership during the first nine months of its existence, and as this plant is a representative one of its class a description of it, together with an account of its first year's financial operation, as shown in the first annual report, just issued by the Detroit Lighting Commission, will be of special interest.

In four successive messages Mayor Pingree of Detroit strongly urged the building of a municipal lighting plant for that city. In 1893 his last message stated reports from 92 cities owning their plants had been received and that in these cases the cost of lighting was only about one-half of what it was where the service was secured under contract. A bill to this effect was introduced in the State Legislature and it became a law on March 18, 1893.

The Common Council of Detroit authorized the issue of $600,000 in bonds to defray the cost of building and equipping a public lighting plant, and in February, 1894, the proceeds of these bonds were deposited to the credit of the Public Lighting Fund. A committee of six gentlemen was appointed by Mayor Pingree, known as the Public Lighting Commission, and this body appointed Mr. Alex. Dow as city electrician on June 14, 1893.

THE BUILDINGS.

During the summer of 1893 the commission secured eleven lots lying on the river front containing in all 64,175 square feet. On this property the office and station buildings were erected. These buildings are shown in the illustration, Fig. 2, and a rear view of the station building taken from the river is shown in Fig. 1.

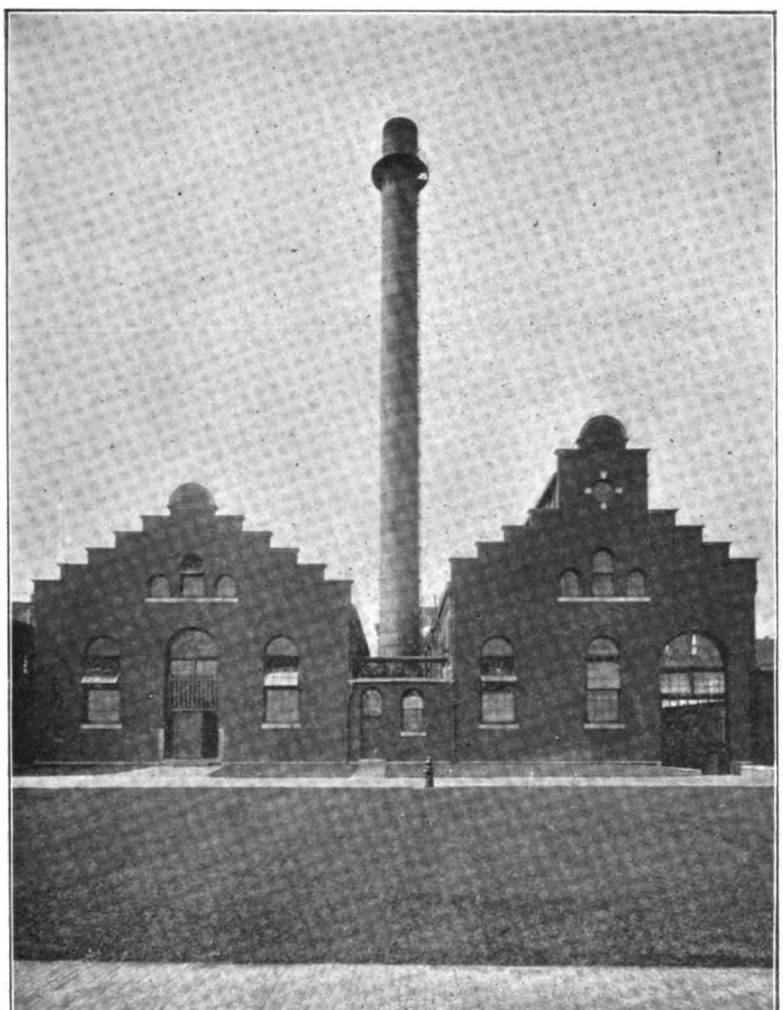


Fig. 1.—Detroit Municipal Electric Light Station. View from River.

General outline plans of these buildings were prepared by Mr. Dow, and the consulting engineer, Mr. Jesse M. Smith. In general terms these plans provided for a brick office building three stories high, having a frontage of 136 feet on Atwater street with a width of 35 feet at the west end and of 14 feet at the east end. The first floor of the office building is divided into convenient rooms for machine and blacksmith shop, storeroom, trimmers' room, carpenter shop and supply store room. The second story is devoted to the offices of the commission and secretary, the electrical engineer, draughting room and lamp repair room. The third floor is divided into two large rooms for storage of globes, patterns and bulky supplies.

In the rear of this building and separated from it by an alley 16 feet wide, is the power house, the foundations for which were made by excavating to the river level and driving 1,893 elm piles 23 feet long. These piles were capped with oak timbers and the timbers cross planked with oak. The power house contains an engine and dynamo building 50 x 150 feet in size and a boiler house 48 x 150, the two being joined together by a smaller building 17½x 150. The floors of the boiler room and basement of engine room are of artificial stone and the floor of the engine room proper is of 4-in. Norway pine plank eight feet above the basement, the plank covered with 1¼-inch matched hard maple. The small building between the engine and boiler houses contains the office of the station where the engineer on watch has his headquarters. Adjoining is a wash room with lockers for the men's clothing; shower bath and closets for the engineers. Next to this is a similar wash room for the firemen, oilers and other men about the plant. Then comes the stack room out of which rises the smokestack, built of steel plates and bricked inside, having an average diameter of nine feet and being 150 feet in height with a 15-foot foundation, making the top of the stack 165 feet above the level of the river. This room also contains the heater and hot well. Next comes the pump room, containing the condensers, fire pump and engine and dynamo for the incandescent lighting necessary in the day time. The last room next the office building is fireproof and contains tanks for the lubricating oils, kerosene oil, paints and other inflammable material.

THE STEAM PLANT.

The steam plant contains seven tubular boilers built by Chas. A. Strelinger & Co., of Detroit. Each boiler has a heating surface of 3,000 square feet, and the feed water enters through

a Hoppes purifier attached directly to each boiler. The furnaces are of the Hawley down-draft type which were selected with special reference to the smokeless consumption of soft coal. In this respect they have proved very satisfactory and the station smokestack has never given off the black discharge which usually accompanies the use of soft coal.

There are five engines, each having three cylinders 11¼, 18 and 29 inches in diameter, respectively, with a stroke of 18 inches, and running at 200 revolutions per minute. The initial steam pressure is 160 pounds and the best economy is obtained when indicating not less than 250 nor more than 340 horse-power. There are two flywheels to each engine, each wheel weighing 7,500 pounds. The engines were built by S. F. Hodge & Co., of the Riverside Iron Works, Detroit. The combined condensers and feed pumps are of the Worthington make. The exhaust steam from the cylinders of the pumps is not condensed but is used during the winter months for the heating of the buildings and during the summer months to increase the temperature of the boiler feed water.

The main system of steam piping was constructed by the station employés, the flanges being machined and the pipes cut in the commission's shop.

ELECTRIC PLANT.

The electric plant is in two sections, the first and much the larger one, being that designed for the lighting of the streets; the second being that required for the incandescent lighting of the public buildings within a half mile circle, about the station.

A very wide investigation was made by the commission during the latter part of the year 1893, and they became convinced that the only improvement to be looked for at an early date was the development of the arc lighting dynamos of 60 or 70 lights capacity into larger sizes of greater efficiency; and believing that this progress would be assisted by a call for such machinery in a plant of the size and character of the one to be installed in the city of Detroit, they prepared specifications for dynamos of 50 kilowatts output at 500 revolutions, and of 86 per cent. commercial efficiency.

A contract was entered into with the Western Electric Company for the supply of eighteen 50 kilowatt constant current dynamos for series arc lighting. Another contract was entered into with the Brush Electric Company, for the supply of 1,500 series arc lamps.

The arrangement of the station is shown in Fig. 3. There was not found in the market a satisfactory main switchboard, although a unit switchboard suitable for the operation of each group of dynamos was secured without difficulty. The commission, therefore, directed the construction, in its own shops, of the main switchboard which is a modification of the plug and cord style long in use, equipped with Weston standard instruments and with a bank of incandescent lamps for testing purposes. This board, after a year's service, has proved entirely satisfactory.

Besides the arc lighting plant there are 2,500 incandescent lamps run from this station which supply the City Hall and several municipal buildings. The machinery for this service is of the Westinghouse type. It consists of three 55 kilowatt alternatng current dynamos of the two-phase type, with transformers and station instruments. The primary voltage is 1,100; the secondary is 110 volts.

Two of these alternators are connected to the engines which run the arc lighting dynamos; the third alternator is connected to a non-condensing, compound Westinghouse engine which runs during the daylight hours, so that it is not usually necessary to operate a triple expansion engine or condensing machinery excepting during street lighting hours. The exception to this is during the two mid-winter months when the incandescent lighting load in the evening rises above the capacity of one alternator.

The eighteen arc dynamos and two alternators are connected to the five triple expansion engines in sets of four by rope driving gear. Each dynamo has seven endless cotton ropes of ⅞-inch diameter, and each of the two fly-wheels of the engine has fourteen grooves; so that the four sets of seven ropes are divided equally between the two wheels. It has not been found necessary to use any tension carriage with these ropes. The diameters of the pulleys are, on the engines 84 inches, and on the dynamos 34 inches.

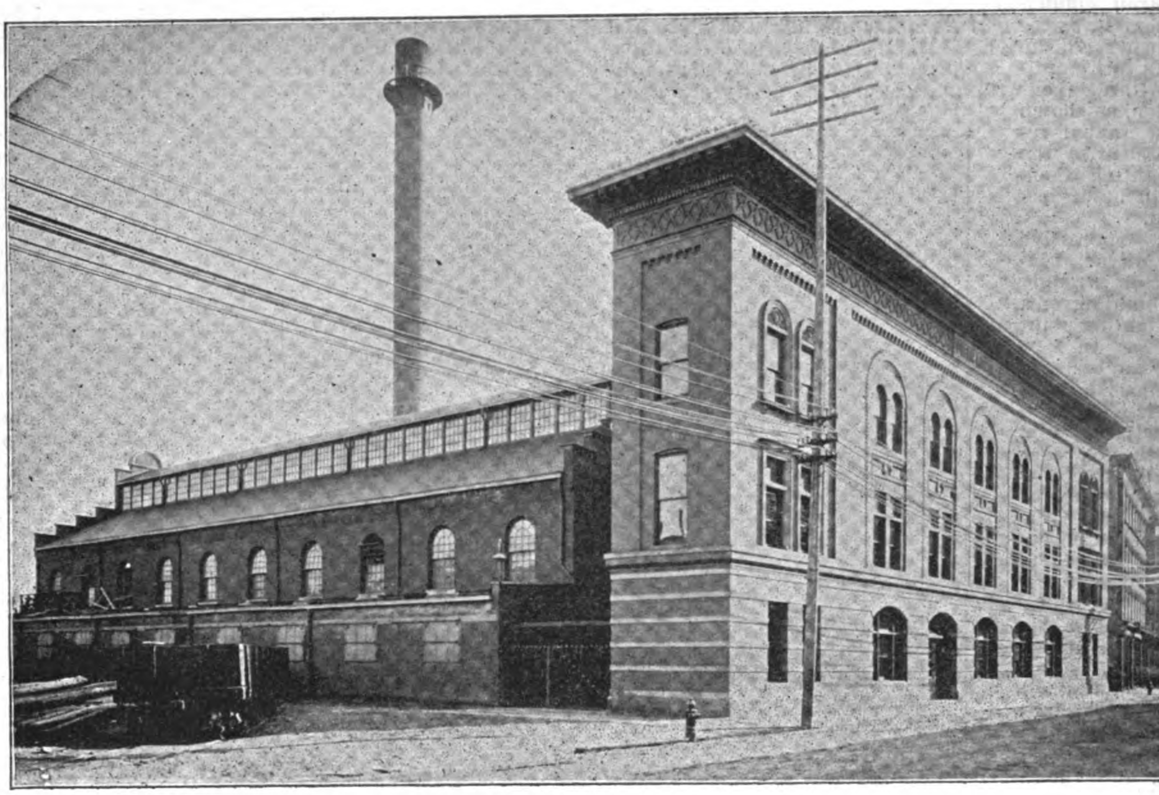

FIG. 2.—DETROIT MUNICIPAL ELECTRIC LIGHT PLANT. OFFICE AND STATION BUILDINGS.

DISTRIBUTION SYSTEM.

The distribution system is divided into two sections: The first is the underground district, in which there are connected 184 arc lamps and the 2,500 incandescent lights. The cables are rubber insulated, with tape and lead covering over the rubber. The arc circuit cables have a rubber insulation 7-32-inch thick around a No. 4 conductor. The feeder cables of the alternating system are identical with the arc cables. The mains have a 9-64-inch insulation around a No. 8 conductor. They were furnished by the Safety Insulated Wire and Cable Company, of New York.

The second section is the overhead district, which supplies all the street lighting excepting that within the half mile circle. There are connected to these lines 1,309 arc lamps. The

poles number 4,378 and vary in length from 40 to 70 feet. The location of the plant in the underground district involved a special study of the manner of connecting with the lines in the overhead district. A special line of high poles was run through the streets nearest to the river, the poles being so located as to cause a minimum of obstruction to traffic and of such height as to cause a minimum of interference in the operations of the fire department in case of fire.

As between overhead construction and underground construction the experience of the Lighting Commission is that the underground construction is infinitely preferable. The only fault to be found with it is its first cost. Underground cables will certainly last longer than overhead circuits. The conduits are of imperishable material and under the conditions of the Detroit underground insulation interruptions of service are entirely unknown.

CONSTRUCTION COSTS.

On the first day of July, 1896, the following amounts had been expended in the construction of the plant, $32,675 having been raised by taxation in 1895 in addition to the amount realized from the sale of bonds:

Land for Central Station	$63,125.00
Erection of buildings	66,661.25
Services of architects	3,453.80
Inspection, Board of Public Works	1,483.00
Dock building	3,746.60
Boiler room floor	649.73
Paving and sodding grounds	1,393.60
Sidewalks	220.69
Water intake system	2,608.21
Central Station fixtures	23,865.04
Pole line construction	107,779.81
Conduit construction and cables	87,602.53
Railway track	9,665.60
Towers	85,099.13
Engineering	16,585.25
Lamp posts	6,956.82
Steam plant	82,152.33
Arc lamps	29,628.62
Electric plant	40,842.53
Machine shop	5,378.19
Miscellaneous	2,349.54
	$641,247.27
Less sale of material, rent of lines and labor for other boards, included above	11,105.55
Net cost of plant to date	$630,141.72

OPERATING COSTS.

The following shows the total cost of operation and maintenance for the nine months from October 1, 1895, to June 30, 1896:

Coal, at $2.19 per ton	$12,208.09
Labor and management	55,821.63
Carbons	5,820.49
Oil and rags	1,149.76
Teaming	1,970.10
Globes and nets	476.40
General supplies	4,472.12
Printing and stationery	237.01
Freight and transportation	126.06
Incandescent lamps	327.70
Surgeon and hospital	194.00
Total	$82,803.36

During this nine months there was an average of 1,483 arc lamps in operation each night from one-half hour after sunset to one hour before sunrise. The total cost of $82,803.36 is divided by the Commission into two accounts, $6,606.35 for the incandescent service and $76,197.01 for the arc light service. This brings the price per arc lamp per year $68.52, and to this is added $16.18 per lamp for interest on the bonds, making a total cost of $84.70 per lamp per year, as reported by the Commission. The item of maintenance is included in the report under the items of general supplies and labor, and no charge for depreciation is made. The only cost for insurance given is $125 for the boiler insurance of $25,000.

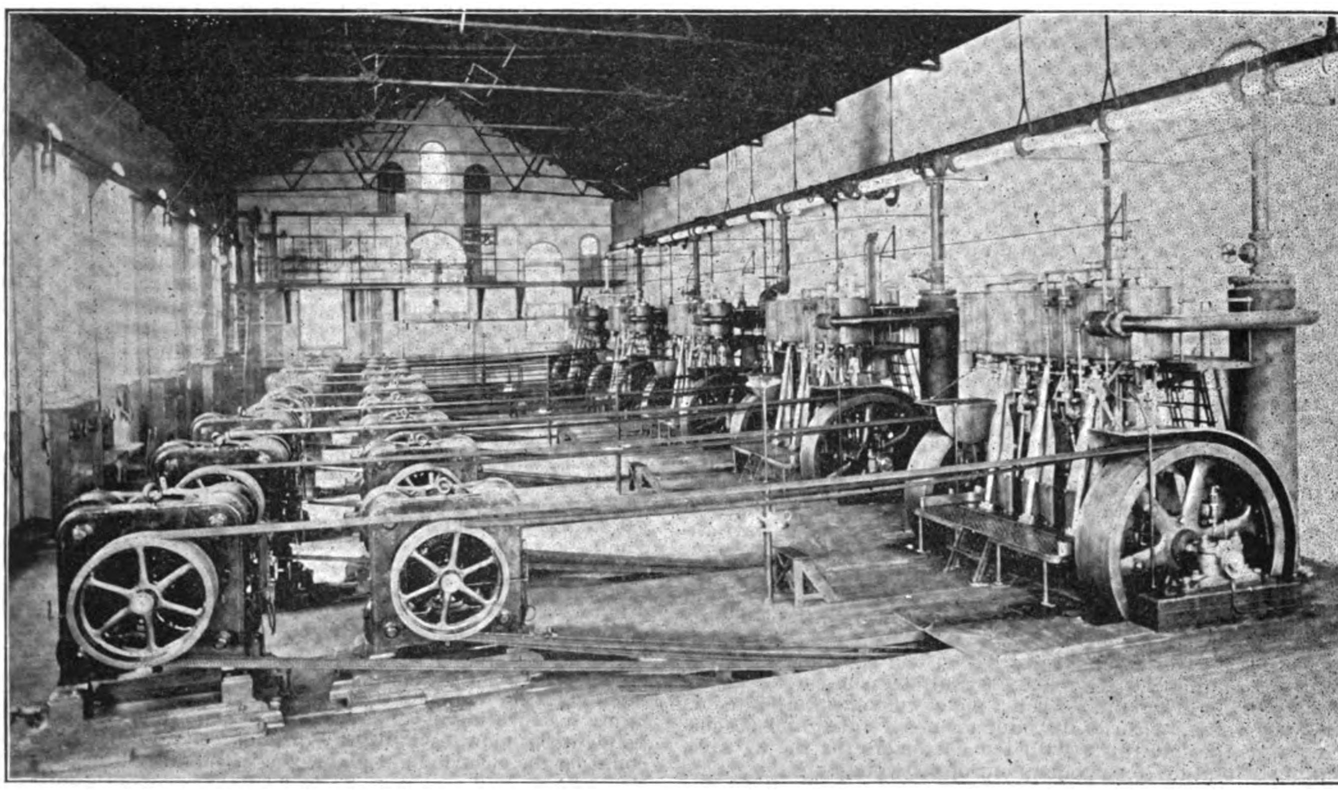

FIG. 3.—DETROIT MUNICIPAL ELECTRIC LIGHT STATION. ENGINE AND DYNAMO ROOM.

ELECTROYLTIC ESTIMATION OF THE HALOGENS.

George Vortmann described, a short time ago, a method for the electrolytic estimation of iodine, and he now calls attention in the "Monatshefte," XVI., page 674, to several important improvements in the process. An anode of pure silver, shaped like a clock-glass, a cathode of platinum or copper, and a current which does not exceed two volts in the case of cold solutions containing no alkali tartrate, or 13 volts when the solution is warm and contains alkali tartrates, are employed. The electrolysis is continued until the solution no longer gives the iodine reaction, or until a new anode placed in the solution does not gain in weight. Under these conditions, no silver is dissolved from the anode, which retains on its surface the whole of the iodine in the form of silver iodide.

MISTAKES OF MUNICIPAL CONTROL.[1]

As the question of electric lights for this city has been brought to the notice of the public by its Common council requesting the Board of Public Works to examine into the same, about six months before the contract expires, and I have been respectfully requested by the Board of Public Works to give prices on the same, I desire for the benefit of my patrons and the taxpayers of St. Joseph, Mich., to submit a few facts and some information that I have obtained personally from the South Haven (Mich.) waterworks and electric light plant, from the fact that South Haven prices have been quoted to me on various occasions as 25 cents for incandescent lights and $3.50 for arc lights, per month, same candle-power as is used in St. Joseph.

To any one not acquainted with the facts and not understanding the cost of producing electric lights, it would seem on the face of it that I am charging my customers an outrageous price for lights. When the subject has been fully considered and all the facts taken into consideration, it will readily be seen that my prices are reasonable. I will be as brief as possible with this long subject and give it as it was furnished me by the mayor, clerk, engineer and electrician of South Haven, Mich.

INVESTMENT.

Waterworks bonds (at 5 per cent.)	$40,000
Waterworks extra construction (at 6 per cent.)	2,000
Electric light bonds (at 5 per cent.)	10,000
Electric light extra construction (at 6 per cent.)	3,000
Total	$55,000

The city has to show for the above outlay the following: The power station near the lake, with two Hughes pumps, capacity three to four million gallons each per day; some 6 or 8 miles of mains and a standpipe, 67 hydrants; 378 taps and about 400 customers. The plant has been in operation for over three years.

In the electric light plant they have one Buckeye engine, cylinder 13 x 16, 240 revolutions per minute, carrying 85 lbs. of steam, three 40 horse-power boilers, one 1,000 light alternator of 2,000 volts, one 50 light arc machine, 1,200 candle-power, one Deane condenser, not in use. The dynamos are belted in tandem.

The city has 80 32-candle-power Bernstein lamps in series in the streets, consuming 5½ amperes on a 2,000-volt machine, and also has seven arc lights of 1,200 candle-power in the business district.

They have 31 commercial arc lights, one customer using 11 or 12 out of the 31. Between 500 and 600 commercial incandescent lights in circuit, with ten meter customers, at 10 cents per 1,000 watts, with no discount on meter rates and 50 customers on the flat rates, with ten customers for the 31 arcs, making a total of 70 customers out of 600 voters.

The flat rate for incandescent lights is 30 cents each for the first five, 25 cents each for an additional five and 20 cents each for another additional five or more, on a 9 o'clock p. m. circuit. If the lights are used after that time 5 cents per light additional is charged. Arc lights are $3.50 each, and $3 each for two and over, on a 9 o'clock p. m. circuit, under yearly contracts. Where arc lights are taken for less than one year the rate is $5 per month for the first three months. The station shuts down at 12 midnight and in the winter time it starts up again at 5 a. m., and runs until 7 a. m., for the benefit of the stores and houses. The incandescent lamps are 100 volt and the customers pay for renewals.

There are two oil tanks near the station, with a capacity of 6,790 and 7,800 gallons. Oil for fuel costs them $2.43 per hundred gallons. Before the electric light plant was constructed it took between 60 and 70 gallons of oil per day to run the waterworks, one tank lasting two and one-half or three months in winter. During the months of December and January it required a tank of oil every two weeks to run the two plants, making the full account $243 per month.

The city owns the meters and charges 10 per cent. rent to the customers. As will be seen, there are only 180 incandescent and 12 arc lights on sale. If new customers are obtained it will require more arc lamps and more transformers for the new customers, which means an additional cost to the taxpayers. If additional revenue is obtained the operating expenses will increase in proportion.

[1] Facts and figures presented to the Citizens of St. Joseph, Mich., by Mr W. Worth Bean, President St. Joseph and Benton Harbor Electric Railway and Light Co. [After thorough investigation the municipal plant idea was abandoned and a contract made with the company.—Eds. E. E.].

STATEMENT.

Waterworks receipts, 1895	$2,250.00
Electric light receipts (July to December 31, 1895)	1,200.00
Sixty-seven fire hydrants at $20 each	1,340.00
Seven arc lights in the streets, 1,200 candle-power, at $16 per month, until 12 o'clock only	672.00
Eighty incandescent lights in the streets, 32 candle-power, $3.46 per month until 12 o'clock only	1,663.00
Total	$7,125.00

OPERATING AND GENERAL EXPENSES.

Interest on $40,000 at 5 per cent., waterworks bonds	$2,000.00
Interest on $2,000 extra construction waterworks bonds at 6 per cent.	120.00
Interest on $10,000 electric light bonds, 5 per cent. 6 months	250.00
Interest on $3,000 extra construction electric light bonds, 6 per cent., six months	90.00
Depreciation and repairs on waterworks, 2 per cent. 1 year	800.00
Depreciation and repairs on electric light plant, 5 per cent. six months	325.00
Taxes on $5,000 valuation on $5,500 cost, at 3½ per cent. on waterworks, 12 months; lighting plant six months	125.00
Insurance on entire investment	50.00
Day engineer, 1 year, waterworks	600.00
Night engineer and electrician, 6 months at $60 per month	360.00
Trimmer, six months at $35 per month	210.00
Waterworks superintendent, 1 year	40.00
Clerk, 2½ per cent. for collecting all money	86.25
Fuel 1 year	1,800.00
Lubricants, $110; waste, $15	125.00
Carbons, globes, street lamp renewals, packing for water pumps, packing for engine and other pumps, dynamo brushes, etc.	143.75
Total	$7,125.00

It will be found from the above figures that the seven street arc lights cost the city $16 per month each until 12 o'clock midnight, and the 80 32-candle-power incandescent street lights cost them $3.46 each per month, until midnight, when any private company would be glad to furnish them arc lights at $7 per month each, and incandescent lights at $1.50 each for 32 candle-power until 12 o'clock midnight, in small quantities and at $1.25 for 80 incandescents, and still make a reasonable profit.

It must be borne in mind that the depreciation and repairs on waterworks plant is only 2 per cent. and on the electric light plant is only 5 per cent., which makes the price, as above stated, $16 per month per light for arc lights, and $3.46 per month per light for incandescent lights for streets. If you will figure a depreciation and repair account of 4 per cent. on the waterworks plant and 10 per cent. depreciation and repair account on the electric light plant, you will find that incandescent street lights will cost them $5.80 per light per month until midnight.

It is claimed by some waterworks men that 4 per cent. for the depreciation and repair account is low enough for a period of ten years on a waterworks plant, and it has been fully demonstrated that at the end of ten years, if the electric light apparatus should be put on sale it would be found to have depreciated fully 80 per cent. A further fact is that nothing has been figured on for a sinking fund with which to meet this debt at the end of ten years, or twenty years, as the bonds may run. If the bonds run for ten years an additional 10 per cent. must be figured and if they run for five years an additional 5 per cent. must be figured and added to the above prices or the city will owe the entire debt when it becomes due, and the entire payment of this debt does not lessen the investment as it stands as cash paid out, whether by a private company or municipality.

This plant had to be figured as a combination plant, as steam is provided by the waterworks boilers and the electric light plant is operated in the waterworks station.

What will interest consumers and taxpayers most are the following figures: If the South Haven street arc lights are charged at $7 per month and the incandescent street lights are charged at $1.25 per month for a 32 candle-power, it will readily be seen that the city of South Haven, in order to furnish her present customers lights at a trial cost would have to charge them $5.03 per month per light for the $3 arc lights and $5.53 per month per light for the $3.50 arc lights, and 65 cents per month per light for the 30-cent incandescent lights, 62½ cents for her 25 cent lights, and 60 cents for 20 cent lights, taking as a basis that her 20 cent lights averaged 25 cents and her 30 cent lights

averaged 27½ cents, and this is all figured on the 9 p. m circuit, after which time 5 cents should be added to each amount for incandescents, making 70 cents, 67½ cents and 65 cents respectively, until 12 o'clock.

The city of South Haven, or any other city, has a right as the law stands to tax the entire taxpaying community and furnish electric lights to customers at less than cost, but the proposition is not legal and it is not a fair business transaction to all taxpayers concerned.

It is supposed from the above figures that South Haven would not have as many customers at the proper price as she now has at the low prices, which would make matters still worse as to the cost of production. The above facts explain how 70 customers out of over 600 voters and taxpayers (and every voter is a taxpayer, directly or indirectly) gets electric lights at 50 per cent. of the cost of production, while 530 citizens are all called upon to make up the deficit. The price of street lights, both arc and incandescent, as paid by the taxpayers, is out of all reason.

My reception in South Haven was courteous and gentlemanly and I have the kindest words and expressions for the city and her officials, but they evidently have not had the experience which should teach them not to sell goods at less than cost. The Mayor explained to me that municipal ownership was brought about by a young man who had a dynamo in the city, and received his power from a sawmill engine, sending notices to the citizens that if a certain number of lights were not subscribed for within a given time he would remove his dynamo from the city. Hence, the citizens of South Haven, in order to keep their city from being left in darkness, put in a municipal plant, which I am informed would not have been done only under these circumstances.

The report of the clerk to me in detail may change these figures a few cents in regard to carbons, globes, and fuel, but the other data will be found correct. I believe the figures given by the officials are true, and that I have shown that my prices have been reasonable and I will look after the welfare of my customers in the future as I have in the past.

ALTERNATING CURRENT MOTORS.[1]

BY DUGALD C. JACKSON.

Messrs. J. H. Perkins and W. H. Williams undertook last winter to make careful comparative tests of alternating current motors in my laboratory. Five horse-power, alternating current motors of the following American makers were available for the purposes of the tests: Fort Wayne Electric Corporation, single-phase; Stanley Electric Manufacturing Company, two-phase; Westinghouse Electric and Manufacturing Company, two-phase; General Electric Company, three-phase. A 5 horse-power three-phase made by the Allgemeine Electricitäts Gesellschaft of Germany, was also included in the tests, and results of tests on machines made by the Oerlikon works and by C. E. L. Brown, of Switzerland, were obtained. A 10 horse-power Westinghouse two-phase was also tested. A capacity of 5 horse-power in the motors to be tested was chosen, as that may be considered to be near the average capacity of motors used in the service of ordinary central stations. The results of the tests may, therefore, be accepted as representing, for the central stations, comparative results between the average motors which they may use on alternating current systems, and the results may also serve as a basis for comparison between average conditions of operating with continuous current and alternating current motors.

When Silvanus P. Thompson wrote his book on polyphase currents, in 1895, he set forth as the requisites for a good alternating current motor that: 1. It shall exert a good torque at starting. 2. It shall be capable of running at a nearly constant speed at all loads. 3. It shall yield in mechanical power a high percentage of the power put into it. That is, it shall have a high commercial efficiency.

There are three additional requisites which Professor Thompson overlooked, but which determine to fully as great an extent the success of the motor. These are: (a) The motor shall have a high power factor; (b) it shall not require an abnormally large current from the lines at the instant of starting; (c) it shall not cause a large unbalancing of the pressures on the lines of a polyphase circuit.

The requisites, (a), (b), and (c), are so important that if they are overlooked, a motor cannot give satisfaction to the central station man. Messrs. Perkins and Williams made tests of the following points: (a) starting torque and current; (b) speed regulation; (c) commercial efficiency at all loads; (d) power factor at all loads; (e) starting current; (f) effect on the line pressures when starting.

The results of the tests were shown in a table and a series of curves.

Four out of the six motors tested affected the incandescent service disastrously, and showed the absurdity of attempting with them a combined service on the same circuits as the incandescent lighting in those plants where regulation and the satisfaction of the customers is considered of importance. The tests show that the alternating current motors give equally satisfactory regulation and efficiency as is given by continuous current motors, but the power factors of most of the machines are small for part load, the starting currents excessive, and the starting torques with the present arrangement of starting resistances are unduly small. The best performance of the American 5 horse-power machines lies between No. 3 and No. 5 of the tables. These machines will stand well above the others. They are about even in starting torque, but No. 5 will carry considerably the higher load before dropping out of its pace; No. 5 also regulates the better and has the higher efficiency. On the other hand, No. 3 has a power factor incomparably better than any of the other machines.

The author then showed how the question of efficiency and power factor affected the central station. The power factor strikes the central station directly, since a low power factor causes an increased current output, with an accompanying increased loss in the lines and transformers, and, even worse, with a demand for an excess capacity and therefore of cost in the generating machinery and transformers.

The question of power distribution for alternating current stations, as it now stands, resolves itself into this: 1. If you have a 500-volt, continuous current power service, stick to it. 2. If you can develop a large power service within a radius of two miles from the station, put in a 500- volt, continuous current outfit. 3. If you can develop a small power service only, which can not afford a duplication of apparatus, or your distances are excessive, then arrange to use alternating current motors. 4. In this case, arrange to operate all the lamps on one phase to avoid, as far as possible, difficulty in regulation, and use such a generator and system of lines as will enable the use of motors. 5. Motors intended for such use should be guaranteed to have a high power factor and to start without taking an excessive current from the lines. 6. Never use recording amperemeters with alternating current motors if you really intend to develop a power service, but use recording wattmeters to indicate the power absorbed by the motors. 7. Where two-phase or three-phase motors are used, place two recording wattmeters, properly connected, to indicate the total power by summing their readings. (A single special meter, made up to serve the purpose of the two, may be used, but such an instrument is not now on the market as far as I know.)

This summation is based on the assumption that uniformity of pressure at the lamps is valued by the central station man.

CENTRAL STATION INSURANCE.[1]

BY C. C. PAIGE.

The subject of insurance which I am requested to take up for the purpose of getting it before this convention for discussion is of great importance to central stations. There was a time when insurance companies advised their policy-holders, and the public generally, that there was less liability to fires in buildings lighted by electricity than in those lighted by any other method. These statements became common talk and were used by central station owners in soliciting business. It is not so now; the insurance companies serve a notice on the policy-holder that is lighting by electricity that a survey of the electrical equipment of his premises had been made on a certain date, the general condition of which was poor or very bad. The summary of defects and specifications for changes and improvements discloses the fact that nearly or quite all the material, including wire, in most cases, must be thrown aside and other materials substituted in its place. Thirty or sixty days are allowed for the changes to be made, and if they are not made within the specified time, the insurance rate will be raised 50 per cent. This course is taken in all localities with which I am familiar. The cost of making these changes is not an insignificant item, and causes more or less trouble between the property owners and the wiring company who did the work originally. In some cases the electric service has been suspended on account of the failure of the interested parties to make the improvements required. Here the question naturally arises, Are these changes and improvements necessary to prevent fire and accidents? In localities in which the electric service has been used for ten years or more without the record

[1] Read Before the Northwestern Electrical Association.

of an accident to man or beast, or a fire even of the most insignificant nature, the answer from the property owner and the wiring company would naturally be, No. All of these requirements are not necessary; poor material and improper workmanship has probably caused the insurance companies to be alarmed even when fires and losses have not occurred. I am of the opinion that the underwriters' rules for wiring and installing electric apparatus for both public buildings and residences could be somewhat modified, thereby making quite a saving on the first cost of the installation, and not in the least depreciating its efficiency or safety. It behooves the central station operators and managers to watch carefully the cost of wiring and installing electric service, otherwise electricity will attain the unpopular reputation of being a luxury that only the rich can afford.

I hope this question, which is of great importance, will be freely discussed by electricians and wiring experts, and their suggestions and recommendations be adopted by this association.

THE INSURANCE OF ELECTRICAL PLANTS.[1]

BY R. H. PIERCE.

One of the most serious problems to the owner or manager of a central station is the reducing of the fire hazard to a minimum. The problem of safety is the real question, and when this is solved we at the same time solve the problem of insurance.

In the opinion of the writer, the insurance question which the central station manager has to answer is simply the question of making his plant insurable. This may appear to be a radical view, but I believe it is logical. A large proportion of existing plants were installed at a time when the electrical manufacturers and electrical constructors did not understand what materials and methods should be used in order to secure safety; and finally, and worst of all, many plants have been installed by companies or individuals whose only thought was to get the largest price for the cheapest installation, leaving the unfortunate station owners and managers to wrestle with the question of safety, as well as those of reliability and economy. But however serious the question may be, it must be met and if attacked in the right way, the solution may not be as difficult as it at first appears.

The results of a central station fire are twofold: First, there are the losses due to interruption of service, and second, there is the loss of plant. I have placed the losses due to interruption of service first, as these must be considered whether we consider the question of insurance or not. The interruption of service for any considerable time or a decrease in patronage due to irregular or uncertain service may, and often does, mean a difference in revenue, which is the difference between a profit and a loss in the operation of the station, and operating a station at a loss is worse than losing it.

The way to secure safety and reliability is to have proper construction and proper care, protection and attendance. The proper methods for securing safety are laid down in the rules and requirements of the National Board of Fire Underwriters and are well known to all engineers and constructors of any standing.

The question of insurance can be met in three ways: 1st, by insuring in responsible and reliable insurance companies; 2nd, by the formation of a mutual company by central station owners; 3rd, by securing the maximum safety through the use of proper construction, care and fire protection, and taking the chances of a fire loss.

As a general proposition the only reasonable course is the first one indicated, namely, the insuring in responsible and reliable companies. The plan of forming a Central Station Owners Mutual has been "weighed in the balance and found wanting." Theoretically, it may be possible to form such a mutual company, but it would be an additional burden to the central station business, which I take it has trouble and problems enough to face already. If fire insurance is a legitimate business,—and it appears to be as legitimate a business as electric lighting—, then we may as well assume that the insurance people know their business and that the competition between insurance companies will produce as low a rate as could (with equal protection) be given by a mutual company. The third method mentioned, of securing maximum safety and then taking the chances, may be the best in some, but only in very special cases. If the central station plant is so designed, installed and operated as to reduce the fire hazard to a minimum, insurance companies will ask a minimum rate of insurance which, in most cases, will be so small as to be no burden to the owners. Discarding then the two plans just mentioned, we are brought to the first plan of insurance in reliable companies. Accepting this as our line of action, the problem now is to so install and operate our plants that the hazard is reduced to a minimum or at least to a point where further improvements would increase the cost out of proportion to the additional safety secured.

Before this point is reached, we will usually have secured a plant in which the fire hazard is very small and on which the insurance rate should be surprisingly low. We must not figure too close on our investment. Even if the interest on the added investment is equal to the amount saved by reduction of premiums we are ahead, as the improved construction, care and attendance, means a smaller chance of interruption of service and usually better service, less repairs and smaller depreciation.

The great problem is, as I have said, how to best secure safety. Competition in the electrical manufacturing and construction business has not led to increased safety. On the contrary, it has led to cheapness in both appliances and methods and cheapness does not mean safety. On the other hand, we must not think that we must be extravagant in order to have safety. The use of proper methods of construction and of intelligence and care in operation are what is most necessary to secure safety. If, however, we cannot look to the electrical companies for protection, to whom shall we look? Who should judge of what is necessary for safety? Who has devoted most time and thought to this subject? The National Board of Fire Underwriters beyond a doubt. Whether we insure or not, the regulations of the Underwriters are to-day the best, and we may say only, guide to safety. Their requirements can of course be improved, but the insurance people are ready and anxious to receive suggestions from all engineers and central station men. I sincerely believe that a study of the requirements of the Underwriters, and a free discussion of their merits by central station men and engineers is the one thing that will lead to an understanding of the insurance question and will eventually lead to an understanding between owners and insurance companies, which will be mutually satisfactory.

Everyone of the Underwriters' rules represents thought, investigation and experience, and if time permitted, it would be profitable for us to discuss each rule by itself. I shall have to be content, however, with calling attention to the rules and to a few lessons which they seem to teach.

The base rate or the rate of insurance for central stations which conform in all respects to the requirements of the underwriters is 50 cents per $100. For every point in which a station fails to conform to the requirements, a certain addition is made to the rate.

The underwriters recognize thirty-four specific causes for raising the rate above the base or minimum amount. These causes are violations of the rules and regulations, and do not consider "External fire protection," "Other occupancy, "Condition," "Exposure." A specific addition is made to the rate for inadequate fire protection, and an addition is made for other occupancy, condition, exposure, according to hazard. The thirty-four causes just mentioned are all violations of the regulations concerning construction of building, electrical arrangements, or care and attendance, and are therefore, all causes within the control of the owner.

These thirty-four causes may, if they all exist, raise the rate to over $10 per $100, but of this sum, over $5, or more than half the amount, is due to the following causes: Improper arrangement of stack, defective wiring, improper construction of switch board, improper construction and placing of rheostats, storage of oils, gasolene, etc., in station and improper storage of ashes. All of these are defects that should and always can be avoided, and usually at small expense.

Time does not admit of taking up the thirty-four violations separately, but I can cover the ground in a general way by saying that if a station was built and operated so as to be defective under all or the majority of the thirty-four counts, an intelligent man would consider that it was only a question of time when it would burn down. The additions to the rate are not unreasonable. The causes for which the greatest additions are made to the rate are conditions which no sensible man would allow to exist in his station. In most cases a station can be designed or remodelled by one familiar with the underwriters' requirements so as to have a very low total rate and without any extravagant expenditure, and where the surroundings are favorable, a station can be cheaply built which can be insured for the minimum rate, or very close to it.

[1] Abstract of a paper read before the Northwestern Electrical Association.

THE BERLIN IRON BRIDGE COMPANY, of East Berlin, Conn., has a contract for furnishing steel trusses for the new building which is to be erected by the Holyoke Gas Company, of Holyoke, Mass. The building is 50 feet wide and 60 feet long. Roof trusses are entirely of steel, and the covering is slate. No woodwork or inflammable material will be used anywhere in the construction.

THE RIGHTS OF ELECTRICAL COMPANIES.[1]

BY W. CLYDE JONES.

THE subject will be discussed under three principal heads: (1) the relation of the electrical industry to the governing power upon whom it depends for the exercise of the essential franchise for the use of the streets and highways; (2) the relation to private persons and abutting property owners, and (3) the relations between various companies, electrical and otherwise, which conflict in the exercise of their franchises.

There are few electrical pursuits which do not require for their proper exercise the enjoyment of a public franchise, as the right to use the public streets or highways for the placing of their wires and conductors. The obtainment and enjoyment of such a franchise brings the electrical company into contact with the governing power of the community. But though the government may permit the company to exercise a franchise, the franchise cannot be exercised in derogation of the rights of others without due compensation therefor, and this brings into consideration the much vexed question of the relation of the company to the abutting property owner.

The modern view relieves the inquiry of legal subtleties and reduces the inquiry to a simple question of fact as to whether the new use does or does not affect the enjoyment of the street by the property owner, and, if so, to what extent? The tendency of decision, however, is toward the view that the use of the street for electric light wires is a proper use of the street, not imposing a new burden on the street such that abutting property owners must be compensated.

It is argued that the telegraph is not a use of the street for its original purpose of transportation, and therefore introduces a new burden. On the other hand, it is argued that the use of the streets for the carrying of the mails and the carrying of messages is one of the contemplated uses, and as the telegraph serves the same purpose, thus relieving the streets to that extent, the telegraph is a proper street use.

The telephone has also called the streets into service for its pole lines and has been attacked on the same grounds as the telegraph, since the telephone is but one form of telegraph. The argument may be made with more force, however, that the telephone assists in the use of the street for transportation purposes, hence the many telephone conversations relieve the streets of the passage of the individuals who would otherwise have to meet in order to hold the conversations. The tendency of decision is nevertheless toward the view that the telephone imposes a new burden on the street for which the property owner is entitled to compensation.

Considering the conflicts which arose in the operation of electrical franchises the first disagreement arose between the telephone companies and the electric light companies. The variations of the currents used for electric lighting induced currents on the telephone lines where the lines ran parallel, thus introducing disturbances on the telephone lines, materially impairing the operation of the telephone system. This disturbance led to suits by the telephone companies against the electric light companies.

A more serious controversy, however, arose between the telephone and the electric railway. Most of the telephone lines had ground returns, thus employing the earth as a part of the electrical circuit. The electric railway likewise employed the earth as a part of the circuit, and the earth at different points along the electric railway was thus charged to a considerable difference of potential, such that telephone lines grounded in the vicinity of these points were traversed by currents which rang the bells, operated the apparatus and otherwise disturbed the system. At the same time trouble was experienced by the inductive action of the electric railway currents upon the telephone lines. The telephone companies brought suit against the electric railway companies to enjoin the use of the earth as a part of the electric circuit of the railway.

The next serious conflict arose between the electric railways and water and gas mains. The earth currents of the electric railroad travel along the water and gas mains. The result is the decomposition of the metallic pipes, resulting in the eventual destruction of the pipes. Suits have been brought against the electric railway companies for damages done to the mains, but as yet no decisions of the ultimate courts have been reached.

It is a well established doctrine that every one should so use his own as not to interfere with the rights of others, and it would therefore seem to be the duty of the electric railway companies to so operate their systems as not to interfere with mains laid in the street, and, if the use of the ground circuit is essential, to devise some means to prevent deleterious action upon the pipes. A number of methods have been proposed which are claimed to prevent the destruction of the pipes, and if this be the fact the question arises whether the courts will not hold the electric railway companies responsible for damages done to the mains when it is within their power to prevent such damage by the employment of available means.

[1] Abstract of paper read before the Northwestern Electrical Association.

LIGHTNING ARRESTERS.[1]

BY W. R. GARTON.

The lightning arrester, pure and simple, is nothing more than a convenient path or outlet from the condenser or charged body to a point of lower or no potential. By this we mean that a certain body has by contact or communication with a statically charged body, which may be air, wire or what not, become charged with the influence predominating the adjacent body, or in other words the originally charged body, which, in this instance, is the atmosphere, has given off to the conductor, which it surrounds, the same influence which pervades it, until the conductor has attained a high electric potential. Oftentimes the opposite conductor is far from being equally charged, and in this case a great strain is brought to bear on the insulation between the two sides of the circuit. To relieve this strain the little device known as the lightning arrester is used.

The simple and fundamental principle of the lightning arrester is some form of an air gap with serrated or plain surfaces. The only changes made have been the addition of circuit interrupting or arc prohibiting features which the different currents employed have necessitated. The success or failure of lightning arresters in general can be attributed mainly to the successful or unsuccessful performance of the duties devolving upon these additional features.

There have been very few of the numerous forms of lightning arresters devised which have not in one form or another employed the air gap. The chief reason for the employment of the air gap, in preference to that of substituting some form of resistance, is that it is of variable resistance depending upon the conditions; under ordinary circumstances it is a splendid insulator, but to a discharge it offers far less impedance than an artificial resistance of much less resistance.

It is found also that the dynamic currents of high potentials will leap certain air gaps and permanently establish a flow. Thus we have to guard against the employment of too small an air gap and still not have it so large as to prohibit a free passage of the discharge. Having determined the proper and most advantageous air gap, we have yet another problem with which to baffle; that is, a means of automatically opening the lightning arrester circuit, should an arc be established.

At this point we have all come to a halt. There are, however, a few who apparently have employed better methods than others, and have been enabled to get very good results. One of the original ideas for accomplishing the desired effect was the addition of a fuse to the air gap, so that when the flow of current was established the fuse would be blown, and in this manner the circuit restored to normal, but we were not satisfied with this form of an arrester, for we wanted something which did not require constant attention aside from being unreliable in case of discharges following in quick succession, and thus proving a constant source of annoyance.

The next step in advance was the increase in the number of fuses placed in multiple. But even this must be carefully watched and regularly inspected. To overcome the annoyance of blown fuses and interrupted service, various methods have been employed. Among those best known is the "air jet arrester," which automatically blows out the arc by a jet of air forced from a chamber in which an arc has been established in series with the outside arc. By the expansion caused by the heating of the air in the chamber the air is given impetus, and when directed upon the arc it tends to blow it out; but even this form of arrester proved inadequate and unsatisfactory.

An early principle and one which is recognized to-day as fundamental, is that of the magnetic blow-out with which you are all familiar. Other and various forms have been used—such as the iron and mica washers, "Keystone," "tank," etc., but in many of these forms either the mechanical portion has been a drawback or the construction was such as to render a barrier rather than an inducement to the discharge.

The tank arrester has in most instances proved very satisfactory. The two chief drawbacks are the constant consumption of energy while in circuit and the possibility of a storm approaching without warning and finding you without your tank cut in.

I think that I may safely say that there are three forms of

[1] Abstract of a paper read before the Northwestern Electrical Association.

arresters being used to-day which are considered standard. They are the Wurts non-arcing, the G. E. magnetic blow-out, and the Garton. In the non-arcing and magnetic blow-outs different methods of construction are employed in dealing with the various currents, while in the Garton the same form and same principle enter into the arresters for all of the different currents.

After describing the two former arresters, the author stated that in the Garton arrester the idea is to provide the best possible course for the discharge and to instantly cut off the current flow after the discharge. This is done by providing as straight a path as possible, with ohmic resistance reduced to a minimum and no inductive resistance at all.

In the Garton arrester, that which prohibits the constant consumption of energy or the flow of normal current to earth is the employment of an air gap. After the discharge has leaped the air gap and a flow is established, the small coil or solenoid becomes a magnetic field and the small plunger is suddenly drawn from its contact in the tube. The act of drawing the plunger from its contact establishes in the circuit a secondary arc which, being in series with the originally established arc, instantly interposes an additional resistance which goes on increasing by reason of its lengthening until the circuit is broken. Another means of destroying the arc is that of elongating it in the tube which prohibits its assuming its natural form. The element of time also enters greatly into this device from the fact of its being mechanical in its operation.

True it is that in many instances lightning arresters have not proved a source of protection, but in nearly every instance it will be found that the fault lies somewhere in the installation and not in the apparatus, which is generally the first to be condemned.

Trouble invariably occurs in circuits which are inadequately equipped. No station, whether direct or alternating, should be operated without the insertion into every feeder of a kicking coil in conjunction with the lightning arrester. This applies to street railways as well as stationary motors, but it is not necessary on series arc circuits. Different circuits require different localities for the installation of arresters. For instance, on railway circuits we equip each car and station feeder and scatter them along the line at varying intervals from one-half to one mile apart, and at the terminals, while on alternating circuits we place arresters at the individual transformers or banks. But there is one thing that should not be tolerated, and that is to make a lightning arrester a part of or in any way connected with a transformer. It should be the purpose to keep the lightning just as far from the transformers as possible, for, although of high inductive resistance they can very rarely ward off disruption unless they are supported by some good lightning arrester.

THE RECONSTRUCTION OF THE ROYAL ELECTRIC LIGHT CO.'S MONTREAL STATION.

In reply to an inquiry we have received the following interesting account of the work of reconstruction now being carried out in the Montreal station of the Royal Electric Company, under the direction of Mr. P. G. Gossler, the company's electrical engineer:

We are practically turning this station inside out, as you may judge from the following outline of work which we are now carrying out. We are replacing seventeen alternators by five 300 kilowatt, two-phase generators, doing away with all line shafting, belting the generators directly to three engines, which practically makes 600 kilowatt units on two of the engines; the many advantages to be gained by doing this are obvious.

We are building an entire new switchboard for serving light and power from the same two-phase circuits. This switchboard construction, we think, is as good as can be found. It consists of a white oak frame work, covered with a layer of asbestos; over the asbestos is a layer of mica and for mechanical protection the edges are protected with angle fibre. Upon this board will be mounted the different instruments, switches, etc. This framework is mounted on an iron structure with slate base, the whole overlooking all of the generators and engine room.

We are rearranging all of our lines for two-phase work, and changing our present system of 1,000 volts to a 2,000 volt system. We are also replacing all of our transformers by modern transformers, making as many small secondary systems as possible. We have so far decreased our station leakage load, within the last three months, by about 200 amperes.

In connection with this we are making preparations to receive power from Chambly Falls, located fifteen miles from Montreal. This will allow of our present steam plant being used as spare capacity, also the present 300 kilowatt generators, which we are installing will, more than likely, be used as synchronous motors for operating our city lighting arc machines.

At Chambly Falls there will be wheels and generators installed for the generation of 20,000 horse-power, which will be transmitted to this city at a pressure of 10,000 volts.

The changes we are making at the present time must eventually be made by all light and power stations if they propose to meet competition.

EXHAUSTING INCANDESCENT LAMPS BY CHEMICAL MEANS.

A method of exhausting incandescent lamps has been described in the "Zeitschrift für Beleuchtung," in which a chemical process is used in conjunction with the air pump. It is stated that most of the lamp factories in Germany are now using such chemical processes. In the tube attached to the lamp for exhausting it a piece of amorphous red phosphorus is introduced, the amount of which must be found empirically for each type of lamp. While it is being exhausted with the pump, this tube is heated carefully with a Bunsen burner; and when the vacuum is sufficient, the normal current is passed through the lamp and then increased gradually up to about three times the normal voltage, when a violet light will appear at the end of the filament. A few moments later a blue light will appear around the filament. The current should be reversed frequently, and after having run for 10 to 20 seconds at the high voltage the blue light will expand throughout the whole globe, and at that moment the lamp must be sealed off so as to include the phosphorus. The lamp is then run again and heated at the tube which contains the phosphorus. A reaction will suddenly take place and the blue light will disappear, a scarcely visible light-brown deposit being formed on the glass, which, it is said, does not affect the candle-power. When a lamp exhausted in this way is tested with a Ruhmkorff coil, neither phosphorescence nor a current will be found to exist.

ROENTGEN RAYS.

EFFECT OF ROENTGEN RAYS ON GERMINATING PLANTS.

One of the earliest recorded experiments with Röntgen rays in regard to their effect on plants is given in an article by Alfred Schober, presented to the German Botanical Society. Schober was led to the investigation by the similarity between X-rays and ultra violet light, which was pointed out by Röntgen in his first paper. The subject appeared particularly worthy of investigation, as Sachs had shown that heliotropic curving is incited in plants by blue, violet and invisible ultra violet rays in about an equal degree with full white light; while the red, yellow and green parts of the spectrum are apparently inactive. Rothert in his extensive work on heliotropism found that the cotyledo or leaf-like organ in the form of an almost cylindrical closed sheath which appears first after the roots of germinating oat plants to be particularly sensitive to the action of light, and these were thus selected for the experiment. Vigorous plants germinated in full light, with cotyledos from 1 to 2 centimetres long, were selected and set in damp sand in a dark box, the walls of which were about 1 centimetre thick and blackened on both sides. A Hittorf's tube was placed at one end of this box at the height of the seedlings and about one centimetre distant from the box. The seedlings were arranged at one end of the box so that they were about 2 centimetres distant from the tube. The inductor had a spark length of about 12 centimetres, and was kept at its highest capacity during the experiment. A photograph of a hand could have been taken under the same conditions at a distance of 30 centimetres in five minutes.

The plants were first exposed to the action of the rays for 30 minutes, after which an examination showed that no apparent effect had been produced. The box was then closed and the exposure continued for another half hour. A careful examination at the end of this time led to the conclusion that no visible effect had been produced. It was found impracticable to continue the experiment longer, as the tube in this time had become excessively heated.

After the experiment was concluded the plants used were proved to be normally sensitive, as an exposure of one hour to diffused daylight, passed through a small horizontal slit, resulted in a noticeable curvature which in four hours had reached 60° from the vertical.

As the coil was excited to its greatest capacity during the experiment, the plant being placed in as close proximity to the light as possible—and as after the experiment the plants were found to be normally sensitive, showing noticeable curvature on an equal exposure to diffuse white light—the author concludes that the new rays appear to differ from light in that they do not stimulate heliotropic curvature.

Power Transmission.

TEST OF AN OTIS ELECTRIC ELEVATOR WITH LEONARD MOTOR CONTROL SYSTEM.

BY W. H. MAC GREGOR AND R. T. KINGSFORD.

THE great increase in the number of electric elevators now in use and the sufficiency of reliable data as to their cost of operation led the writers to undertake a test of an Otis electric elevator on the Leonard system in the Fahys building, Maiden Lane, New York. Being undertaken as a graduation thesis and not in the interest of any person or concern, our only object could have been to arrive at the facts.

An inspection of the cards, Figs. 1 and 2, will show the impossibility of indicating the engine in the ordinary way. The pencil was kept on the paper during the entire up and down trip of the car, the time in each case not being over thirty seconds. An apparatus was therefore devised, which will be described later.

Method of Making the Test.—By measuring the power supplied at the steam engine and that supplied in the form of electric energy to the fields of the dynamo and motor, the total energy supplied to the system becomes known. Comparison with work at the elevator gives efficiency, and using the proper figure for the evaporation of the boiler the economy is determined.

Description of Elevator Plant.—The elevators are of the drum type with a counterpoise of 1,100 lbs., the design being that the weight of the counterpoise should exceed the weight of the empty car as much as the fully loaded car exceeds the weight of the counterpoise.

The drum is driven by a separately excited Eickemeyer motor through a worm of high efficiency running in oil. Connected directly to its brushes is the armature circuit of the generator. This dynamo is directly connected to a high-speed 10 x 10 Harrisburg "Ideal" engine and has its fields separately excited from the same source as the motor; the only difference being that the magnetic field of the dynamo can be varied in intensity and direction at will by the rheostat and lever in the car.

This method of regulation by governing the intensity of the field of the dynamo instead of cutting down its external circuit by resistance and thus wasting energy in heat, is claimed by Mr. H. Ward Leonard, the inventor, to give increased economy, as the current is supplied at a voltage corresponding to the speed of the motor.

Description of Apparatus.—To indicate the engine two ordinary indicators were used as a basis. To the one at the head end was attached a bracket supporting a roll of paper. This paper was unrolled and drawn by the drums of both indicators by rubber rollers fastened to a bracket on the indicator at the crank end. The rubber rollers were driven by belting and countershaft from the shaft of the engine. The indicator pencils being pressed against the paper, traced continuous wavy curves from which the indicated power of the engine could be calculated for any instant.

The water used by the engine was determined by weighing the exhaust condensed by means of a surface condenser. As the fields of the dynamo and motor were both separately excited a plating bath was introduced to measure the variable current.

Details of Test.—Six tests in all were made with loads of 300, 1,100 and 2,200 lbs. in the car, both with and without stops. The i. h. p. of the engine for each test was plotted as a curve having horse power as its ordinate and time for its abscissa. One of these curves is shown in Fig. 3. It will be noticed that the work on the down trip is less than that on the up, due to the work supplied by the descending load. The effect of the six stops is clearly shown by the negative area.

Ordinary cards taken at one of these moments of negative work are shown on Fig. 4. The engine is clearly being accelerated by the dynamo running as a motor, driven by the motor, running as a dynamo, caused by the inertia of the load and counterpoise.

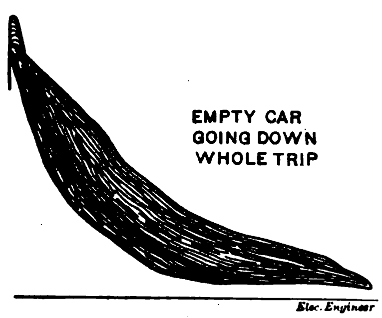

FIG. 1.

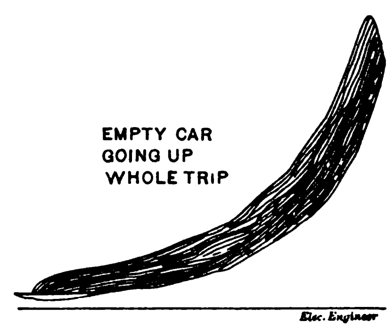

FIG. 2.

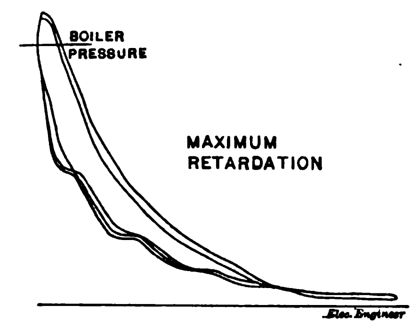

FIG. 4.

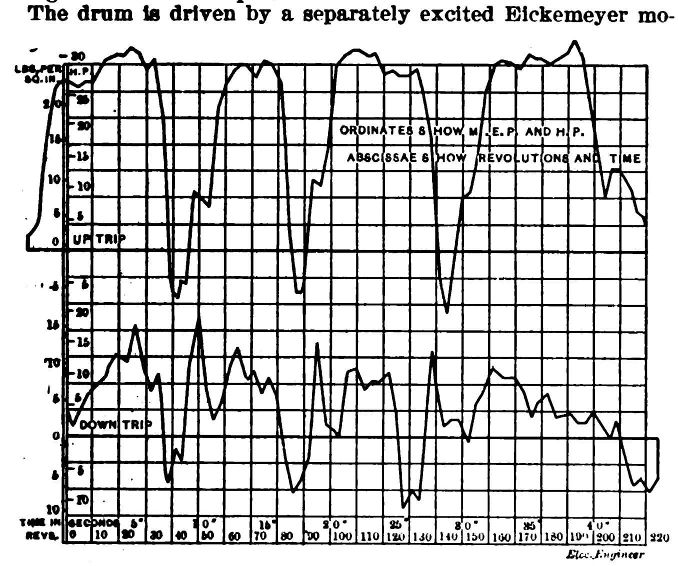

FIG. 3.

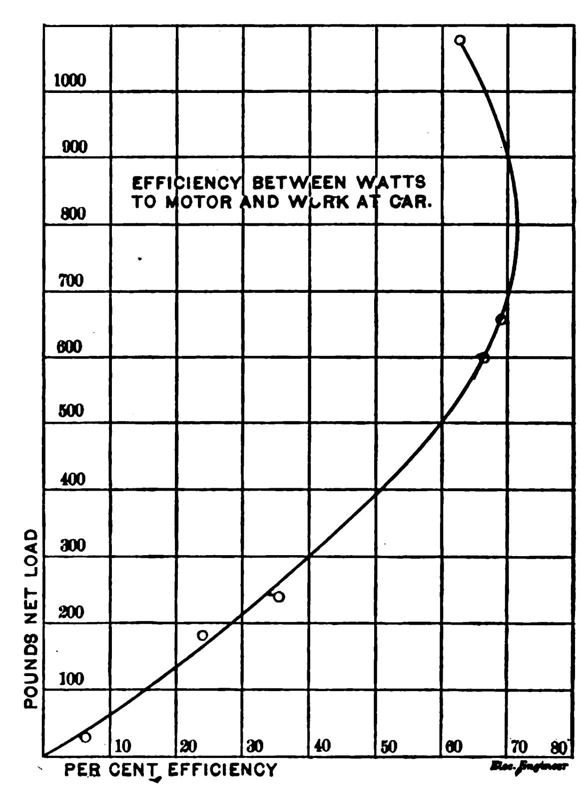

FIG. 5.

The following table shows the results of the engine tests in condensed form:

Test.	Average I. H. P. at engine.	Water per hour. per H. P.
1	10.98	43.7
3	10.78	38.9
4	11.09	38.2
5	14.14	41.65
6	12.83	39.9
Average	11.9	40.5

The average current supplied to the fields at 110 volts was 7.4 amperes, which, reduced to i. h. p., gives 1.35. This gives the following:

Total average I. H. P. per elevator	H. P.	13.25
Water per hour per elevator	lbs.	535.6
Coal per car mile per elevator	"	32.2
Cost per car mile per elevator	cts.	4.8
Kilowatt hours per car mile		2.70

The combined efficiency of motor and elevator gear or between watts delivered to motor and net weight lifted at car is shown as a curve in Fig. 5, the maximum efficiency observed being 69 per cent. The curve shows a probable maximum efficiency of 72 per cent at a load of 850 lbs. The combined efficiency of engine and dynamo under steady load at 13 horsepower was about 50 per cent.

Discussion of Results.—The relatively poor showing of the engine, 40.5 lbs. per hour per horse-power is accounted for by the fact that a 50 horse-power engine is called upon to work under a load varying from minus 10 horse-power to an occasional maximum for a few seconds of 33 horse-power, the average being, as given in the table, 12 horse-power.

The demand of the owner of the building was for entirely independent units. Had the plant been designed to run from one engine with a duplicate in case of breakdown better economy might have been attained. It seems probable that under these circumstances a 60 horse-power engine would have sufficed to operate the three elevators in the building, whereas three 50 horse-power engines are used. Even if separate units are retained the size could be much reduced.

There seems to be no data available showing the combined efficiency of an engine and dynamo under variable load, but if on one hand by reducing the size of the separate units the water consumption could be reduced to 35 lbs. per hour per horsepower and the efficiency be increased, say, to 60 per cent.—or, on the other hand, if by running from one engine the variations demanded by one car were to offset those of the others, thus raising the combined efficiency of engine and dynamo possibly to 70 per cent.—we should then have the following results:

	Separate units effi. 60 p. c.	1 eng. for 3 cars effi. 70 p. c.
Average horse-power per elevator	11 h. p.	9.5 h. p.
Water per hour per elevator	385.5 lbs.	331 lbs.
Water per car mile per elevator	209 "	183 "
Coal per car mile per elevator	23.2 "	19.9 "
Cost per car mile per elevator	3.46 cts.	2.97cts.
Kilowatt hours per car mile	2.70	2.70

The cost as given above includes the coal only, no addition being made for labor, interest, or repairs.

THE management of the Exposition Company have sent a letter to the E. S. Greeley & Co., extending to them their high appreciation and sincere thanks for the loan of the gold key, used by President Cleveland, in opening the World's Fair, at Chicago, in 1893, for use at the Exposition Building on Saturday evening, May 16, 1896, in transmitting the message from Dr. Chauncey M. Depew to Edward D. Adams, around the world.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST MILLENIUM EXHIBITION.—II.

BY ALFRED O. DUBSKY.

As the polyphase network of conductors is not extended over the whole exhibition—the three-phase plant not being large enough to supply all the electric power—there is a very large number of single-phase motors fed from the single-phase lighting central station of the city of Budapest. Besides, the polyphase central station of the exhibition works only in daytime, therefore the motors working in the evening and at night must be of a different type. The alternating current motors are either synchronous, or induction or asynchronous series motors.

The synchronous motors are all self exciting. Fig. 7 shows the winding diagram and the Blathy starting device employed for this type of motors. The motor has a stationary armature and revolving field magnets, and a commutator is fixed on the motor shaft. The black and white segments, Fig. 7 are well insulated from one another, but in electrical connection among themselves.

The diagram, Fig. 8, shows the arrangement of this motor. The armature and field magnet are in parallel on the same mains. Switching them on the mains an alternating current flows through armature and field; without any special device the armature would take a larger current than the field magnets, which latter have a larger self-induction. Moreover, with such a method the phase of the currents would be widely different in both windings, while for good starting it is required that current should be always exactly in phase in both parts of the motor. Therefore it will be quite advantageous to put a choking coil in the armature circuit on account of the difference of self-induction.

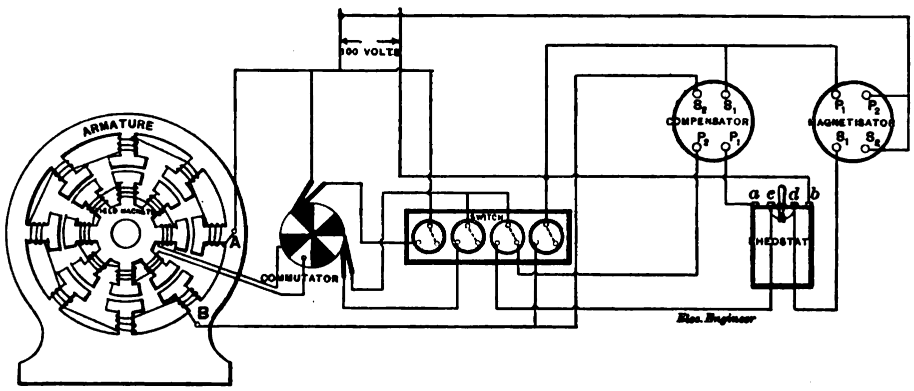

FIG. 7.—STARTING DEVICE FOR SYNCHRONOUS ALTERNATING MOTORS.

In order that a large alternating current may flow through the field magnets at starting, notwithstanding their large self-induction, the electromotive force applied at such times at the terminals should be four or five times greater than at full speed. For this purpose the full main tension is applied during the starting on the field magnets; but these latter are wound for a lower tension and at full speed, when the commutator is already at its regular work, a transformer supplies this low tension current from the main circuits.

The commutator has two brushes on each terminal. The passage of the brush from one segment to the other is made at the instant the alternating e. m. f. changes its sign; in regular work there would be a sparking disastrous to the commutator on account of the field self-induction. In order to prevent this, the field windings are short-circuited just a little before the alternatng e. m. f. changes its sign. The short-circuiting at this instant is made by the second brush; the current induced in this way in the field windings is of the same direction as the current circulating before. In this way the undulations are much equalized, the sparking is reduced and the magnetic field is more constant. The necessary connections for the starting are made by an ordinary two-throw switch. While starting, the connections are are shown by the dotted lines, Fig. 7. The current enters the armature at A; leaving it at B, the current flows through the choking coil, serving to increase the lag of the current. For this purpose the secondary winding S_2S_1 of a transformer is used. This is the "compensator" of Fig. 7. The current returns thence to the other main.

The field magnets are wound for low tension, 25 volts, for instance, and in regular work a special transformer or "magnetisator" furnishes the current from the principal mains. At the moment of starting this current is simple alternating current, and the field winding offers considerable inductance.

Therefore the 100 volts tension of the mains is increased by the primary winding of the "compensator," the secondary of which is in the armature circuit. This increased tension is applied at the terminal instead of the 25 volts in regular work at full speed. The "compensator" is, therefore, employed as a choking coil for armature current; at other times it serves as an ordinary transformer.

The field magnet circuit contains in the starting arrangement fixed resistance in order to diminish its inductance. In this way the phase of currents will be nearly the same in the armature and field magnet circuits. The current flowing from one main passes though this fixed resistance between a and b; the main

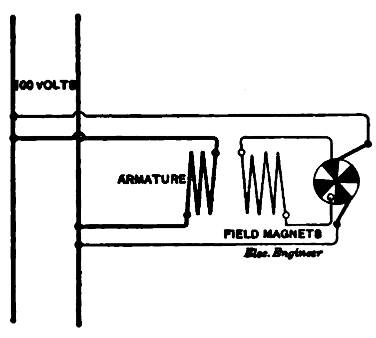

FIG. 8.

tension is then raised by P_1P_2, the primary of the "compensator," and this higher tension is on both brush terminals.

The motor will start with this device and will reach synchronism very quickly. At that instant the current in the revolving field magnets is already entirely commutated, though always very undulating. Connections are then changed by throwing the switch handle to the other side. The secondary winding of the "compensator" is short circuited and full pressure is on the terminals of the armature. The "magnetisator" is fed with current directly from both mains and its secondary low-tension current flows to the field winding. The resistance, c, b, in this secondary circuit is variable and regulates the intensity of this exciting current. The two brushes at each terminal

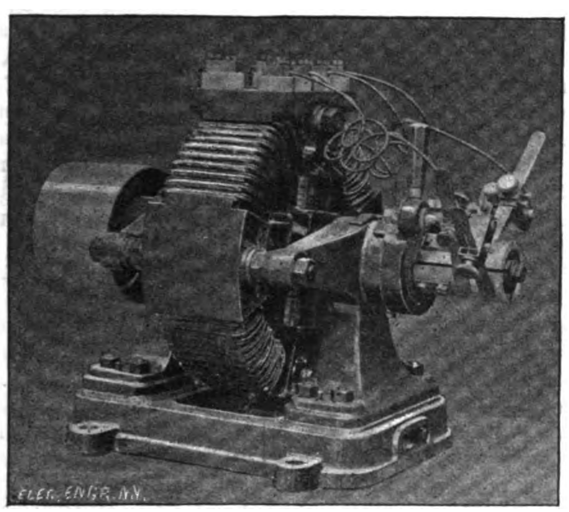

FIG. 9.—GANZ 3 H.-P. SINGLE-PHASE SYNCHRONOUS SELF-STARTING MOTOR.

are short-circuited in order to diminish the undulations of the alternating current. Sparking at starting is larger than at full speed, when there is almost no sparking, on account of the short-circuiting of the double brushes. Fig. 9 gives a view of one of these motors.

Induction Motors.—Single-phase induction motors have come into general use during the past few years, on account of the simplicity of their construction. They resemble greatly in their manner of operation and in their construction polyphase motors, but never attain all their advantages. Not only is their efficiency below that of a polyphase motor of the same size, but the starting requires also different artificial means, which are not necessary in polyphase work. Besides, the motor stops, if it is run much above its rated power.

Fig. 10 shows the winding diagram of a two-pole induction motor. The winding is divided into two separate parts, namely, I-III. and II-III. It is a regular two-phase winding and by sending two currents into them, which have, even approximately, a difference of phase of 90 degrees, the armature will revolve. In regular work, at full speed, a single-phase current between I. and II. will be sufficient to maintain the revolution of the armature.

At the moment of starting the currents are split by the use of resistances and choking coils. Let a and b, Fig. 11, be the secondary terminals of a transformer; c, the middle of this secondary winding is so connected that the potential between a and c is equal to that between c and b. If R is an ohmic re-

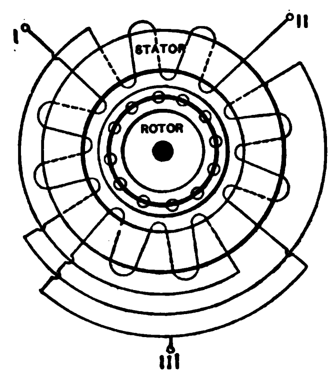

FIG. 10.

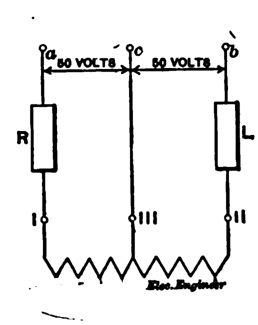

FIG. 11.

sistance and L the choking coil above mentioned, the motor will start if the connections are made as indicated. Both R and L must have a certain value determined by experience in order to split the phases in the proper degree. Starting can be effected only at no load, as the torque is not large enough to start with any load. At full speed a switch is thrown over; in this way R and L are cut out from the circuit and the motor can be loaded. Fig. 12 shows a view of one of these induction motors. The smaller motors up to 8 horse-power, as shown, have double pulleys. One pulley is keyed to the motor shaft, while the other is loose and is supported by a special outboard bearing. Both pulleys have a flat rim on the inside. While starting, the belt is on the loose pulley and the motor

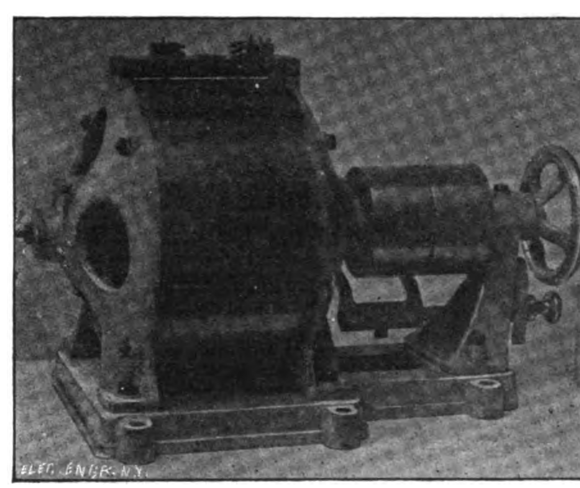

FIG. 12.—GANZ 3 H.-P. SINGLE-PHASE INDUCTION MOTOR.

can be started with the device described above. When full speed is attained the loose pulley is slowly pressed on the keyed pulley by turning the hand wheel on the outboard bearing. In pressing the loose pulley to the keyed one there is friction set up between the rims sufficient to transmit the speed of the keyed pulley to the loose one. When they are both revolving at full speed, the belt is thrown over to the keyed pulley. In this way the load is put slowly on these motors and not with a sudden jerk.

SMYRNA, DEL.—The Town Council has accepted the resignations of H. S. Anthony, Superintendent of the electric light and water plant, and George W. Rose, engineer of the electric light plant, and appointed a committee to solicit applications for the positions.

CONTENTS.

GROWING REQUIREMENTS OF ELECTRIC TRACTION.

THE transition from animal power to electric power on almost all of the street railways in this country has taken place so rapidly that railway engineers have found it difficult in the absence of any precedents to keep pace with the additional requirements which are made necessary by the introduction of electric traction. In order to design and install a modern high-class electric railway system it is necessary to combine a considerable knowledge of electrical, mechanical and civil engineering, and in each of these branches the necessary knowledge has had to be acquired by experience growing out of early failures. In almost every detail of the system the size and strength of the various parts were greatly underestimated, owing no doubt to the much less rigorous requirements of horse roads, which were at first the only guide to street railway practice. It is interesting to notice the additions and changes which have gradually been brought about with advancing experience. Mr. Sprague started to equip his earliest motor cars with two 7½ horse-power motors each, and at first sight 15 horse-power would seem ample to replace the power of two horses, even with allowance for the additional weight of machinery on the car, but it was soon found necessary to double the capacity of the car motors, and later the standard car equipment was increased to two 25 horse-power motors, which is the capacity of most of the trolley cars in general use to-day.

The line-wiring is another matter which has undergone a very great change. At the start the return circuit through the tracks and the ground was considered not to offer any resistance, and the wiring was calculated as though the entire resistance of the circuit was that of the overhead line. As a result of this it was found that in a good many cases the station pressure of 500 volts was reduced to about 300 volts at the ends of long lines, and burn-outs of the machines were of almost daily occurrence. The resistance of the return circuit soon became a very apparent evil, and extra bonding and the addition of grounded wire to the tracks were increased gradually until the standard practice now is to supply a metallic return circuit of carrying capacity equal to that of the overhead lines. The same change of practice has been noticeable in regard to the size and strength of rails employed in street railway service. In the days of the old horse cars rails weighing from 30 to 40 pounds per yard were generally employed, and these were always laid on stringers. The tread of these flat rails was not more than from an inch to two inches deep, and the flange less than half an inch thick. With the grinding action of the trolley car wheels, and the greatly increased weight of the cars, the tread of these rails was soon worn so thin that the wheel flanges came in contact with the rail flange and pressed out all the rivets which held the bonds; so flat rails had to be entirely abandoned. Practice has been constantly increasing the weight of rails, which now generally run from 60 to 90 pounds per yard, and are always of the tee, or the girder pattern.

Another point is now being forced upon the attention of the owners of trolley roads, which is of the greatest importance, and that is, the subject of railway bridges. With the horse cars almost any bridge that would carry ordinary wagonloads was sufficient for the purposes of a street railway, but with the advent of the electric car with its greatly increased speed and weight a great many of the bridges formerly used became entirely inadequate for the new service. A writer in the "Railroad Gazette" points out the fact that bridge acci-

dents on trolley roads are beginning to be reported, there being no less than four during the past six months. The most disastrous of these occurred on May 26 last, at Victoria, B. C., by which forty-three lives were lost. Steam railroads have learned by long and often unfortunate experience that a bridge is the worst possible place to skimp on material, and most roads of any considerable size now employ their own experts to not only design all bridges on their lines, but to periodically examine them; but it is doubtful if any trolley car companies have taken this precaution yet. Such accidents, however, should draw the importance of this subject to the attention of those who are in any way responsible for such bridges. In building bridges for the use of trolley cars the tendency is to underestimate the loads which they will have to carry. It should be remembered that the average load is not the one which is liable to prove dangerous, but the adventitious loads which are liable to occur at any time. It is also inevitable that a car having a capacity of fifty passengers will at some time be loaded with perhaps 150 passengers, and it is for these exceptional cases that the bridges should be designed. If the fact is considered that there is very slight difference in the cost of a good bridge and that of a poor one there is very little excuse to be found for the failure of a bridge.

THE THREE WIRE PATENT IN ENGLAND.

THE efforts which have been made to extend important patents beyond their natural life in this country have been numerous. It appears that America, however, is not alone in this respect, as, now that the English three-wire patent of Dr. John Hopkinson is approaching its expiration, application was made to the Privy Council for an extension of the same, based principally on the ground that the inventor has not yet received adequate remuneration from this method of distribution. According to the story told in the petition for the renewal of the Hopkinson patent it appears that in spite of its large adoption by central stations and other plants which are using the system under license, the petitioners—the Westinghouse Electric Company, who control the patent—have lost considerable money in exploiting it. The patent was granted in the early days of electric lighting and for the first eight years of its life there was practically no opportunity to apply the invention, and prior to 1889 Dr. Hopkinson had succeeded in licensing only three stations in England from which a net profit of only $1,000 was derived. At this date the Westinghouse company acquired an interest in the patent, and, according to the figures submitted, their experience with it has been a costly one. They received in royalties the gross sum of $106,956 up to the close of the year 1895, which, after deducting the expenses incurred in the purchase of the patent rights, the payment of renewal fees, legal and other expenses up to the present time, leaves them a net loss of $36,235, not allowing any deduction for interest on the capital expended on the patent! It has also been the subject of considerable litigation, which has been long and costly.

Considerable objection was urged against any renewal of this patent by a number of municipal lighting corporations who are licensees of the Westinghouse company and who objected to paying any further royalties after the date of July 27, 1896, when the patent would naturally expire. The objection was also urged against its extension that the patent was acquired by the Westinghouse company as a trading speculation and not with any view of assisting the inventor, and even if the company had not received adequate remuneration from the patent, that afforded no ground on which an extension ought to be granted.

After a short hearing the Judicial Committee of the Privy Council rejected the plea of the owners of the patent, evidently taking the view put forward by the objectors that as Dr. Hopkinson had actually received $47,000 from the Westinghouse Company, it could not be held that the patentee himself had not been sufficiently rewarded. The three-wire system is, therefore, now public property in England, though it is still subject to the Edison patent in this country.

There is one phase of this litigation, however, which is well worth noting. The three-wire system is now in use by a considerable number of municipal plants in England, and it is also noticeable that the objections came, with one exception, from such plants. Many of the devices and details of construction in connection with electric light and power service are patented, and most of the important electrical patents both in Europe and America have been objects of infringement suits involving large sums of money both in legal expenses and in damages. Herein lies a difficulty which is liable to occur in the case of municipally-owned plants and which is worthy of consideration by the advocates of municipal ownership. As long as any electrical patents remain in litigation any municipality operating its own plant is liable to be put to heavy expense in the defense of infringement suits and may possibly be called upon to pay large sums in damages if infringement is proved. We have seen in this country electrical concerns obliged to suspend business owing to adverse patent decisions, and while private corporations are obliged to take risks of this character it would seem that they would hardly be voluntarily incurred by any municipality.

MUNICIPAL CONTROL OF ELECTRIC LIGHTING PLANTS.

THE communications which have reached us during the past few weeks indicate unmistakably the fact that information is still desired in many quarters on the pros and cons of municipal ownership of electric lighting plants. We have but recently printed Mr. Allen R. Foote's able paper showing the fallacies and ignorance displayed in many arguments advanced by advocates of municipal ownership, but, after all, we believe the best arguments are those which many existing municipal plants themselves afford for the opponents of the system. Probably the station most discussed of any city plant in the United States is that situated in Detroit, which has now been in operation one year, and the first annual report of which is before us. According to this report, it costs the city of Detroit $84.70 per year to operate each lamp. This figure, however, does not include any allowance for sinking fund, depreciation or loss of taxes, etc. We have it on no less an authority than Mr. Alexander Dow, late electrical engineer of the Detroit city plant, that, making due allowance for all these items, the cost per lamp would practically be $100 per annum. Mr. Dow, who ought to be well acquainted with the conditions, admits that Detroit was an exceptional case, both in the condition of its local lighting companies, and in its arrangements as a municipality, and the circumstances which led to the establishment of a municipal plant at Detroit may never be duplicated in the experience of another city, and that conditions equally favorable to non-political management exist in few cities of its size. If, therefore, with such ideal conditions the cost per lamp is not less than $100 per annum, we scarcely see what benefit can be gained by cities installing their own plants, when many cases could be cited in which the rates charged by private companies are no greater and in some cases even less than those quoted above. In order to bring home still further the argument, we print in this issue an excellent series of facts and figures prepared by Mr. W. W. Bean for the benefit of the taxpayers of St. Joseph, Mich., which ought to convince any one who is open to conviction in the matter. It is gratifying, indeed, to know that light is at last beginning to dawn on some who have been carried away by the allurements of city lighting plants; thus Grand Haven, Mich., by a large majority recently rejected the proposition to issue bonds for the purchase of an electric light plant, and the voters of Pontiac, Mich., rejected the proposition to issue $9,500 in bonds to pay the expenses of themunicipal electric light and water works plant.

ELECTRIC TRANSPORTATION.

THE CLARET-VUILLEUMIER ELECTRIC RAILWAY, NEAR PARIS.

In the early part of June, the Claret-Vuilleumier Street Railway was opened and is now in regular operation on the surface contact system. The power house, a part of which is shown in Fig. 1, is situated at Lilas, near Paris, France. It contains three semi-tubular boilers which operate the three Garnier-Corliss engines, shown in the illustration. These are of a capacity of 200 horse-power each at 85 revolutions per minute. The cylinders are mounted in tandem and the engines are run condensing. They are belted each to a Hillairet four-pole,

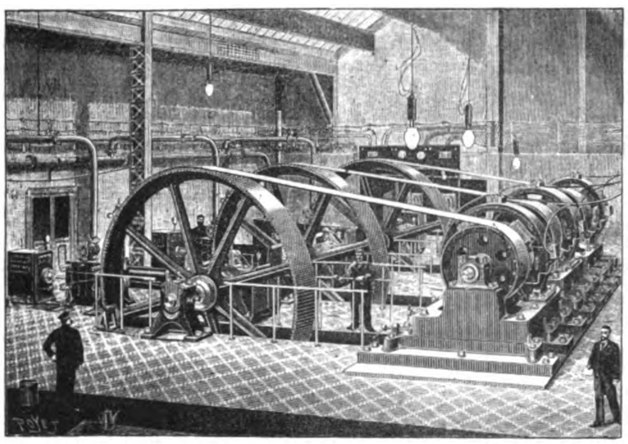

FIG. 1.—VIEW OF POWER STATION, CLARET-VUILLEUMIER RAILWAY SYSTEM, PARIS.

compound wound dynamo running at 300 revolutions per minute.

The three dynamos are connected to the switchboard, shown at the rear in the illustration, each dynamo being first led to a switch at the center of the board, where it may be connected to either the railway circuit or to an entirely independent lighting service which the station also supplies. In the evening one machine supplies the lighting, while the other two operate the railroad.

The road is partly single and partly double track and one lead from the dynamo is connected directly to the track. The other line from the dynamo is a lead-covered cable, which is laid directly in the ground beneath the sidewalks, and to this cable the distribution boxes are connected. These boxes are situated

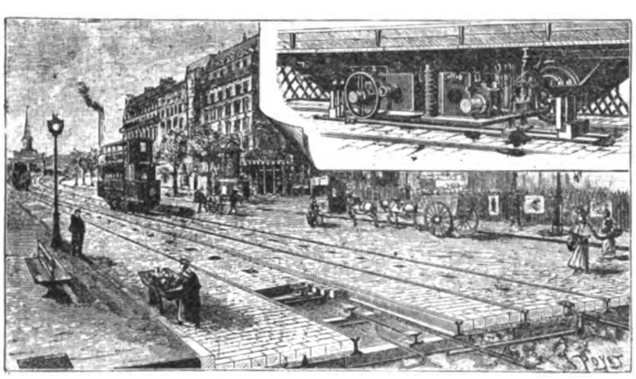

FIG. 2.—VIEW SHOWING CONSTRUCTION OF CLARET-VUILLEUMIER RAILWAY SYSTEM.

100 metres apart and are of cast-iron, each having two covers. A distributor situated in each box is in the shape of an arc of a circle upon the periphery of which twenty metallic contacts are placed. Each of these contacts is provided with a cable connecting the distributor to a copper wire, which unites two adjacent surface contacts. This network of cables is shown in Fig. 2. On the sidewalk to the left is an iron box which encloses a distributor; a wire leads out from this box and it is shown further on at the place where it joins the connecting wire between two contact blocks. These blocks are made in two parts, an upper and a lower piece connected by a vertical web. They are insulated from the earth by a mixture composed of pitch and bitumen which provides sufficient insulation. The wire running between them is insulated in the same manner. The blocks are set in the pavement so that they only project above the surface of the ground about 5 mm. It is evident from what has been said that each distributor will be able to feed twenty successive contacts along the road.

Fig. 3 shows the details of the distributor. Against the metallic plates appropriate brushes make contact and these are carried on a central arm which is in electrical connection with the station. The movement of this arm is secured by means of two electro-magnets, F and G, one for the forward and the other for the backward direction. Both become active at the moment the car arrives at a contact block. A diametrical bar carrying the contacts is drawn by an electromagnet against a pawl held by a spring. This pawl fits in the notch of a toothed wheel which forms part of a train which moves the arm along the plates, A, B, C, etc., and establishes an electrical connection to the surface contact boxes. The movement of the arm is continued successively as the car passes each contact.

In order to pass from one distributor to the next the two last plates of the first distributor are connected to the first two plates of the following distributor. Two suitable contact bars are carried on the bottom of the car to make contact with

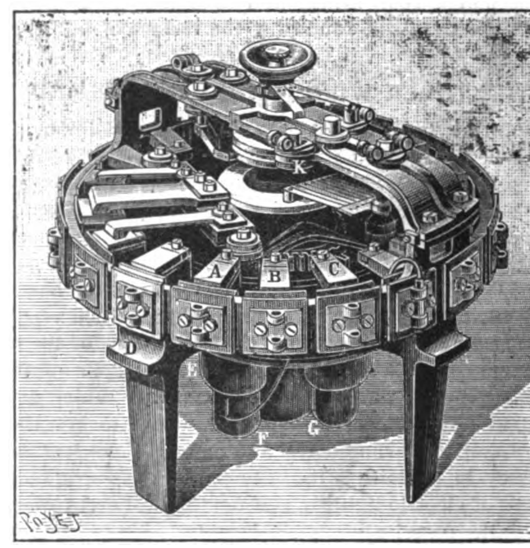

FIG. 3.—THE AUTOMATIC DISTRIBUTOR.

the metal blocks from which they receive the current. The cars are also provided with two Hillairet motors each.—"La Nature."

THE WORK EXPENDED IN BICYCLE PROPULSION.

As frequent attempts have been made to drive bicycles by electric power from storage batteries carried on the wheel, some recent experiments of the power consumed, made by Mr. Bouny, will be of interest to workers in this field. Mr. Bouny shows that there is no absolute dead point such as occurs with an ordinary connecting rod and crank motion, and, secondly, that there is always some pressure on the pedal during the rise, the negative work due to which has to be subtracted from that done during the down stroke to obtain the net amount used in propulsion. The experiments were made at speeds ranging from 10⅝ to 21¼ miles per hour, the machine being run on a wooden racing track. The results were as follows:

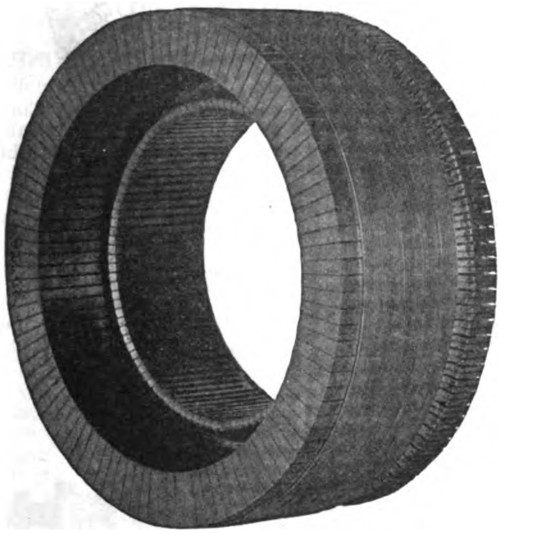
Speed. Miles per Hour.	Work Done per Semi-Revolution. Ft. lb.
10	18.58
10⅝	20.96
12.5	33.98
15.0	47.50
17.5	56.75
20.0	63.62
21¼	66.08

It will be seen from the above figures that the average pressure of the foot required on the pedal increases rapidly with the speed, being at 20 miles an hour nearly 3½ times as much as at 10 miles per hour. Unfortunately the gear used is not noted by M. Bouny, and so it is impossible to deduce from the

above figures the average tractive resistance of the machine at the different speeds. Probably at the higher speeds named a large proportion of the total work done was expended in overcoming atmospheric resistance, and the run of the figures might be changed considerably if the trials were conducted on a rough road instead of on a smooth track.

NEW G. E. 800 RAILWAY COMMUTATOR.

The maintenance of the quality of a railway motor depends to a large extent upon the accuracy with which those parts which are subject to wear can be replaced to render the motor as perfect as when new. In refilling the commutator, for instance, considerable difficulty is usually experienced on account of the necessity for great accuracy in turning the segments to fit the cones of the shell, which cannot readily be done unless special tools are employed. To obviate this difficulty the General Electric Company have devised complete sets of segments and segment insulations for all types of railway motors, securely bound together by a band of wire to prevent



New G. E. 800 Railway Motor Commutator.

movement and finished ready for assembly on the old shell. In addition to the preparation of the cone fits, the segments are slotted and tinned for the reception of the armature leads. The only work necessary in the shops is to screw together the cap and shell clamping rings, to solder in the leads and to true off the face of the commutator. Practically all the machine work formerly done at the operating company's shops is eliminated and as the segments are clamped together by hydraulic pressure, they are much firmer than those usually manufactured on the premises of street railway companies.

Hard rolled copper only is used for these segments and to give a longer life to the commutator, the depth to which the segments can be turned has been increased by 40 per cent.

BICYCLE CARS NOT WELL PATRONIZED.

The experiment of running cars for the accommodation of wheelmen, which the Brooklyn Heights Railroad Company, of Brooklyn, N. Y., began about three weeks ago, has not been as successful as was expected, according to General Manager Weeks. Bicyclists are allowed to check their wheels without the payment of an extra fare. It was believed that many wheelmen would take advantage of the opportunity to get rid of the roughest and most unpleasant part of their suburban trips. The objections to the bicycle cars apparently are the delay in getting a wheel checked and waiting for the cars. The service will be continued, and an attempt will be made to improve it and to make it more satisfactory to the wheelmen. Then, if it is not better patronized, it will be discontinued.

STRINGING LIVE TROLLEY WIRE.

A system for the rapid stringing of trolley wires has been devised and applied on the lines of Sioux City. The reel containing the wire is placed on the platform of a car, so that it may revolve and put a tension on the wire. From here the wire passes over a wheel on the roof, where the men standing on an insulated platform can readily attach it to the supports. What is most novel about the system is that the wire that is thus strung supplies the current for the propulsion of the car, and is, consequently, a "live" wire, the current supplying power to the motors constantly passing through it.

AN UNDERGROUND ELECTRIC RAILWAY FOR BRUSSELS.

The electric underground road has earned such golden opinions in London that the Belgians are turning their attention to the system for their city passenger traffic. A railway, based on the Greathead system of tunnels, is now proposed for Brussels. It is to be worked by electricity and to run 50 feet below the surface. The first portion is to consist of a complete circle about four miles long, with double track, having eleven stations, and a future extension of a second circle of about two miles long, with four stations; the two tunnels for the different directions will be quite distinct from each other; they run almost entirely below the public streets. The subsoil appears to be clay. There is to be a two and a half minute service each way. The total cost of the first circle is estimated at $3,000,000, a less rate than the City and South London line, which cost $1,000,000 per mile. The elevators are to be operated by hydraulic power, and will hold forty people.

TELEPHONY AND TELEGRAPHY.

TELEPHONE EXPERIMENTS IN BRUSSELS.

The Belgian authorities have recently made some interesting experiments with the loud-speaking telephone instrument and electrical firm-alarm appliances of the Single Wire Multiple Telephone Signal Company, of London. In addition to the apparatus to test the adaptability of which the experiments were arranged, a new portable loud-speaking combined telephone and telegraph instrument, specially designed for military purposes in the field during operations, formed a feature of interest, the extreme portability and light weight of the whole apparatus attracting considerable attention. It was proved that although the wires connecting the instrument were cut, Morse signals were quite audible even when several feet of damped twine were interposed in the circuit. We understand that the British military authorities are taking an interest in the instrument, and that a demonstration of its special suitability for military purposes will shortly be given.

UNDERGROUND TELEPHONE WIRES IN BALTIMORE.

Mayor Hooper has signed the ordinance authorizing the Home Telephone Company to lay its wires and cables in unused conduits of the Police and Fire Alarm Telegraph's subway system, and to erect poles for temporary use in sections of the city to which the subway system does not yet extend.

Under the ordinance the company is required to pay the city as rental 7 cents a year for every linear foot of duct occupied by its lines. This rental must be paid semi-annually. Should the company be in arrears for three months, the Mayor is authorized to have the lines removed at the company's expense. Within two years the company is required to have no less than 2,000 telephones in actual service.

JAPANESE TELEPHONE ENGINEERS INSPECTING OUR SYSTEM.

Mr. Okomoto, Engineer of the Ministry of Communication of Japan, visited Brooklyn, N. Y., recently and spent a long time at the headquarters of the Telephone Exchange, on Smith street, where he studied the switchboards and the underground system. He was also shown how the wires were strung on the elevated railroad structures and also placed under ground in the subways. He said it was the intention to extend the telephone system over the entire Empire of Japan. A long-distance line was now being constructed, he said, from Tokio to Kobi, a distance of 350 miles. There are no underground subways in Japan, and the wires are stretched from place to place by means of poles. Mr. Okomoto expects to visit all the larger cities, and return home by way of San Francisco in September.

THE DETROIT TELEPHONE CO.

The subscription lists of this new telephone company have reached 4,000 names, of which nearly 3,000 have signed three year contracts. It is claimed that the cost of a plant for 5,000 telephones will not exceed $600,000. If this includes instruments, switchboards, real estate, underground distribution, etc., it is a phenomenally low figure.

LITERATURE.

THE MAGNETIC CIRCUIT IN THEORY AND PRACTICE. By Dr. H. Du Bois. Translated from the German by Dr. E. Atkinson. New York, 1896. Longmans, Green & Co., 360 pp. 5½ x 8½ in. 94 illustrations. Price, $4.

The plan of this work arose out of a lecture delivered by the author on the occasion of the International Congress of Electricians at Frankfort in 1891, and the book fulfills the desire from many sources for a systematic and critical account of the most important developments in the direction of magnetism. The historical side of the subject is touched upon but lightly, and the author has chiefly directed his efforts to describing the actual state of theoretical and experimental inquiry. The book is formed of two parts, Part I. pertaining to theory and Part II. to applications of magnetism. The two introductory chapters are as elementary as the nature of the work will permit and deal with the mathematical theory of the electromagnetic field. Chapter III. summarizes the theories of the "rigid" magnets on one hand, and of absolutely "soft" cores on the other. In Chapter IV. the theory of magnetic induction is outlined and a few special cases of magnetic induction are considered. The author states what is obviously true, that we are still a long way from determining the general problem of induction, namely, to determine completely the magnetization of a body of arbitrary shape when the inducing field is distributed in any manner whatever.

Part I. closes with a chapter on the theory and experimental tests of the magnetization of closed and of radially divided toroids or rings of circular section. Kirchhoff was the first to investigate mathematically the magnetization of a ring of either rectangular or circular section and subsequent investigations of Professor Stoletow and Professor Rowland have up to the present time given us no reason to doubt the correctness of Kirchhoff's theory. The experimental tests include the investigation of the iron toroid by H. Lehmann, whose experiments were conducted with the object of testing the author's theory of the magnetization of a radially divided toroid, and with the result that the theory here developed was confirmed by the experiments with sufficient accuracy for most purposes.

The second part of this work commences with a study of the general properties of the magnetic circuit, and this treatment of the subject is from the standpoint of applied physics. This part of the work relates to the application of the principles developed in the early part of the book to the machines and apparatus used in actual practice or in the laboratory. A chapter follows, which is devoted to the analogy of the magnetic circuit with other circuits. Maxwell first noticed that the problem of induced magnetism when considered with respect to the relation between magnetic induction and magnetic force corresponds exactly with the problem of the conduction of electric currents through heterogeneous media, and later Lord Kelvin in his theory of magnetism has frequently dwelt on the complete analogy existing between the mathematical theories of magnetic induction, of dielectric polarization, and of Fourier's theory of thermal conduction on the one hand, and the theory of a number of hydrokinetic processes on the other.

The purely practical part of the book commences with Chapter VIII., on the magnetic circuit of dynamos and electromotors, and includes the experimental determinations of leakage, calculation of air reluctances, armature reaction and multiple magnetic circuits. This is followed by a chapter on the circuits of various electromagnets and transformers and the book concludes with two chapters on experimental methods of measurements of magnetization and of induction. The book will be found of great value to the advanced student in electricity.

SOMETHING ABOUT X-RAYS FOR EVERYBODY.—By Edward Trevert. Lynn, 1896. Bubier Publishing Co. 75 pp., 5 x 6½ in. 42 illustrations. Price, 25 cents.

This little book is a compilation of odds and ends in regard to Röntgen rays intended for the general reader, and is not in any respect a technical work. It commences with a detail description of the manner of manufacturing an induction coil, giving dimensions, sizes of windings, patterns of vibrator, etc. A number of different shapes of Crookes tubes are described and the manner of connecting up the apparatus for taking shadow pictures is shown. The remainder of the work is devoted chiefly to illustrations and descriptions of Röntgen photographs which have appeared in the technical and daily press.

A THEORY OF THE STRUCTURE OF NATURE.—By James S. Alden, M. E., Passaic, N. J., 1896. Published by the author, 48 pp., 5½ x 9 in., paper. Price, 50 cents.

The author's theory of the structure of matter is premised by the assumption that an atom of matter consists of a vortex ring of luminiferous ether, and this theory is elaborated by a study of the mechanical effects which such vortex rings would produce, and the comparison of such effects with the known phenomena of matter.

The author starts with the assumption that "an elementary atom cannot exist without all of its vortex rings in combination," and shows how the movements and vibrations of these vortex rings might produce the phenomena of gravity, electrostatic attraction and repulsion, heat, light, electricity, and, in fact, all the physical characteristics of matter with which we are familiar.

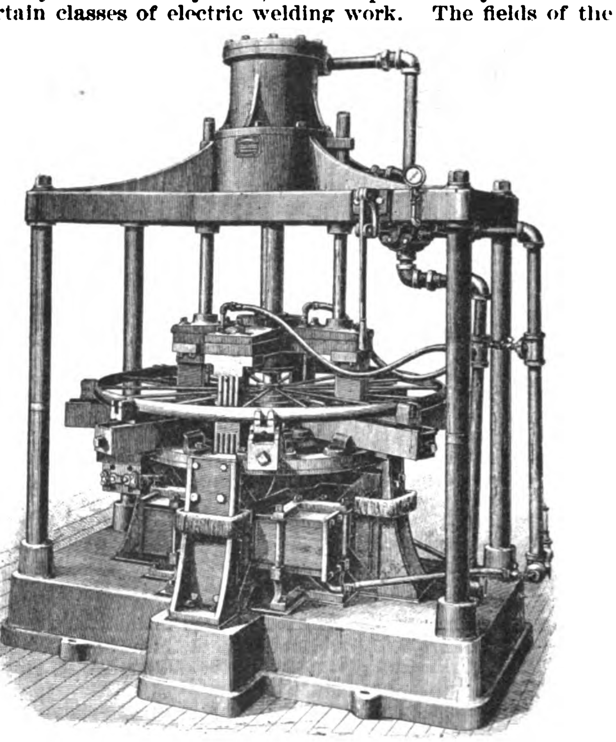
The subject matter of this pamphlet is entirely hypothetical, and the arguments are based purely on mathematical deductions. The author closes with a short appendix in which he attempts to trace an analogy between the structure of matter and the structure of the spirit. In conclusion he states "the combined teachings of the Bible and science seem to indicate that faith and ether are one and the same thing." The appendix could have been omitted to the advantage of the work.

MISCELLANEOUS.

ELECTRIC WHEEL WELDING MACHINE.

The accompanying engraving represents an electric welding machine built by the Thomson Electric Welding Company of Lynn, Mass., especially for the Niles & Scott Company, of La Porte, Ind. It is intended particularly for making wheels having metal hubs and spokes, the parts being welded together by means of electricity. The machine was designed by Herman Lemp, electrician for the Thomson Company, and combines many novel and extremely interesting mechanical and electrical features.

Electricity is supplied by an 80-kilowatt alternating current, separately excited dynamo, built particularly for use in certain classes of electric welding work. The fields of the



ELECTRIC WHEEL WELDING MACHINE.

dynamo are excited by a 6 D Thomson-Houston type dynamo, 110 volts. The speed of the dynamo is 1,000 revolutions per minute, giving 50 cycles per second. The potential of the dynamo is governed directly by a rheostat in circuit with the field, which is manipulated by the operator of the welding machine, varying the potential according to the cross section of the work to be welded. The maximum difference of potential is 350 volts. The dynamo is of extremely rigid construction, large heavy bearings of the self-oiling type, laminated iron pole pieces and the ordinary tooth type armature.

The electrical part of the welding machine consists of four 20-kilowatt transformers, connected in multiple, which form, together with the magnets, the bottom part, as clearly shown in the engraving. These are surmounted by a brass ring supporting the various chucks for holding the wheel central with

the hub. It may be added that this centering device, as the machine is used to-day, has been removed, as it was not found necessary to have it, the center readily adjusting itself. The secondary of the transformer is separable. On top of the machine is a hydraulic cylinder, through the piston rod of which the necessary pressure is transmitted to the parts being welded. By means of the hydraulic apparatus the upper section of the secondary circuit is raised entirely clear and the parts to be welded are placed in the center of the machine. The secondary circuit is then closed and brought down so that the upper half of the circuit rests upon the top flange of the hub to be welded, the bottom resting on the lower part or section of the secondary circuit. The secondary circuit is made operative by means of sliding contacts. The primary circuit is then closed, and at once the two sections of metal forming the hub, by means of the pressure brought by the cylinder, begin to weld. The current is then kept on until such time as the entire outside diameter of the metal flanges together with the spokes which the flanges inclose is brought up to a welding heat, at which time the water pressure is again applied and the two parts of the hub pressed together at a welding heat. The time varies from fifteen seconds to two minutes, according to the cross section of the stock to be welded. The secondary current varies from 10,000 to 30,000 amperes, according as the cross section of the stock to be welded increases or decreases.—"Iron Age."

A ONE-VOLT STANDARD CELL.

BY W. AIBBERT.

FOR the last two years, the writer has been trying, with the Electrique," from which the following points are gath- volt cell as a standard potential difference. The original stimulus in that direction was partly sentimental, arising from the frequency with which students asked why the nominal standard volt was not actually on sale, in the same way as the standard ohms. Other reasons, however, were not wanting, and I determined to test the merits of a cell which was first designed by Helmholtz for other purposes.

The general construction of the cell is easily explained. It is in most respects like the Latimer Clark cell now used, with the substitution of chlorides for sulphates. Thus, the active metals are zinc and mercury, the liquid is a solution of chloride of zinc, and the paste is made with mercurous chloride. A diaphragm is required, and the details of this are of some importance.

The voltage of the cell depends chiefly on the proportion of zinc chloride that the liquid contains. The density required for one volt, is always near 1.380, but impurities are of considerable importance. The temperature coefficient is less than 0.0002 volt per 1 deg. C. This means such a small variation for ordinary temperature changes that it can be neglected. A thermometer is unnecessary, even though there is a certain lag of voltage behind temperature.

We have tested our cells at temperatures as high as 35 deg., a week's work under these conditions producing no detectable changes. We have notes of cells running over the best part of two years, showing a constancy as good as can be wished, so that there seems every ground for confidence that the cell may take a lasting position, and claim to be an improvement on the Latimer Clark.

ELECTROCHEMICAL ACTINOMETRY.

MR. MARECHAL has published an article in "L'Eclairage Electrique," from which the following points are gathered:

The apparatus described is designed to measure the electrical energy resulting from the impingement of light upon a copper plate covered with a thin film of oxide and opposed to a second plate with a clean metallic surface. Both plates dip into a solution of a haloid salt of an alkali metal, and the non-oxidized plate is protected from light by a suitable envelope. The electrolyte should be dilute, e. g., it should contain about 1 gramme of the salt per litre. On connecting the electrodes with a sensitive galvanometer it is found that the potential difference between the plates responds to small variations in the lights falling on that which is exposed, and that the plate with the film of oxide is always positive to the plate with a clean surface. Diffused daylight gives a reading of some thousandths of a volt, and direct sunlight one of nearly 0.1 volt.

The author has observed that for comparatively weak sources of light (taking daylight as a standard), e. g., the oxy-hydrogen light, the voltage is inversely proportional to the square of the distance of the source of light, i. e., it is proportional to the intensity of the light; with sunlight, on the other hand, the voltage lags behind the light intensity. Using monochromatic light it is found that the voltage is much influenced by the wave length of the impinging ray. Using sodium chloride or bromide as the electrolyte, the effect increases from the red end of the spectrum, gradually to a maximum at the green or green-blue portion; with sodium iodide the maximum voltage ranges from the yellow to the green-blue. Blue rays give only a feeble result, and the violet almost none. By promoting selective absorption the sensitiveness of the arrangement can be greatly increased. For this purpose it suffices to dip the oxidized copper plate in a weak solution of some coloring matter. Thus, using the dyestuff known as "crystal green" the sensitiveness of the couple is increased three or fourfold, while, with "malachite green," the increase is some eight times the original value. In this case the sensibility of the plate is naturally greatest for red rays.

It appears that in all the cases quoted the light does not act by virtue of accompanying heat radiations nor by its so-called chemical rays of the violet and ultra-violet, but by what Maréchal dubs its "actinicity." The reaction brought about by the impinging light may be simply represented thus:

$$4CuO + 2NaI + H_2O = 2NaOH + CuI_2.3CuO.$$

Numerous uses for the actinometer are suggested. It may be employed for the direct electrical registration of optical signals. It is also proposed as a photometer.

ELECTRICAL RESISTIVITY OF BISMUTH.

PROFESSORS DEWAR AND FLEMING recently communicated to the Royal Institution the following:

"In continuing our experiments on the electrical resistance of bismuth at low temperatures and in magnetic fields by the aid of a powerful electromagnet kindly lent to us by Sir David Salomons, we have observed the fact that a wire of electrolytic bismuth, when cooled in liquid air to a temperature of —186° C., has its resistance increased more than forty-two times, if it is at the same time transversely magnetized in a field of 14,000 units. The bismuth, when cooled in liquid air and thus magnetized, has its electrical resistance increased more than fifteen times, even when compared with its resistance at ordinary temperature (19° C.) and not in a magnetic field. There is no reason to believe we have reached the limits of this increase. We reserve further details for a full communication to the Royal Society later."

Supplementing this letter Professor Fleming writes as follows:

"It may be interesting to give the exact figures of observation: A bismuth wire was used having a resistance of 1.46 ohms at 19° C. when not in a magnetic field. If placed transversely to the field, in a field having a strength of 14,150 C. G. S. units, its resistance was increased to 2.34 ohms at 19° C. or 1.6 times. This, of course, is a well-known effect. If the same wire, however, was placed in liquid air and cooled to—186° C. its resistance fell to 0.53 ohm. If then placed transversely to the field in a field of 14,150 units, its resistance immediately increased to 22.4 ohms, or 42.2 times. Hence the bismuth cooled to —186° C. and in the field of 14,150 has a resistance 15.3 times greater than when at 19° C. and not in the field. There is a certain value of the field which just neutralizes the diminishing effect of the cooling on the bismuth resistance and leaves the wire when cooled in liquid air, and in the field, of the same resistance as when not cooled and not in the field."

A DANGEROUS PROTECTOR.

Our French contemporary, "La Vie Scientifique," in a recent number, illustrates and describes an apparatus which has been devised by M. P. Woog, with the object of protecting a lineman from the effect of a premature switching on of the current while he is working on a high tension single line circuit. The device consists of an arrangement for making contact between one end of a flexible wire and the line wire, either on both sides of the point at which the man is working, or on the machine side thereof only, the other end of the flexible wire being connected to earth. There is no doubt that if the line wire is properly earthed the lineman will be protected, although the machine may suffer unless it also is protected by an effective fuse or other cut-out; but everything depends upon the resistance to earth being sufficiently low.

PASSAGE OF ELECTRICITY THROUGH GASES.

Experiments by Otto Lehman are described in the "Zeit. Physical. Chem.," vol. 18, p. 97, in regard to the electric discharge through various gases, vacuum tubes, mixed gases with different forms of electrodes, and the discharge in a strong magnetic field. Illustrations of a large number of discharge phenomena are shown, and the author concludes that the views of Goldstein and Hertz, viz., that the discharge takes place into the ether and not into the gas, are erroneous.

RELATIVE COST OF IRON AND COPPER AS CONDUCTORS.

The accompanying table, given by Mr. J. R. Allen in "The Technic," shows the relative cost of copper in cents per pound as compared with wrought iron, Bessemer steel and cast iron in dollars per ton. The comparison is made for conductors having equivalent carrying capacity. In using Bessemer steel rails for conductors it is possible to use those that are winding

Cost of copper, in cents per lb.	Cost of equivalent wrought iron conductor in dollars per ton.	Cost of equivalent Bessemer steel conductor, in dollars per ton.	Cost of equivalent cast iron conductor, in dollars per ton.
7.	19.25	18.10	14.50
7.5	20.75	19.50	15.50
8.	21.50	20.30	16.75
8.5	23.75	22.25	17.75
9.	25.00	23.50	19.00
9.5	26.50	25.00	20.00
10.	28.00	26.25	21.00
10.5	29.25	27.50	22.00
11.	30.75	29.00	23.00
11.5	32.25	30.25	24.25
12.	33.50	31.75	25.25
12.5	35.00	33.00	26.25
13.	36.50	34.50	27.25
13.5	38.00	35.75	28.50

and imperfect. Such rails may be purchased at a greatly reduced price. Let us consider the saving that can be made by the use of Bessemer rails, assuming the rails to cost $25 per ton, as compared with copper at 11 cents per pound. Let the current to be transmitted be 1,000 amperes at 500 volts and the distance it is to be transmitted be three miles with 5 per cent. drop in voltage.

Cost of copper conductors	$39,000
Cost of Bessemer steel conductors	23,711
Difference	$5,289
Deducting $400 per mile for bonding	1,200
Total saving	$4,089
Saving per mile	1,363

The first use of steel rails as conductors was on the intramural road at the World's Fair. The Metropolitan Elevated Road, of Chicago, has also adopted steel rails as conductors.

TO RESTORE OIL WELLS BY ELECTRICITY.

An invention is about to be put on the market which, it is claimed, will start the dry wells running as freely as when they were first sunk. This invention is the work of a Washington gentleman, Mr. Tapley W. Young, and consists of an electric heater, which can be lowered into the well.

To understand the principles upon which this invention is founded, it will be necessary to explain that the theories as to exhaustion of so many wells is that the oil, in passing upward through the stone, has clogged the porous stone with paraffin in such quantities that the further flow is stopped and the well ceases to produce. Some think that it is because the supply in the earth has given out, but the generally accepted idea is that the oil is still in abundance, and only ceases to flow when the exit is stopped.

The stone through which the oil passes is of a very porous nature, and as the liquid is in a crude state, the thick matter becomes as dregs, settling in the rock near the edges of the bottom of the well. It has been common to use torpedoes to shatter the stone at the bottom of the well, thus breaking up the clogged matter, but this is an expensive process.

By the Young method the machine, which is about 3 feet long and resembles an iron cartridge, is placed at the bottom of the well, and the current turned on so that it receives just enough current to produce an enormous heat without melting the metal. By the peculiar construction of the carbon-packed chambers the intense heat is radiated about into the rock in all directions. Thus the paraffin and other refuse are softened and melted up so that they run, and when the well is started a fresh flow takes place, just as strong as it did when the well was first sunk.

THE SEYMOUR MANUFACTURING COMPANY, of Seymour, Conn., are enlarging their boiler house, and the new portion of the building will be constructed entirely of steel in order to make it absolutely fireproof. The contract for the steel work has been let to the Berlin Iron Bridge Company.

MARRIED.

DR. FREDERICK BEDELL was married to Miss Mary Louise Crehore, in London, on Wednesday, July 1.

PERSONAL.

MR. T. C. MARTIN, by special invitation, repeated his Niagara lecture, recently delivered at the Royal Institution in London, before the Société Internationale des Electriciens, in Paris, on July 8. Mr. Martin was ably assisted by M. Hillairet.

MR. JOHN W. LIEB, JR., has been appointed general manager of the Edison Electric Illuminating Company of New York.

MR. HENRY B. CRAM.

It is with feelings of regret that we have to announce the resignation of Mr. Henry B. Cram from the position of treasurer of the Bernstein Electric Company, of Boston, a post which he has filled for so many years with ability and conscientiousness. Mr. Cram is one of the old timers in the electrical business, and his name and that of the Bernstein Company have got to be considered almost as synonymous. His headquarters have for the past eight or ten years been at 620 Atlantic avenue, Boston, and most electrical visitors to that city never failed to run into the pleasant suite of offices on the first floor, and were always sure of a cordial welcome. One might say that Mr. Cram has grown up in the incandescent lamp business, and has followed all its varying conditions with the most absorbed interest, and has indeed made the study of the lamp situation his life work. Unassuming in manner and never at any time coveting publicity, Mr. Cram has yet made for himself in the electrical profession hosts of warm friends, who will all join with us in expressing the hope that he may soon find another sphere of usefulness, where his great experience in the electrical business must be of value.

OBITUARY.

ABRAHAM L. BOGART.

We regret to announce the death of Abraham L. Bogart, who died at his home in Jamaica, L. I., on Saturday, July 25, aged 80, years. He was the senior member of the firm of A. L. Bogart & Co., of this city, and was the inventor of numerous devices for electric gas lighting.

EDWARD A. ECKERT.

Edward A. Eckert, brother of General Thomas T. Eckert, president of the Western Union, died on Sunday, July 26, at the Commercial Hotel, Asbury Park, of heart disease. Three weeks ago Mr. Eckert was injured in a bicycle accident at Allaire, but had almost recovered from it. His physician, who was with him when he died, does not connect the death with the accident. Mr. Eckert was superintendent of exchanges of the Metropolitan Telegraph and Telephone Company, of New York.

JOHN N. GAMEWELL.

John N. Gamewell, inventor of the Gamewell fire alarm system, which is in use all over the United States, died at his home in Hackensack, N. J., on July 19, after an illness of three weeks. He was born in South Carolina seventy-three years ago, and during the war was superintendent of a powder mill in Columbia, S. C. Mr. Gamewell had lived in Hackensack 35 years. He made a fortune from his invention, but met reverses a few years ago in a railroad speculation. He leaves a widow and five children. His only son, the Rev. Frank Gamewell, is a missionary in China.

WALTER O. LEWIS.

The death is announced of Walter O. Lewis, for many years manager of the New York Ship News Office. He was one of the early advocates of the feasibility of the Atlantic cable, and was a warm friend of Cyrus W. Field. Mr. Lewis was the organizer of the Ship News Office for the old Associated Press. When the Boston and New York Telegraph Company was organized he was one of the managers. It was greatly owing to his industry and intelligence that the company was put upon a paying basis. He was about eighty-two years of age at the time of his death.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Biographical:

SIR JOHN PENDER.—Obituary with a complete review of his life.—London "Elec.," July 10, 1896. "Elec. Engr.," July 15, 1896.

Electro Therapeutics, Diagnosis, Etc:

NOTES ON ELECTRO-THERAPEUTICS.—By Drs. G. Gautier and J. Larat.—"Journ. of Electro. Ther.," July, 1896.

A NEW METHOD OF DILATING WITH FARADISM.—By Jennie W. Martine, M. D.—"Journ. of Electro Ther.," July, 1896.

ELECTRICITY AS A MEANS OF DIAGNOSIS IN GYNECOLOGY.—By G. Apostoli, M. D.—"Journ. of Electro Ther.," July, 1896.

ELECTRICITY IN DISEASES OF THE PHARYNX.—By Thomas L. Shearer, M. B., C. M.—"Journ. of Electro Ther.," July, 1896.

GALVANISM IN DISEASES OF THE LARYNX.—By J. B. Garrison, M. D.—"Journ. of Electro Ther.," July, 1896.

ELECTRO CAUTERY IN NASAL DISEASES.—By Wesley A. Dunn, M. D. Some suggestions as to the proper application.—"Journ. of Electro Ther.," July, 1896.

ELECTRO MEDICAL AND SURGICAL INSTRUMENTS.—By Laurence Stevenson. Their construction and use.—"Journ. of Electro Ther.," July, 1896.

Measurements:

LORENZ APPARATUS.—See synopsis July 15, 1896; also London "Elec. Rev.," July 10, 1896.

Mechanical:

STEAM PIPING FOR ELECTRIC RAILWAY POWER PLANTS.—By Geo. H. Davis, M. E. A discussion of eight distinct types of live steam fitting systems.—"Street R'way Journ.," July, 1896.

Mining:

PRECAUTIONS UNNECESSARY IN THE USE OF ELECTRICITY IN COAL MINES.—By H. W. Ravenshaw. Abstract of paper read before the Federated Institution of Mining Engineers. Author offers suggestions which may serve to minimize the risk from shock and fire. He discusses main conductors, junction boxes, switches, motors, motor magnets, motor armatures, and enclosed (ironclad) motors.—London "Elec. Engr.," July 3, 1896.

Miscellaneous:

MUNICIPAL ELECTRICAL ASSOCIATION OF ENGLAND.—The address delivered by Mr. Arthur Wright and an abstract of papers presented.—"Elec. Engr.," July 8, 1896.

Railways:

MILEAGE, LONG-DISTANCE RIDING AND TRANSFER SYSTEMS IN AMERICAN CITIES.—Information bearing upon the question of how much a passenger on the street railways of the larger American cities receives for his money. The total track mileage of the entire system, the longest distance which any passenger can ride, on payment of 5 cents or by transfer and general transfer privileges—"Street R'way Journ.," July, 1896.

TRACTION DIAGRAMS.—By Thomas Tomlinson, B. E. The unsatisfactory manner in which diagrams are now prepared is pointed out, and a general discussion on such diagrams from the points of view of their production, interpretation, and utility is commenced in London "Elec. Rev.," July 10, 1896.

ELECTRIC TRACTION.—By R. St. George Moore. Read before the Assoc. of Munic. and County Engs., Brighton, Eng. A review of the application of electric traction and a comparison with other methods.—London "Elec.," July 10, 1896.

ELECTRIC RAILWAY CONSTRUCTION IN GERMANY.—By Louis J. Magee. Artistic poles, various views of streets, a view of conduit construction in Berlin, and a general review of the German railway systems.—"Street R'way Journ.," July, 1896.

STUDIES IN ECONOMIC PRACTICE.—By C. B. Fairchild. Shop methods, tools and labor saving devices of the Chicago City R'way Co.—"Street R'way Journ.," July, 1896.

POWER DISTRIBUTION FOR ELECTRIC RAILROADS.—By Louis Bell, Ph. D. Author states that the following conditions must be met in planning a direct feeding system: (1) The maximum fall in voltage at any point in the system under all working conditions must not exceed a fixed amount. (2) The average drop throughout the system under normal conditions must equal a certain predetermined amount. (3) The feeders must be so connected that accidents to the working conductors shall interfere with traffic to as small an extent as possible.—"Street R'way Journ.," July 1896.

HARTLEPOOL ELECTRIC RAILWAYS.—By Albert H. Bridge. See synopsis of July 15, 1896, and "Elec. World," July 11, 1896.

PRINGLE AND KENT'S SURFACE RAIL ELECTRIC RAILWAY.—A closed conduit or surface sectional rail system, having all supply equipment underground. Details described and illustrated in London "Elec. Rev.," July 3, 1896.

A NOVEL SEASHORE ELECTRIC RAILWAY.—By Magnus Volk. A self-propelling car on a railway submerged in the sea.—"Cassier's Mag.," July, 1896.

Roentgen Rays:

ELECTROSTATIC DEFLECTION OF CATHODE RAYS.—By G. Jaumann. It is shown that electrostatic deflection of cathode rays is as characteristic of them as their magnetic deflection.—London "Elec.," July 10, 1896.

EFFECTS OF A STRONG MAGNETIC FIELD UPON ELECTRIC DISCHARGES IN VACUO.—By A. A. C. Swinton. Paper read before the Royal Society. Magnetic lines of force traveling parallel with the cathode rays develop some peculiar changes in the exhausted tubes.—London "Elec.," July 10, 1896.

NEW DEVELOPMENTS.—By Dr. Leroy. Presented to the Physiol. Soc., at Berlin, June 13, 1896. The results of successful diagnoses made by Profs. Goldstein, DuBois-Reymond, Grunmach, are recorded in "Zeitschr. f. Elektrotech.," July 1, 1896.

Telegraphy, Telephony, etc.:

CABLE WITH SELF-INDUCTION COILS.—By S. P. Thompson. Author's cable system with self-induction coils for the neutralizing of electrostatic capacity is explained in "Elektrotechn. Anzeiger," July 2, 1896.

UNDERGROUND CABLES FOR TELEGRAPHY AND TELEPHONY IN PARIS.—By N. Bean. A thorough treatise on the cables, subways, construction of underground lines, maintenance and repairs. The treatment is entirely from the practcial point of view.—"Ann. Télégraph.," July-August, 1896.

DUPLEX AND DIPLEX ON THE FRANCO-ENGLISH AND FRANCO-BELGIAN LINES.—By H. Toussaint. Description of the methods.—"Ann. Télégraph.," July-August, 1896.

INDUCTANCE AS A NEGATIVE CAPACITY IN SUBMARINE CABLES.—By A. Davidson. A record of experiments made on a length of submarine cable of modern type with steel wire and coiled in an iron tank.—"Elec. Engr.," July 8, 1896.

STORAGE BATTERY FOR FIRE ALARM AND POLICE TELEGRAPH PURPOSES.—By John L. Hall. Illustrated description of an installation just made.—"Elec. World," July 11, 1896.

INTER-IMPERIAL POSTAL AND TELEGRAPH ROUTES. Discussion at the third Congress of the Chambers of Commerce of the empire, held June 11, 1896.—London "Elec. Rev.," July 3, 1896.

INTERNATIONAL TELEGRAPH CONFERENCE, Budapest, 1896. List and addresses of government delegates and representatives of telegraph companies.—London "Elec. Rev.," July 3, 1896.

Transformers:

THE ALTERNATE CURRENT TRANSFORMER.—By J. D. Morse, and J. E. Pfeffer. A dissertation on the theory and construction.—"The Technograph," Univers. of Ills., May, 1896.

PENSON'S VENTILATOR.—A concentric ventilator for transformer boxes is illustrated and described in London "Elec. Rev.," July 10, 1896.

SINGLE-PHASE ALTERNATE CURRENT TRANSFORMER IN PRACTICE.—By A. F. Berry. Paper read before a meeting of student members of Lond. Inst. of Elec. Engrs. Discussion of open circuit losses with special reference to hysteresis effects.—London "Elec. Rev.," July 10, 1896.

Transmission of Power:

ELECTRIC TRANSMISSION OF POWER IN MINES.—By C. Költgen. Illustrations of various applications of electric power in mining. The figures bring out clearly the two chief individualities of electric transmission of power, viz., the possibility of leading the current to any desired point in the mine, and the flexibility of the wire leads to the motors. A short description accompanies the illustration in the Lond. "Engr.," July 3, 1896.

COMBINED ELECTRIC LIGHTING AND TRACTION PLANTS.—By John Hesketh and John H. Rider. Paper read before the Municipal Electrical Association with the object of showing that it is wrong to try to separate lighting from railway plants.—"Electricity," July 8, 1896.

Wiring.

EFFECT OF TEMPERATURE ON INSULATING MATERIAL.—By Chas. F. Scott. See synopsis of July 15, 1896, also "Elec. World," July 11, 1896.

HOPKINSON THREE-WIRE PATENT.—Arguments in favor and against an extension of the English patent.—Lond. "Elec.," July 3, 1896.

LOCALIZATION OF FAULTS IN ELECTRIC LIGHT MAINS.—By F. C. Raphael. From a forthcoming work. Description of Murray's loop method with numerical example.—Lond. "Elec.," July 3, 1896.

REGULATIONS FOR FITTING UP CONSUMERS' PREMISES.—Principally a discussion on the advisability of employing consulting engineers.—London "Elec. Rev.," July 3, 1896.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED JULY 20, 1896.

Alarms and Signals:—

AUTOMATIC FIRE ALARM SYSTEM. A. Speer, Toledo, O., 564,229. Filed May 3, 1895.

Comprises a circuit containing a relay and battery and controlled by a two-point thermostat, a second circuit controlling an alarm, a battery in said second circuit, and means controlled by the second point of the thermostat for throwing the batteries into combined action for sending the fire alarm.

ANNUNCIATOR. J. B. Rogers, Zillah, Washington, 564,314. Filed Oct. 31, 1894.

Adapted for hotel use.

ELECTRIC SIGNAL APPARATUS FOR ELEVATORS. S. C. Stickle, New York, 564,344. Filed Aug. 4, 1894.

Car-calling apparatus.

ELECTRIC MAT. O. H. Hicks, Chicago, Ill., 564,485. Filed Nov. 29, 1895.

The springs afford bridges for connecting the terminals when pressure is exerted upon the mat.

THERMOSTAT. H. F. Maxim, Norfolk, Va., 564,567. Filed Sept. 9, 1895.

Designed to sound an alarm in more than one place.

Batteries:—

CELL. J. Mercer, Rumford Falls, Me., 564,311. Filed Jan. 10, 1896.

A suitable body having an opening through its wall for the feeding of salt, a funnel upon the outside of the body and surrounding said opening, and a hood upon the inside of the body opposite the opening.

Conductors, Conduits, and Insulators:—

CABLE CLIP. R. H. Lewis, Providence, R. I., 564,433. Filed Dec. 30, 1895.

A sheet metal hook adapted to suspend the cable and draw the flanges together by the weight of the cable.

CONDUIT OUTLET BOX FOR ELECTRIC WIRES. C. A. Mezger, Brooklyn, N. Y., 564,527. Filed Jan. 25, 1896.

An outlet box having a series of weakened portions capable of being broken to form openings, the weakened portions serving to regulate the form of the break.

Distribution:—

ELECTRIC ARC LIGHTING. G. R. Lean, Cleveland, O., 11,559 (reissued). Filed Feb. 4, 1896.

Means for operating arc lamps in series on multiple arc circuits of high voltage and constant potential.

Dynamos and Motors:—

ALTERNATING CURRENT DYNAMO. M. Hutin and M. Leblanc, Paris, France, 564,200. Filed May 10, 1894.

Composed of field magnets of constant polarity, an armature of the Gramme or Siemens type having its commutator brushes short circuited, and a number of external circuits, looped from and in series with the armature coil-sections, and each containing a translating device.

ELECTRIC MOTOR. G. J. Scott, Philadelphia, Pa., 564,455. Filed Sept. 19, 1895.

Electroller fan motor.

SPEED REGULATOR FOR ELECTRIC MOTORS. R. Eickemeyer, deceased; R. Eickemeyer, executor, Yonkers, N. Y., 564,558. Filed Oct. 6, 1891.

Comprises the armature of the motor, the armature of an electric generator serving as a governor for the motor, a casing embodying a central frame and affording seats for a shaft common thereto, and provided with cheek pieces detachably secured to frame.

DYNAMO ELECTRIC MACHINE. R. Eickemeyer, deceased, Yonkers, N. Y.; R. Eickemeyer, Jr., executor, 564,559. Filed Oct. 7, 1891.

Two pairs of cheek pieces located on opposite sides of the armature, each pair similarly magnetized, and a counter field coil which strengthens the magnetism in diagonally opposite cheeks to both pairs, and weakens the magnetism in the other diagonally opposite cheeks.

Electro-Metallurgy:—

ELECTRIC METAL WORKING APPARATUS. H. Lemp, Lynn, Mass., 564,331. Filed June 15, 1891.

Comprises a flexible transformer secondary composed of pieces or strips of conducting material and having a single turn or bend, in combination with two work holders opposed to one another and fixed rigidly and directly to each piece of the secondary.

ELECTRIC METAL WORKING APPARATUS. E. E. Ries, Baltimore, Md., 564,453. Filed Nov. 9, 1889.

Comprises clamps for holding the metal to be operated upon and constituting the terminals of an electric heating circuit, and an electrically operated cutting tool mounted adjustably between the clamps.

Miscellaneous:—

ELECTRIC MASSAGE APPARATUS. G. Rossbach, Lichtenfels, Germany, 564,258. Filed Jan. 14, 1896.

Composed of a casing lined with metal and inclosing loosely a ball coated with a metal or other conducting substance.

MEANS FOR GENERATING ELECTRICITY FROM CAR WHEEL AXLES. M. Moskowitz, Newark, N. J., 564,333. Filed Nov. 1, 1895.

Means for securing the dynamo to the framework of the truck and having it operated by a friction wheel on the car axle.

MEANS FOR GENERATING ELECTRICITY FROM CAR WHEEL AXLES. M. Moskowitz, Newark, N. J., 564,335. Filed March 14, 1896.

Similar to above.

TRICK PLATFORM FOR BICYCLE RIDERS. C. M. Peck, New Haven, Conn., 564,392. Filed May 11, 1896.

Comprises a platform, a series of circuit changers arranged therein in position to be operated by the passage of a bicycle wheel over them.

ELECTRIC BLASTING MACHINE. J. Macbeth, Brooklyn, N. Y., 564,437. Filed Oct. 31, 1895.

Consists in a dynamo electric machine mounted in a case, with the axis of its armature arranged vertically, in combination with a propelling screw and a sliding nut for operating the same.

ELECTRIC ELEVATOR. G. T. Francis, Chicago, Ill., 564,480. Filed April 20, 1896.

A main frame, a motor mounted to travel back and forth in said frame and connections between said motor and the car.

ELECTRIC IGNITER FOR GAS ENGINES. Louis M. Bourgeois, Jr., New Orleans, La., 564,182. Filed June 7, 1895.

Embodies a rod sliding in a gland, properly insulated from cylinder of engine, with a pair of bent levers pivoted to sliding rod and a tapered rod fixed to piston, acting in conjunction with bent levers.

MAGNETIC CHUCK. Oakley S. Walker, Worcester, Mass., 564,296. Filed Feb. 13, 1896.

Comprises polar faces and adjustable magnetic strip, the edges of which form a raised surface from the chuck-face to extend the action of the magnetic lines at an angle to the face of the chuck.

Railways and Appliances:—

RAIL BOND FOR ELECTRIC RAILWAYS. F. H. Daniels, Worcester, Mass., 564,243. Filed June 15, 1895.

A cylindrical hole leading in from each end for the drift pin, and a separate tube or bushing open at both ends, and not split longitudinally, to fit over each end of the bond wire, and be secured thereon and in the hole in the rail, by the driving in of a drift pin.

ELECTRICAL TRANSPORTATION SYSTEM. P. K. Stern, St. Louis, Mo., 564,262. Filed Oct. 7, 1895.

A horizontally rotatable armature on the vehicle for propelling the same, and a primary arranged along the route for influencing said armature.

ELECTRIC CAR BRAKE. John C. Henry, Colorado Springs, Colo., 564,195. Filed July 15, 1895.

MEANS FOR GENERATING ELECTRICITY FROM CAR WHEELS. M. Moskowitz, Newark, N. J., 564,334. Filed March 14, 1896.

Employs flexible shafts to drive dynamo, said shafts being connected to the car axle.

MEANS FOR GENERATING ELECTRICITY FROM CAR WHEEL AXLES. M. Moskowitz, Newark, N. J., 564,336. Filed April 23, 1896.

A dynamo on truck frame, a pulley wheel on car wheel axle, a bracket on said frame, a swinging bar on said bracket, a pulley wheel on said shaft and belts.

ELEVATED ELECTRIC RAILWAY. E. W. Farnham, La Grange, Ill., 564,369. Filed Oct. 14, 1892.

The cars run on an elevated single track, which is particularly suited to promote the rapid transit of mail and light baggage.

ELECTRIC CAR TROLLEY. W. H. Russell, Newcastle, Can., 564,395. Filed Oct. 31, 1895.

Details of construction.

RAIL-BOND. T. Wallace, Ansonia, Conn., 564,415. Filed March 20, 1896.

A band of metal having each end brought to the form of a plug or socket, the metal of which is integral with the band and which plug or socket is shaped and properly adapted to be driven into a properly formed orifice in a rail.

Switches, Cut-Outs etc.:—

ELECTRIC SWITCH. J. T. Hunt, New York, 564,283. Filed May 12, 1896.

Details of construction.

OUTLET BOX. C. A. Mezger, Brooklyn, N. Y., 564,443. Filed May 19, 1896.

A series of openings for conduits, and closures comprising members integral with the box, and a separate member held by said integral member.

Telephones:—

TELEPHONE. E. A. Hickley, Owego, N. Y., 564,196. Filed Nov. 11, 1895.

Carbon balls are employed in transmitter.

TELEPHONE EXCHANGE SYSTEM. W. W. Dean, St. Louis, Mo., 564,328. Filed April 10, 1896.

Means for maintaining at constant strength the current in a system employing centralized batteries.

VOICE CONVEYOR FOR TELEPHONES. C. M. Fleury, Brooklyn, N. Y., 564,371. Filed Oct. 17, 1895.

Consists of a mouthpiece of peculiar construction.

OPERATOR'S KEYBOARD APPARATUS AND CIRCUIT THEREFOR. C. E. Scribner, Chicago, and F. R. McBerty, Downer's Grove, Ill., 564,456. Filed Sept. 28, 1893.

Similar to patent below.

OPERATOR'S KEYBOARD APPARATUS AND CIRCUIT THEREFOR. C. E. Scribner, Chicago, Ill., and F. R. McBerty, Downer's Grove, Ill., 564,457. Filed Jan. 10, 1894.

Consists of a centrally pivoted lever carrying a double wedge, push buttons adapted to act upon the different extremities of the lever to move the wedge in opposite directions, and switch springs and levers controlled by the wedge in its different movements.

KEYBOARD APPARATUS FOR TELEPHONE SWITCHBOARDS. C. E. Scribner, Chicago, Ill., 564,458. Filed May 14, 1894.

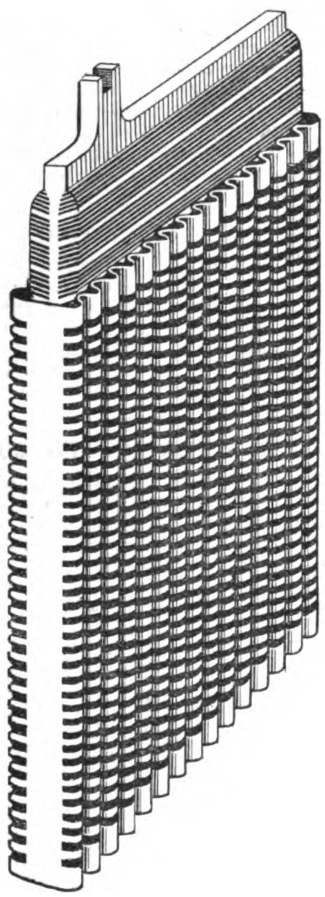
Employs a single key for each operator for signaling to the calling subscriber.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

THE WILLARD STORAGE BATTERY.

THE WILLARD ELECTRIC AND BATTERY COMPANY, of 33 Sheriff street, Cleveland, O., are manufacturing the Willard storage battery, shown in the accompanying engraving. The company claim several points of superiority for their battery, among which the following may be noticed: The plates are made from pure rolled lead in such a manner that there is no waste of material, and after formation they present much larger surfaces than any other plates of the same weight. A



WILLARD STORAGE BATTERY PLATE.

plate 5 x 7 inches presents a surface of fourteen square feet. The manner of protecting the plate with a hard rubber cell, which is corrugated and highly perforated, so as to secure perfect circulation of the electrolyte, makes the battery very durable and long lived. This also enables it to withstand repeated rapid discharges without injury. There is no formation of mud in the Willard battery, and short circuiting or buckling is impossible. Whatever scaling off of formed material there may be, is kept in connection with the central portion and still remains active. These batteries are protected by patents, and, it is claimed, they do not infringe upon any other patents. The batteries are made for all purposes.

THE WATERTOWN ENGINE.

We have received a handsome catalogue from the Watertown Steam Engine Company, of Watertown, N. Y., which deals particularly with direct connected engines which they build for use with dynamos. The details of these direct-connected engines are identical with their well-known regular patterns of engines, with the exception of a long shaft to receive an armature and a special sub-base with an outboard bearing.

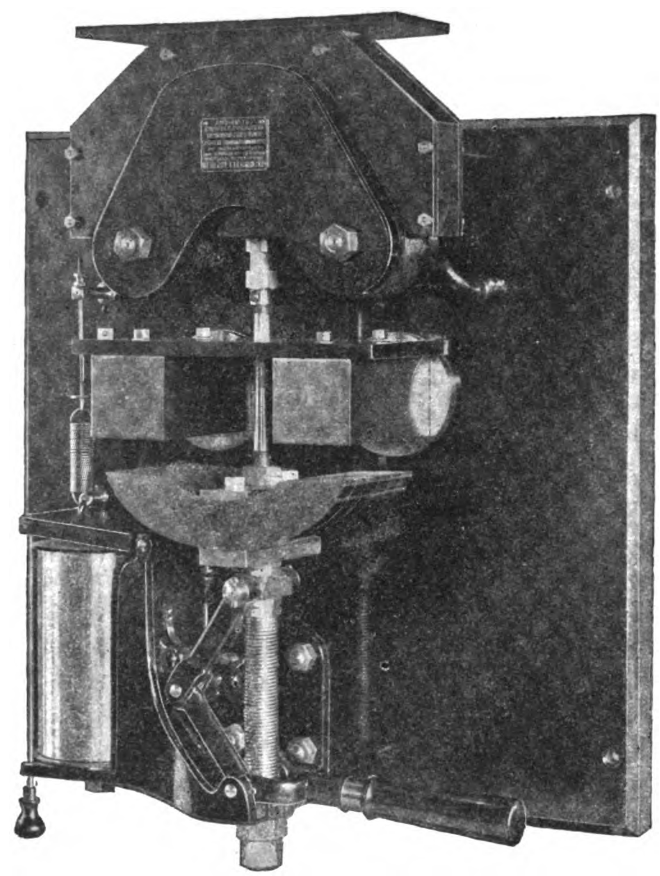
Unless a coupling is preferred the shaft for the armature is made in one forging with the engine shaft. It is cut from one solid forged block and has no weld or seam at any point. To this main shaft two crank discs are attached and their position is adjusted by means of a right and left-handed thread, without the use of soft metal. Both horizontal and vertical direct-connected engines are illustrated in this catalogue.

FISHER & CRAMPHORN SPECIALTIES.

Fisher & Cramphorn, corner of Congress and A streets, Boston, Mass., have published a catalogue of the large line of electrical specialties which they manufacture. Among these may be mentioned station switches of all kinds, fuse blocks and holders, wire terminals and connectors. One of their principal specialties is the Lyon brake handle which is now in use on a large number of surface railroads. Another article to which they call special attention is their electric door lock, of which they have placed large quantities in successful operation. It is of small size and requires comparatively little cutting away of the door. It can be used equally with both right-handed and left-handed doors, which, with these locks, cannot possibly be left unlocked.

AN 8,000 AMPERE CIRCUIT BREAKER.

The largest automatic circuit breaker ever constructed has recently been completed by the General Electric Company. It is designed to break a circuit of 8,000 amperes and is to be used on a 160-volt circuit, although made to handle the current at 600 or 700 volts. This is a form "K" circuit breaker and differs only in size from the well-known "K" instruments used by the General Electric Company on their standard railway generator and feeder panels. The studs which carry the current are 3¼ inches in diameter, the base is 23 inches square. It is constructed to open the circuit automatically at any point between 3,000 and 20,000 amperes, the opening point being arranged by the adjustment of a tension spring on the armature.



THE 8,000 AMPERE CIRCUIT BREAKER.

ELECTRICAL MICA AND MICANITE.

Eugene Munsell & Co., of New York, the well-known miners, importers and dealers in mica for electrical purposes, have issued a standard price list of their goods which include sheet mica cut to any shape or size, micanite products of all descriptions, and oiled paper, cloth and linen, all of which find extensive application for the purposes of insulation. The company will be pleased to quote prices on request to all persons requiring superior insulating materials of this nature.

THE JEWELL BELTING COMPANY have furnished the entire belt equipment for the Norwich, Conn., electric light station, just inaugurated.

ICE MAKING AND REFRIGERATION.

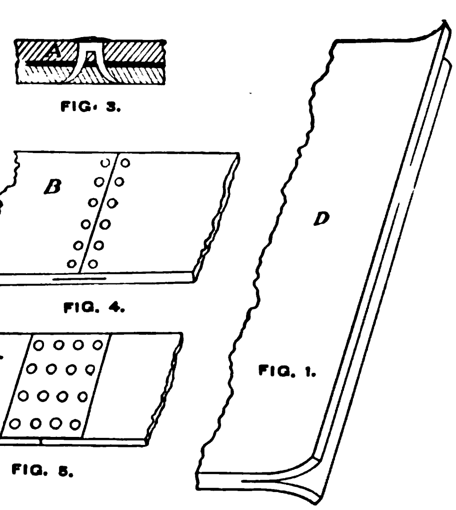
WESTINGHOUSE, CHURCH, KERR & CO., engineers, of 26 Cortlandt street, New York, have issued two handsomely illustrated and very instructive catalogues on the subjects of ice-making machinery and cold air refrigeration. The production of artificial cold and its utilization in an increasing variety of industries has received the attention of the best mechanical ability for the past twenty years. Various experimental stages involving the use of air, ether, sulphur-dioxide, etc., have ended in the universal adoption throughout this country and Europe of liquefied anhydrous ammonia as the refrigerating medium. In the use of ammonia two distinct systems have been exploited, known respectively as the compression and the absorption systems. The greatly preponderating majority of plants are constructed upon the compression system, the advantages of which, briefly stated, are a much higher efficiency in the use of coal and water per unit of work done; greater reliability of action, and a simple form of apparatus easily within the comprehension of the owner.

The two essential parts of an ice-making plant are a compressor and a condenser, both of which are fully described and illustrated in one of these pamphlets. The other one refers to the freezing room where the ice is manufactured and describes a number of methods of producing blocks of artificial ice, as well as pointing out the merits and drawbacks of each system. This company has perfected its systems during its long experience in this class of machinery, and will be pleased to extend full information and estimates to interested parties.

Electric light stations would do well to look into the subject as an additional source of revenue during light load hours.

THE NELLIS BELT FASTENER.

A new belt fastener is now being put on the market making the belt practically endless; it is designed to take the place of cemented joints, but at the same time keep the belt flexible and strong. The accompanying illustration explains this simple and efficient device. With the aid of a hand leather-splitting tool both ends of the belt are slightly split in half, as shown in the illustration, D. In this slit is inserted a specially cured material, stronger than the belt itself, and which at the same time does not increase the thickness of the belt to any appreciable extent. At A is shown a sectional cut of the belt and strip through which is inserted the rivet, A. The fastening as finished is shown at B. When a belt is too thin to split it is joined, as shown at C.



THE NELLIS BELT FASTENER.

The above mentioned belt fastener is manufactured by the Nellis Belt Fastener Company, 284 Pearl street, New York. This firm has also the sale of the Morse electric pulley covering which forms a permanent, continuous, endless and extremely adhesive surface to wood and iron pulleys and admits running machinery without the use of idlers and tighteners.

G. E. AND WESTINGHOUSE PROFITS.

It has been stated unofficially that both the General Electric and the Westinghouse companies are doing better both gross and net than they have done since early in 1893. "The Wall Street Journal" states that the General Electric Company increased its net earnings in June $204,000 over the net of June last year. A prominent operator said: "I believe General Electric to be the cheapest stock on the list, but its net earnings will fall as flat as do the big earnings of St. Paul and Northern Pacific. Important matters like these in ordinary times are now, under the political strain, like a glass of water thrown in the desert."

MR. J. P. MORGAN'S OPINION OF THE BELL CO.

Mr. J. P. Morgan is said to have declined a Bell Telephone directorship, remarking that he bought the stock as an investment, and considered this the best managed corporation in the country.

IRON CLAD FAN MOTOR RHEOSTAT.

In these days of variable temperature and humidity one frequently finds it desirable to change the speed of the refreshing fan, but the changes usually provided by the motor switch rarely give a range of variability commensurate with the changing conditions of the atmosphere. To meet this want the Iron Clad Rheostat Company, of Westfield, N. J., have designed a small 9-point rheostat that occupies no greater space than an ordinary book. One of these baby rheostats which the company has kindly placed at our disposal has helped greatly to mitigate the discomforts of the past few weeks.

ROYAL ALTERNATORS.

The Royal Electric Company, of Peoria, Ill., manufacturers of the well-known Royal alternators, have issued a pamphlet devoted exclusively to testimonial letters for the consideration of all interested in the operation of electrical machinery. We note these machines are in use in all sections of the country and are highly spoken of by numerous electric light station managers and others who have had them in operation.

BROWN & SHARPE MFG. CO.

A handsomely illustrated souvenir catalogue has been issued by the Brown & Sharpe Manufacturing Company, of Providence, R. I., giving a large number of views of their factory and also an illustration of the company's exhibit at the World's Fair, Chicago. The catalogue indicates the nature and extent of the facilities which this company have for the manufacture of machine tools of every description.

PENBERTHY INJECTOR CO.'S 100,000 CELEBRATION.

On Saturday, July 25, 1896, the Penberthy Injector Company, of Detroit, Mich., celebrated the event of the manufacture and sale of 100,000 Penberthy injectors during a period of ten years. Their first injector marked No. 1, was turned out June 5, 1886, and on May 12, 1896, No. 100,000 was manufactured.

The company tendered a holiday and an excursion to their employés, to which a large number of their customers and friends were also invited. A steamer carried the party to Beauvoir, St. Clair River, where refreshments were served, after which music, dancing and games were on the order of exercises. The party returned home after passing a most enjoyable day.

WHITE-CROSBY CO.'S WORK.

THIS enterprising concern report an unusually large amount of work this summer, all of which has been contracted for since February last. Their work on hand comprises about ten miles of track and overhead work for the Norwalk Tramway Company, five of which are completed and in operation; also six miles of complete line for the Rahway and Sewaren Electric Railway, which is about completed, and five miles of overhead work including fifteen miles of feeders for the Bergen County Traction Company. This line is completed and in operation.

Their work in Baltimore includes the following plants: A contract with the Baltimore City Passenger Railway Company for special and overhead work connecting one of their cable tracks with an electric line; five miles of overhead for the Baltimore Traction Company, on their new Westport line; five miles of extra feed wire for the Baltimore Traction Company, to give them sufficient power for their baseball business; equipping the Druid Hill avenue cable line of the Baltimore Traction Company, for electric service; two thousand feet of subway for the Baltimore and Ohio Railroad Company, to enable them to light their new Mount Royal station from their present power house, which operates the Belt Line tunnel electrically; equipping the overhead extension of the Gwynn-Oak line of the Baltimore Traction Company, and building and equipping the smallest electric railway in the country, which connects with the Walbrook extension of the Baltimore

Traction Company. This road is only about three thousand feet long, and is complete within itself.

The White-Crosby Company are the electrical engineers for the Helena and Livingston Smelting and Reduction Company's new plant. This is a power transmission plant, including two 225 kilowatt, and five 150 kilowatt Crocker-Wheeler 500 volt machines, the distance of transmission being 1½ miles.

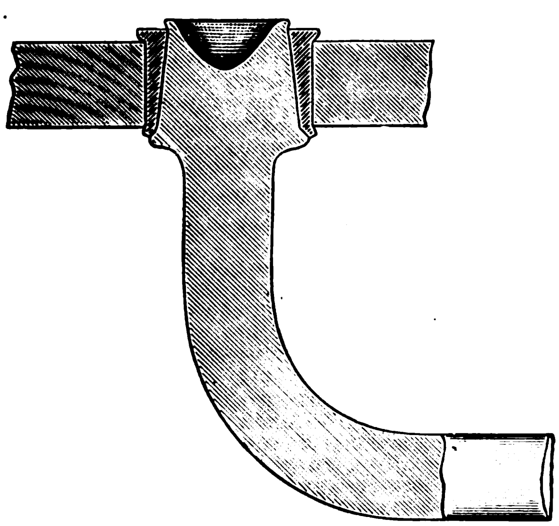
They are also electrical engineers for the Helena Water and Electric Power Company, which is installing Westinghouse alternating apparatus, to transmit power to East Helena and Helena, twelve and seventeen miles, respectively. The station is planned for eight 650 kilowatt generators, four of which are now being installed, step-up transformers, step-down transformers, and the necessary station apparatus. The voltage will be about 10,000 on the transmission line, distributing through Helena and East Helena at required voltages.

They have also completed about five miles of the Atlantic Highlands, Red Bank and Long Branch Electric Railway, and will finish the line by fall.

THE COLUMBIA RAIL BOND.

The Columbia rail bond, manufactured by the John A. Roebling's Sons Company, Trenton, N. J., and which is shown in the accompanying engraving, is composed of three parts, two copper thimbles and the connecting copper rod. On each end of the copper rod is a truncated cone head with a fillet at the base. The inside of the fillet is tapered to fit the head on the bond while its outside is slightly tapered in the opposite way.

In applying the bond, the cone-shaped heads are placed in the holes in the rail from one side and the thimbles are slipped over them from the other. A portable hand-press is then applied, and the wedge-shaped head of the bond is forced into the thimble so that it is not possible to see the line separating



THE COLUMBIA RAIL BOND.

the thimble and the head in a cross-section of the two. The end of the head of the bond is expanded by a center-punch, held in position in the press.

When installed, owing to the pressure exerted between the head and thimble, and also to the fact that they are of the same kind of metal, the two become one, both electrically and mechanically. It therefore has all the advantages which may be claimed for a one-piece bond, and at the same time can be satisfactorily installed, as no riveted bond can be. The contact with the rail is seven times the section of the wire, providing ample contact to compensate for the poorer conductivity of the steel in the rail.

THE BERNSTEIN ELECTRIC CO.

Mr. James Bradley has been appointed treasurer of the Bernstein Electric Company, of Boston, in place of Mr. Henry B. Cram, resigned. The Bernstein Company have recently moved their offices to their new factory, at 355 Congress street, and will hereafter have no office at 620 Atlantic avenue. Mr. Bradley has for years been manager of the Bernstein factory, and has a large and valuable experience in the manufacture of incandescent lamps, both for series and constant potential circuits, and with his intimate knowledge of the wants of the electrical trade will undoubtedly be able to maintain the success which the Bernstein Company has already achieved for the excellent quality of its goods.

THE ELECTRIC STORAGE BATTERY CO.

The adoption of the storage battery in central station practice in this country seems to be an assured fact. Within the past few weeks the Electric Storage Battery Company has contracted to install batteries of chloride accumulators in the stations of the Boston Edison Company (their third plant), the New York Edison Company (their second plant), the Brooklyn Edison Company, the Easton (Pa.), Edison Company, the Hartford Electric Light Company (the largest battery in the world), the Claremont (N. H.), Electric Light Company, the Woonsocket (R. I.), Electric Machine and Power Company, etc.

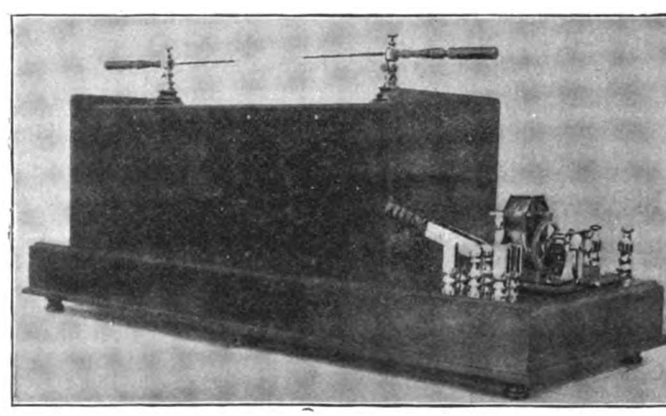
The company has also recently closed contracts with the government for batteries for the New York Custom House, West Point Military Academy, Ford's Theater, Washington, D. C., which is a government building, and the Brooklyn Navy Yard.

Installations of chloride accumulators are now being put down in the Germantown (Pa.), Hospital, College of Physicians and Surgeons, New York, for lighting the Sloane Maternity Hospital, St. Paul's M. E. Church, New York, and in the residences of Mr. Henry Villard and Mr. J. J. McComb, at Dobbs' Ferry, N. Y.

EDWARDS & CO.'S 12-INCH RUHMKORFF COIL.

Messrs. Edwards & Co., of New York, are building a 12-inch Ruhmkorff, for which they claim several points of superiority.

The coil is divided into sections by rubber discs and double covered silk wire is used on the secondary as an extra precaution. The motor interrupter is constructed so that it



THE EDWARDS & CO.'S 12-INCH SPARK RUHMKORPF COIL.

may be operated by hand. Its heavy platinum contact points are arranged with screw cups so that they can be readily renewed. All fittings are made of solid bronze.

The coil is mounted in a heavy hard-rubber case on a polished mahogany base. Its size over all is: Length, 3 feet 4 inches; width, 15½ inches; height, 20 inches, and it weighs about 175 pounds.

THE CENTRAL ELECTRIC CO.

The Central Electric Company, of Chicago, who are doing a large business in Lundell fan motors, are distributing a handsomely engraved card to draw attention to the utility of these machines. The cut represents a lady in classic costume enjoying the breeze from a Lundell fan motor, which she is crowning with a wreath of laurel. The machine is mounted on an ornamental pedestal. One corner of the card also draws attention to the fact that "Okonite never disappoints."

ELECTRIC POWER IN TIFFANY'S FACTORY.

The new factory which Tiffany & Co. are completing at Forest Hills, N. J., will be operated entirely by electricity, not a steam-driven machine being employed beyond the limits of the power house. The present factory and force at 53 Prince street, New York, will be moved out as soon as the electrical apparatus is installed.

The electrical plant will consist of two 125 horse-power, 250 volt General Electric dynamos, which will furnish current to more than twenty motors, scattered through the building. This will be 300 feet long in front and will have three wings each 100 feet long extending back of the main building. Of these motors some may be attached directly to the machines, and some will drive a number of machines by belts from a shaft.

The electrical system of power distribution in the Tiffany factory has been adopted as more economical and desirable than any other known method, and only after careful calculation and comparison with the results obtainable from a distribution of power to shafting by belts from steam engines.

NEW YORK NOTES.

THE E. W. BLISS COMPANY, Brooklyn, N. Y., have recently shipped several of their automatic notching presses for armature disks to France. They do an extensive export business.

MR. T. T. GROVER, who for a long time was associated with the Electrical Construction and Supply Company and R. B. Corey, has accepted a position as selling agent in the lamp department of the Diehl Manufacturing Company.

THE BABCOCK & WILCOX COMPANY publish a card in another column to the effect that no change has been made in the location of any of their offices, and that no outside concern is authorized to build or contract for their boilers.

THE street cars in the City of Mexico are being changed from horse to electric cars. The Sterling Supply and Manufacturing Company, 97 Bank street, New York, are supplying the fare registers for the same. This firm manufactures also brakes, sand boxes, and fenders.

EDWARD J. M'EVOY, 157 Cedar street, New York, since he has been in business, has been furnishing Messrs. Cramps Sons, the shipbuilders, with all their china insulation. The branch cut-outs on the steamers St. Louis, St. Paul, New York and many other ships are of his make.

MR. J. E. SAYLES, late General Agent of the New York Edison Electric Illuminating Company, will henceforth represent the American Electric Heating Corporation in New York. Mr. Sayles has opened an office at 26 and 28 Cortlandt street, and has begun an active campaign in pushing his company's apparatus to the front.

JOHN G. KLUMPP & SONS, 13 Baxter street, New York, are running busy with a force of 20 men on large orders for round switch bases and desk telephone bases. This firm manufactures turned wood work, boxes, etc., for the electrical trade and with improved machinery has special facilities for filling orders at short notice.

THE E. G. BERNARD COMPANY, of Troy, N. Y., have closed a contract for a 10,000 light plant for the House of Refuge, Hudson, N. Y. Work will be commenced at once, and it goes without saying that Bernard dynamos will be used, and Mr. Bernard is now in the market for engines, boilers, lamps and other supplies.

THE VARLEY DUPLEX MAGNET COMPANY, 46 East Houston street, are finding a steady demand for their duplex magnets, which they wind for all purposes. With the peculiar method of winding which they control they are able to produce a magnet of equal power at lower prices than was heretofore possible. They have also a shop thoroughly equipped for experimental work for manufacturers.

MR. C. S. HAMMER, of the Middletown Light and Power Company, reports placing contracts for sixty arcs and 200 32-candle-power incandescent street lamps. He is superintending this installation and in connection therewith is remodelling the whole plant for the town, putting in a 250 horse-power Armington & Sims cross compound engine, a 300 light Stanley alternator and a 125 light Brush machine.

M. R. RODRIGUES, 19 Whipple street, Brooklyn, is handling considerable business despite the general stagnation now prevalent. Mr. Rodrigues is finding quite a demand for his small motors, which have been found to be very successful for the purposes to which they are adapted. Mr. Rodrigues is frequently called upon by other manufacturers to turn out apparatus for them, which, with his thoroughly equipped shop, he is perfectly qualified to do.

BAECHTOLD & PARKER ELECTRIC COMPANY, 79 Washington street, Brooklyn, have been quite successful with their new style of armature, which they have furnished to a number of central stations throughout the country. By the peculiar method adapted in manufacturing this armature the machines in which they are placed have a greater output with the same number of revolutions. This company is also finding quite a little business for the arc lamps which they make.

LINDNER & REMIG MANUFACTURING COMPANY, 329 West Twelfth street, New York, chandelier manufacturers, are making special flower designs in combination electric gas fixtures which they have placed in many churches and public buildings. Their work at the Fort George Casino, 196th street and Amsterdam avenue, New York City, is admired by the thousands who visit this well-known resort. The building has a 100 light and six 50 light chandeliers of this company's make, as well as a few hundred of their electric and gas fixtures.

THE DEWITT BROWN CEDAR COMPANY, Menominee, Mich., have issued a very comprehensive price list to the electrical trade. This list is devoted exclusively to the needs of electric light, telephone, telegraph and street railway companies, and prospective purchasers of poles will find it very useful to have one by them for reference, as it gives the dimensions, weights, and prices of the standard sizes. This young and progressive concern has closed quite a number of good contracts lately, amongst them being those with the Bell Telephone Company, of Missouri; Winona Telephone Company, Winona, Minn.; Bishop Telephone Company, of Central City, Ia.; Beaver Valley Traction Company, Beaver Falls, Pa., and others.

THE J. H. M'EWEN MANUFACTURING COMPANY, Church and Cortland streets, New York City, report the following sales of Thompson-Ryan dynamos and their engines, for the month of June: One 60 kilowatt belted and one 100 kilowatt direct-connected dynamo, with a 16 x 16 in. McEwen engine, to the Jeffrey Manufacturing Company, Columbus, O.; one 50 kilowatt and one 100 kilowatt dynamo, direct connected to 12 x 12 in. and 15 x 16 in. McEwen engines, to Bissell, Dodge & Erner Company, Toledo, O.; 100 kilowatt and 150 kilowatt belted machines to the Link Belt Machinery Company, Chicago; a 30 kilowatt belted machine to the Jeffrey Manufacturing Company, Columbus, O.; a 25 kilowatt belted machine to the New York Safety Insulated Wire Company; one 200 kilowatt and one 400 kilowatt dynamo direct connected to a McEwen tandem compound engine, to the Tacony and Frankford Electric Railway Company, Tacony, Pa. The latter order is the second one placed by this company, who have been using two of the 200 kilowatt direct connected units.

The other engine sales for the same month were as follows: One 9 x 10 in., to M. W. Johnston & Co., Chicago; one 6 x 10 in., to the Elk Tanning Company, Philadelphia; one 13 x 14 in., and one 8 x 10 in., to the Jeffrey Manufacturing Company, Columbus, O., and one 13 x 14 in., to the Scranton Electric Construction Company, Scranton, Pa.

PHILADELPHIA NOTES.

MR. R. H. ENGLE, inventor of a novel illuminating sign for street cars, is preparing signs for cars on the Arch street line.

THE many friends of Mr. D. C. Spruance will be pained to learn of his severe attack of nervous prostration while stopping at The Senate, Atlantic City, N. J.

MR. CHAS. PARKER BREESE, formerly of Breese & Mansfield, has opened offices as consulting engineer at 57 to 59 Manhattan Life building, Fourth and Walnut streets.

THE firm of Sheble & Pallor has been dissolved by mutual consent and will be continued by Mr. Franklin Sheble, as electrical engineer and contractor at the old quarters, 1028 Filbert street.

MR. F. MANSFIELD, of 1120 Betz building, who has for some time acted as Philadelphia representative of the Walker Company, of Cleveland, has admitted as a partner Mr. Wm. G. Bain, formerly of Boston. The firm will be known as Mansfield & Bain, electric railway engineers, and will continue to act as agents for the Walker Company.

THE PARTRICK & CARTER COMPANY'S employés' annual outing was held at Wenonah, N. J., a large number of those participating making the run on their bicycles under the leadership of Capt. Tom Townsend. After a lively game of base ball lunch was served and with the cigars and coffee came speeches. Mr. Charles M. Wilkins, a member of the firm, praised the faithfulness of the employés, and was replied to by Capt. Townsend, who presented Mr. Wilkins with two photograph groups of employés. The affair will be long and pleasantly remembered by those who participated in it.

NEW ENGLAND NOTES.

MR. H. W. HOBBS has opened an office at 57 North Main street, Fall River, Mass., for the sale of Westinghouse dynamos, motors, etc., and Westinghouse engines, together with general supplies. Mr. Hawks will also act as agent for the Hawks Electric Company, with which company he was for four years, in the capacity of superintendent.

THAYER & CO. were incorporated this month to place on the market the Caball vertical and Babcock & Wilcox horizontal safety water tube steam boilers, built by the Aultman & Taylor Machinery Company. The company have offices in the Tremont building, Boston; Drexel building, Philadelphia, and in the Taylor building, 39 Cortlandt street, New York.

MR. AUGUST BECKER, of Boston, is enjoying a well-earned success in the manufacture of name plates for dynamos, motors, engines, machines, and for all mechanical goods where name plates can be used. Mr. Becker has been identified with this class of business for many years and exercises great artistic taste in the design of his plates, having also been an expert designer and engraver for many years. Companies desiring first-class goods at moderate cost would do well to consult Mr. Becker.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

Vol. XXII. AUGUST 12, 1896. No. 432.

Electric Lighting.

ON THE PROPER USE OF SAFETY FUSES AND MAGNETIC CIRCUIT BREAKERS.

Wm. Baxter Jr.

In the days when electricity was truly in its infancy, one of the first facts discovered by those who were engaged in the actual operation of dynamos was, that some means must be provided for opening the circuit whenever the current strength rose beyond a certain limit. Two methods suggested themselves for accomplishing this result: The blow-out fuse, and the magnetic cut-out.

The fuse became the most popular, owing principally to its cheapness and extreme simplicity. Notwithstanding all the good things that may be said of the fuse for past services, it is a crude device, and should only be used in what may be termed its own sphere of usefulness. This sphere is for the protection of branch circuits.

In a lighting plant all the branches may be protected by fuses, but in the main circuit they are of little, if any, value, owing to the fact that their carrying capacity must be considerably above the normal current to avoid blowing out with such frequency as to be annoying. In branch circuits, if a fuse is used that will give way with a current of double the normal capacity, it will afford all the protection necessary, providing the wiring is of such proportions as to keep the line loss within reasonable limits. But if a fuse of similar proportions were used to protect a generator, it would be of no value. If the load on a generator is very uniform, a fuse may be used that is nearer to the normal current than two to one; but even under the most favorable conditions, if the margin is made less than fifty per cent., the frequency with which the fuse will blow out will be greater than would be admissible in most cases. Considering the foregoing facts, it is evident that a fuse placed in the main circuit of a generator will afford very little protection.

A question that has been agitating the minds of quite a number of central station managers of late, and one which is worthy of very careful consideration, is, whether it is advisable to use station safety cut-outs of any kind? Those who advocate discarding them claim that the occasional discontinuance of the current, when these devices act, causes dissatisfaction among the customers, and that it is better to suffer the loss caused by a burnt out armature now and then to loss of prestige in consequence of unsatisfactory service. There is a great deal of truth in this, and no doubt the desire to guard against loss occasioned by burn-outs due to excessive current, is a relic of the days when economy of operation was considered of more importance than efficient service.

The use of safety devices may be entirely discarded in central stations without incurring the danger of burn-outs, if the capacity of engines and generators is in proper proportion. In cases where a number of machines are operated by a single engine, each one supplying an independent circuit, safety devices may be used, and the conditions may be made such that the cut-outs will very seldom come into action. To illustrate the truth of these statements, take the case of an engine driving a number of generators in parallel. All the safeguard necessary may be obtained by making the power of the engine less than the combined capacity of the generators, and providing each of the latter with an effective device for maintaining a constant electromotive force.

The common practice has generally been to have the engines of ample capacity to do the work; this, when properly interpreted, means that they should be of sufficient power to drive the generators at their maximum output, and still have a margin left for an emergency. But it is these emergencies that are fatal to the generator, and to provide the engine with a reserve capacity to meet them amounts to providing means for burning out armatures whenever the circuit becomes overloaded. If the steam engine is overloaded, it will suffer no injury, the most that can happen will be that the speed will reduce, and if the overload is sufficient, the engine may be brought to a standstill. The generator is quite different, however, and, like the faithful horse, will work until it drops dead.

It may be said that even if the combined capacity of the generators is greater than that of the engine, there will still be danger of a burn-out, because the current in any one machine may rise above the average. This would be true, providing no provision were made to prevent such contingencies. Generally, generators coupled in parallel are connected by an equalizing wire, which, while not able to maintain a perfect uniformity, tends to keep the difference in current so low as to be within the safe limit. Still greater certainty could be obtained by providing each generator with an automatic switch, that would vary the resistance in the shunt circuit in accordance with variations in the strength of current passing through the armature.

If the generators are not connected in parallel, but are used to supply independent circuits, there will be little or no danger of burn-outs, if the capacity of the machines is greater than the demands of the circuits they supply; and this danger can be made still less by using cut-outs set to act at a point just below the safe limit.

Where each generator is driven by an independent engine, all danger of burn-outs from excessive current can be removed by this simple expedient of increasing the capacity of the generator. If you consult an engine builder, he will say that to drive a 100 kilowatt generator, an engine of at least 175 horse-power should be used, and that 200 horse-power would be better. This advice he gives, because from his experience he believes that the generator will be forced beyond 100 kilowatts so far as to prevent good regulation with a smaller engine. Now if you install a 100 kilowatt generator with a 200 horse-power engine, and then begin to overload the current, the generator will surely get into trouble before the engine begins to feel the strain. If you consult the generator manufacturer as to the size of engine, he will probably say that 150 horse-power is ample, but even this is too much, if perfect safety is desired.

To guard effectually against burn-outs, the proper plan to pursue is to ascertain the demand of the circuit, either actual or estimated, then provide engine capacity sufficient to meet this, making a fair allowance for loss in the generator, and a margin for abnormal demands. Then provide a generator that when working within the limit guaranteed by the makers will absorb the maximum power of the engine.

From the foregoing it will be seen that cut-outs and blow-out fuses in the main circuits of central stations and isolated plants are not necessary, and that all the protection they can possibly afford, can be obtained by simply enlarging the capacity of the generators.

The only proper place for blow-out fuses is in branch circuits, and then they are necessary to prevent overheating the wires in case the current should become abnormally large from any cause.

Fuses are very generally used to protect motors, but for that purpose they are of very little value. A magnetic cut-out is the only proper safeguard for a motor, and to be of real value, it should operate either with an excessive current or no current at all. It is not an uncommon thing for the current through a motor to be interrupted, and in such cases, if the switch is not opened, serious damage may be done when the current is established again. If the cut-out works both ways, mishaps in most cases will be avoided, because as soon as the current stops, the circuit will be opened.

There are cut-out switches of this kind on the market and, judging from their general appearance, they should be effect-

ive, but few of them are in actual use. The fuse is the mainstay and also the source of no small amount of annoyance, owing to the fact that it can be easily blown in the act of starting the motor if the attendant is inexperienced. Whenever they blow out, there is more or less delay in inserting a new one, and also an expense which, although small, runs up to an appreciable amount by the end of the year. Owing to this annoyance and expense, the size of fuse is increased in many cases to a point where it is simply no protection whatever, as it can carry more current than the motor. If cut-outs were used, they would be set to act nearer to the working capacity than is the case with fuses, because if they should act, they could be reset in a few seconds by the simple movement of a lever.

THE BUFFALO AND NIAGARA FALLS ELECTRIC LIGHT AND POWER CO.

BY ORRIN E. DUNLAP.

THE Buffalo and Niagara Falls Electric Light & Power Company have been making large expenditures lately to bring their station to the modern point of efficiency, and the results of their effort show that they are succeeding admirably. The names of the principal cities of Erie and Niagara counties have been included in the company's name because their franchise allows them to operate in both these counties and for the further reason that both Buffalo and Niagara capital is invested in the plant. This company probably has the greatest amount of electric energy at its command of any similar concern in the world. This is so because they are the distribut-

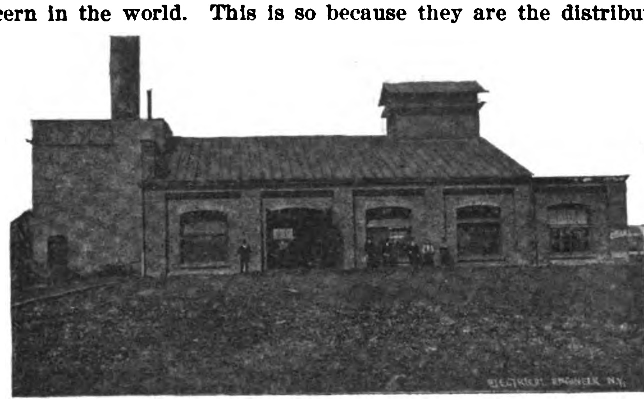


FIG. 1.—THE BUFFALO & NIAGARA FALLS ELECTRIC LIGHT & POWER CO.'S STATION.

ing agents in and about Niagara Falls, beyond the limits of the lands of the Niagara Falls Power Company, for the electricity generated in the mammoth plant of the last named company. This is becoming an important feature of their business, and the fact that their station is located on Buffalo avenue almost opposite the Niagara Falls Power Company's power house gives them an important advantage in operating their plant.

The officers of the Buffalo and Niagara Falls Electric Light & Power Company are: George Urban, Jr., of Buffalo, president; Hon. Walter P. Horne, Niagara Falls, vice-president; Edward Michael, Buffalo, secretary; Henry Koons, Buffalo, treasurer. The superintendent and manager is Mr. J. P. Chapin. This company became the successor of the Brush Electric Light & Power Company in the fall of 1893. Their plant was then located on the canal basin of the Niagara Falls Hydraulic Power & Manufacturing Company. In the summer of 1894 the present fine station, shown in Fig. 1, was built. It is of brick, 95 feet long and 62 feet wide at the foundation. It is divided into a dynamo room, boiler house, oil room, machine shop and offices, the dynamo room being 60x60 feet in size. Two stacks 30 feet high rise from the boiler house. The steam plant of this station consists of one 350 horse-power Corliss engine, 24x48-inch; one 12x12-inch John T. Noyes 100 horse-power engine and two boilers of 175 horse-power each.

The dynamo room is an interesting place for the visitor. It contains two 300 horse-power motors made by the Westinghouse Company, embodying the latest development in electric motors. Fig. 2 gives an excellent idea of one of the motors which are of the self-starting induction type designed to operate at a speed of 500 revolutions per minute when supplied with current of 3,000 alternations per minute and 2,000 volts pressure.

The revolving or primary element in the machines, is shown in Fig. 3. The core is 36 inches in diameter and 14 inches long inside the end plates. It is built of laminated steel; each disc is punched with 120 slots around its periphery and these

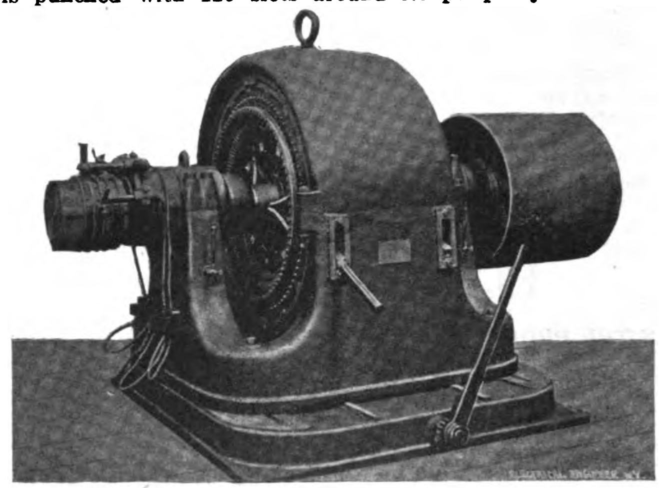

FIG. 2.—SELF-STARTING INDUCTION MOTOR.

discs, when superimposed one upon another, form longitudinal grooves into which the conductors are placed. As will be seen by the illustration the core contains five ventilating ducts, three-eighths of an inch wide. The conductors consist of machine wound coils, separately insulated with fuller-board and mica. The winding is tapped at suitable points and the leads pass through the shaft to the rings, which receive the current from the brushes.

In Fig. 4 is shown the stationary or secondary member which is also built up of slotted steel discs. Each slot contains one rectangular copper conductor, and all the conductors are secured to an iron ring on each side of the machine, as shown. Outside the iron rings are two copper rings, each carrying 82 small copper brushes, one for each conductor. The copper rings are rotated so as to either connect or disconnect the brushes and the conductors, as will be explained further on.

The machine is started as follows: The copper brushes mentioned above being disconnected from the conductors in the secondary, the switch through which current is supplied to the collector rings is closed and the motor starts. As soon as a fair speed is attained, one side of the secondary is short circuited through the copper ring by connecting the copper brushes with the secondary conductors. This is accomplished by means of a ratchet movement and the handle shown issuing from the side of the machine in Fig. 2. Then the other

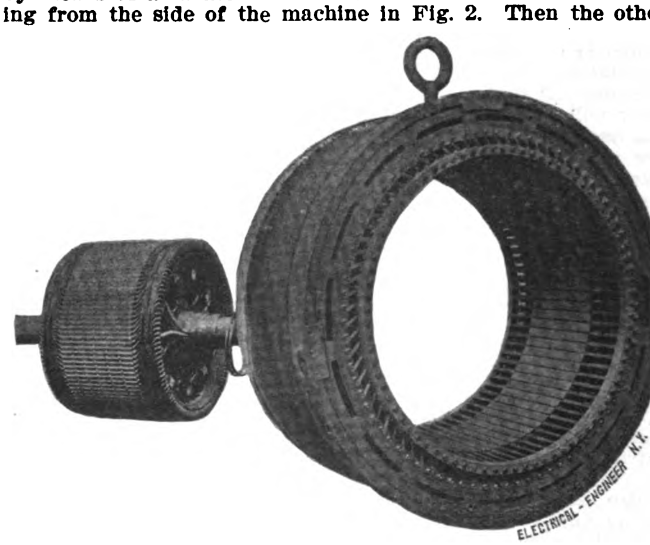

FIG. 3. FIG. 4.

side of the secondary is short circuited in the same manner. The object of the short circuiting device is to limit the flow of current when starting. The iron ring, being of comparatively high resistance, prevents the induction of very large currents in the secondary, which, when the primary is at rest, acts precisely as the secondary of a transformer and therefore if the secondary conductors were short circuited by

the copper rings when the switch was thrown in the primary current would be excessive.

Still another novel feature of this station is that the company buy as well as sell current, their purchases including both alternating and direct current. The current used to operate the Westinghouse motors is of the two-phase alternating type and reaches the station over four cables, each about one inch in diameter, laid in a tile conduit about eight feet underground. As it extends along Buffalo avenue the conduit is composed of eight 3-inch hole tile, to provide for other cables as the future may demand, but on the company's land the conduit is formed of one 8-inch tile in which the cables are laid. The switchboard has Shallenberger recording wattmeters and is in direct connection with the power house of the Niagara Falls Power Company. It controls the current supplied to the 300 horse-power motors.

Besides the current used for operating these motors the company buy power from the Niagara Falls Power Company, which they distribute to planing mills, machine shops, hotels, stores and small factories for running motors. This current passes through the rotary converters in the Niagara Falls Power Company's power house and is taken from the street railway feeders.

The dynamo room of this plant has undergone quite a few changes of late through the installation of the Westinghouse motors and the discarding of old light machines to make room for four new 100 light Brush 5,000 volt machines.

In addition to the motors and light machines mentioned, the dynamo room contains a 4,000 light Westinghouse alternator, the engines mentioned, a 60-light Brush machine and a switchboard connecting the city circuits. Two incandescent and four arc circuits are operated, the field of distribution at present including all the territory within the limits of the city of Niagara Falls.

In all that the Buffalo and Niagara Falls Electric Light & Power Company do they seek to build well and to establish their plant on lines which will be fully equal to the ever-growing demands of the Electric City of the World.

FIRE HYDRANTS AND MUNICIPAL OWNERSHIP.

BY W. S. MONROE

I have been much interested in the various papers which you have published recently descriptive of electric light plants and central stations, and upon the relative advantages of municipal or private ownership of electric light plants. I am of the opinion, however, that it is well nigh impossible to summarize the results of many plants, because the conditions vary so widely in different ones, and lists can easily be made to substantiate either side of the argument. Each plant should be considered separately, giving due value to all the different conditions, although this of course is a lengthy process.

In your issue of July 29 I noticed the report of Mr. W. W. Bean to the citizens of St. Joseph, Mich., in regard to the South Haven plant. If I do not misunderstand his figures, he makes the total cost of operation, including interest and depreciation of the waterworks and electric light plant, amount to $7,125 for one year's operation of the waterworks, and six months operation of the electric light plant. He then gives a statement showing that the seven arc lights cost the city $16 per month, and 80 incandescent lights $3.46 per month. His statement is as follows:—

Waterworks and electric light receipts	$3,450.00
Sixty-seven hydrants at $20 each	1,340.00
Seven arc lights, 1,200 candle power, at $16 per month	672.00
Eighty 32 candle power incandescent lights, six months, at $3.46 per month	1,663.00
	$7,125.00

I cannot see but that in consideration of the figures which he takes for the cost of operation he should charge the 67 fire hydrants for the entire year, and $40 a year is certainly not a high price for hydrants. If this is done, the seven arc lamps may be shown to cost about $6 per month and the eighty 32 candle power incandescent only $1.55 per month, as follows:—

Waterworks and electric light receipts	$3,450.00
Sixty-seven hydrants at $40	2,680.00
Seven arc lights, six months, at $6 per month	252.00
Eighty 32 candle power incandescent lights, six months, at $1.55 per month	744.00
	$7,126.00

This makes a decidedly different showing for the electric lighting account. If I am mistaken in my assumption I should be glad to be corrected.

NATIONAL ELECTRIC LIGHT ASSOCIATION.—PRESIDENT NICHOLLS' INTERIM REPORT.

The following is the interim report issued by President Nicholls to the members of the National Electric Light Association:

When elected President of your Association, I fully realized that much useful work might be accomplished during the interval between conventions, and have earnestly endeavored since our last annual meting to initiate and, with the assistance of our Secretary, to conclude certain matters which I am hopeful will be approved of by our members, and upon which I now have the honor to report as follows:

Relations Between Manufacturing and Central Station Companies.—At our last Convention the Committee on Relations between Manufacturing and Central Station Companies was discharged, and the Executive Committee authorized to take such action as might, from time to time, be found necessary, in an endeavor to protect its active members from having their investments in central station companies destroyed, or seriously impaired, as a result of ruinous competition, directed or fostered by the manufacturing companies. At an early period of my administration such a case arose, in a western town, as justified prompt and energetic action on the part of your Association. After consultation with the members of the Executive Committee, I placed the views of our Association as to this particular case, and as to unwise and unwarranted competition in general, before the executive officers of the following manufacturing companies: Ball Electric Light Company, Brush Electric Company, Fort Wayne Electric Corporation, General Electric Company, Royal Electric Company, of Peoria, Siemens & Halske Electric Company, Stanley Electric Manufacturing Company, Western Electric Company, Westinghouse Electric and Manufacturing Company.

The details of our negotiations, by correspondence and in some cases by personal interview, are too voluminous to here set forth, but it is with much satisfaction that I am able to report that each of these companies, with the exception of the Ball Electric Light Company, has given favorable consideration to the representations made on behalf of your Association, and I have received, in writing, such satisfactory assurances regarding not only the particular case in question, but also as to their future general policy, that I am hopeful of good results. Should, however, any active member have reasonable cause for complaint, he should forward full corroborative details to our Secretary, and the Association will take prompt and energetic measures, if the circumstances warrant such action.

Municipal Lighting Statistics.—Being aware that no recent and reliable statistics of the cost of arc lighting in the cities and towns were available for use by members of the Association, I some time since instituted correspondence with the municipal authorities of each city and town in the United States, with the object of securing from official sources and by official authority reliable information from each place as to (1) the number of arc lamps, (2) their candle-power, (3) the hours of burning, (4) the cost per lamp per night. Accompanying this report you will receive, in pamphlet form, a preliminary bulletin, containing such information from over four hundred cities and towns, which list covers a very large majority of the principal installations. A supplementary list, containing similar information in regard to places now omitted, is in process of compilation, and will be issued to members at an early date. It frequently happens that when a contract is to be renewed, local papers publish very misleading figures concerning prices paid for arc lights in other municipalities, and as these statistics are of the months of June and July, 1896, they are reliable and up to date.

Laws Affecting Electrical Companies.—We have been in correspondence with the Secretaries of State for each of the States in the Union, with a view to making arrangements to have regularly forwarded to the Association copies of all bills introduced in any State that may deal with the rights of electrical companies. I am much pleased to be able to report that a large majority of the States have acceded to our request, and several have already forwarded copies of all bills passed during the past session of their legislature, while others have promised to forward any that may be introduced during future sessions. These will all be filed in the Secretary's office for the sole use and advantage of the members of the Association.

Revision of Constitution.—As the only printed copies of the Constitution and By-Laws of the Association did not contain recent additions and amendments, revised copies have been published, and may be obtained from the Secretary.

Report of Proceedings of Nineteenth Convention.—The report of the recent Convention, held in this city, is now in the prin-

ter's hands, and will be delivered to members not later than September 1, next. There has been some unavoidable delay, caused by speakers at the Convention failing to revise the stenographic copy of their remarks, but, so far as my memory serves, it will be issued much in advance of previous reports.

Improved Office Facilities.—The office of the Association being too small to be of service to our members visiting New York, the Chairman of the Finance Committee made arrangements to rent the adjoining office, with the special object of providing a room for the use of our out-of-town members. The office is centrally located in the down-town business district. Members can use this room for meetings, appointments, etc., and their letters and telegrams can be addressed here. As the records of the Association are increasing in number, two new book-cases have been provided, and already contain many books of reference.

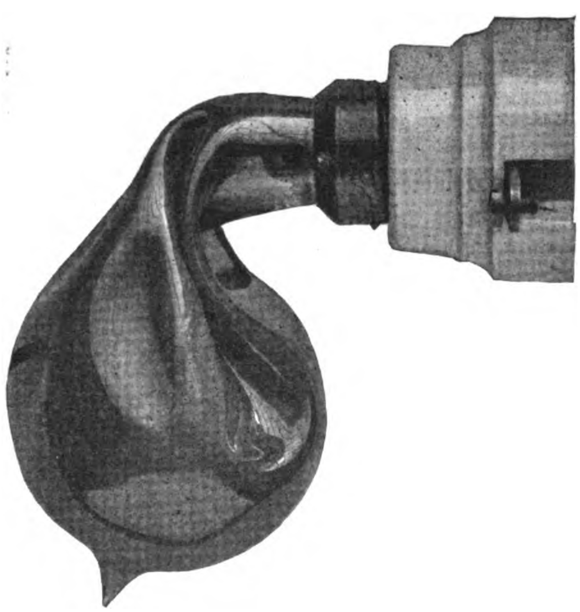
In conclusion, I wish to bear testimony to the zeal of our Secretary, without whose enthusiastic co-operation it would have been impossible to have accomplished so much in so short a time. I also have to request that members will aid me, by suggesting any action that may promote the welfare and add to the usefulness of the Association.

A PECULIAR LAMP ACCIDENT.

BY R. C. EDEN.

I HAVE a curio which you might like to put before your readers which started as a 20 candle-power, 110-volt incandescent lamp with a coiled filament, and was called upon to illuminate the fly gallery of a teutonic theatre. Here it fared wisely and well for some time; attached to the wall in horizontal position it shed its direct current light on carpenters and scene shifters, the good and the bad, impartially and efficiently.

But evil days were at hand, a "super" ignorant of the "laws



A PECULIAR LAMP ACCIDENT.

of the current," and Joule's equivalent, but possessing that perverted ingenuity which is bound to branch out in the wrong direction, was instructed (in German) to cut out this light. The switch, for this case made and provided, he could not or did not find, and here his aforesaid pervertible ingenuity took the road on the wrong track. Seizing a towel on which the remains of "make-up" and make-up grease were well in evidence, with a triumphant "Ach Gott, aber das ist ziemlich gut," he wrapped it round the lamp and descended to the stage.

The result was that the heat of the lamp so softened the glass of the bulb that from a horizontal it fell into a semi-vertical position and the glass coming in contact with the filament broke the latter. The cloth was badly scorched, but did not ignite. The lamp did not break, but is now of the shape shown in the illustration, with the glass much blackened, but intact.

A GAS EXHIBITION IN NEW YORK.

A Gas Exhibition will be held in New York at the Madison Square Garden during two weeks. The exact time has not yet been set, but it will probably be in January, 1897. Why not August?

ROENTGEN RAYS.

TECHNIQUE OF ROENTGEN PHOTOGRAPHY.

THE July number of the "Bulletin," of the electro-therapeutic laboratory of the University of Michigan, is devoted exclusively to Röntgen ray literature and contains, among other contributions, an article by Dr. W. J. Morton, explaining his modus operandi of taking X-ray pictures. Dr. Morton writes in part: "I use the static machine extensively for this work, but on the whole prefer the coil as more convenient and quicker. Both will do excellent work when properly managed. I put the tube in the circuit between the external armatures of Leyden jars in connection with each prime conductor. I use quite small jars. As the vacuum rises, larger jars may be required, and here comes danger, for the tube may break down. But the very high vacua are not essential to a good-working X-ray, and if the tube rises to an impracticable vacuum it should be heated freely with a spirit lamp until, upon passing current through it, the first faint tinge of blue appears at the anode, generally behind it. Now, as the vacuum gradually improves with use, a point will be reached in the history of the tube where it is doing its best work. That point may be judged of by the length of the spark gap between the discharging rods.

"As to coil, I believe only in the direct current as a source in the primary of the coil. A six-inch spark is good, an eight to ten or twelve is better, but a four-inch also will serve fairly well. What has evoluted out of confusion in my experiments is a coil (I use a twelve-inch), direct current from the 110-volt main, a break wheel, 8 breaks and 6,000 revolutions per minute, and the usual condenser. The strength of current to be used is entirely controlled by the vacuum in the tube. If this is low, little current can be used; if it is high, much current must be used. But the operator can, within reasonable limits, govern the situation. He must work with spirit lamp or Bunsen burner in hand. Also with his fluoroscope as a guide. A moderate current flowing steadily will steadily raise the vacuum. Watch the rise by adjustment of the discharging rods. A strong current will cause the vacuum to fall and the tube to heat at the cathode.

"This 'time of exposure' business is a wrong way to look at X-ray work, for one often spends fifteen to twenty minutes taking a picture, which is practically really taken by a very few minutes, or even few seconds, of those exceptionally brilliant moments all tubes have, for the vacuum in a tube never remains the same for half an hour—never, I believe, the same for one minute. I have taken an arm, wrist and hand in two seconds, but I took advantage of the two best seconds out of many more which I could get my tube to exhibit.

"What I have written applies only to present appliances and present methods as I now use them. A different Crookes tube, that is to say, one whose vacuum was not on a sliding scale, would change the tenor of many of my remarks."

EXPERIMENTS WITH CROOKES TUBES.

In a recent communication to the Academia dei Lincei, Prof. E. Villari describes some experiments carried out by him with Crookes tubes. He blew a mixture of sulphur and minium on to the glass of a tube at work. Generally there was a patch of minium coinciding with the fluorescent spot, the sulphur spreading uniformly over the rest of the tube. If the cathode rays were stopped by a sheet of platinum there was no red patch. The glass is thus negatively electrified just where the cathode rays impinge upon it, and is positively electrified everywhere else.

DISCHARGING EFFECTS OF ULTRA VIOLET RAYS.

At the Berlin Physical Society Professor Warburg maintained that the action of ultra-violet rays in facilitating sparking and the discharge of negatively electrified bodies consists in doing away with the retarding force which, according to Jaumann's researches, exists at each discharge. Gases unlike metals whose conductivity is independent of strength of current, only become conductors when the current has reached a certain intensity; hence possibly during the retardation the gas is becoming a conductor, and if so, the action of light consists in the removal of some obstruction to the establishment of conduction. All of which, if it comes to anything at all, only means that if a system in stress is just about to break down, any vibration accelerates the catastrophe. But really very little is known about it. Nor is it any answer to the ques-

tion why the effect is different on positive and negative charges, so far as ordinary ultra-violet light is concerned, while the Röntgen waves show no preference in the matter.

HOW TO PREPARE CALCIUM TUNGSTATE FOR X-RAY SCREENS.

BY C. E. TENNANT, M. D.

As the readers of The Electrical Engineer may be interested in the subject, I give the results of my recent experiments with the calcium tungstate. I find that the compound made after this manner gives the most satisfactory results of any fluorescent substance now known, especially on large screens, the size of the body, and these screens can be made for a price not to exceed twenty-five cents each, by any novice.

The spreading of the calcium tungstate evenly over the surface, offers the greatest difficulty, but with a little practice can be readily overcome.

To two parts of sodium tungstate add one part of calcium chloride; fuse the mass to a red heat. A resulting compound of calcium tungstate and sodium chloride is formed; this latter salt exerts active hydroscopic properties and as a result renders the calcium tungstate quite negative to the X-rays. But immersing the fused mass in water for an interval of forty-eight hours, disposes of the salt as is well known by its property of solubility while the insoluble calcium tungstate remains a precipitate. This latter is now separated by filtration and when dry assumes a crystalline formation and is very sensitive to the X-rays.

An amorphous preparation of calcium tungstate may be obtained by adding a saturated solution of sodium tungstate to a solution of calcium chloride, which results in the precipitation of the calcium tungstate, but this amorphous crystalline form is absolutely worthless for use with the X-rays.

THE X-RAY IN INTESTINAL INVESTIGATIONS.

Mr. Wolf Becher, practicing physician in Berlin, Germany, writes in the German "Medicinische Woehenschrift" as follows: In April of this year I showed that the stomach of guinea pigs may be photographed by the Röntgen method if solutions of lead salts are injected into the intestines. The process is possible since not only metals but also their salts are opaque to the X-ray. Almost the least opaque of all organic substances, are the bones. This fact induced me to test phosphate of lime and also other lime compounds in regard to their transparency for Röntgen rays. It was found that lime water has a great tendency to absorb the rays. This determination is of interest in connection with the work of G. Hoppe-Seyler on radial arteries and E. Grummach on the coronar arteries of the heart which showed that arterio sclerotic changes in the human being can be observed by the Röntgen method.

Another method besides the injection of salts may be utilized to make the stomach visible, that is, by inflating air into the stomach. On a Röntgen photograph of a guinea pig, whose stomach was inflated with air shortly before its death, the larger part of the stomach is visible. There is a considerable difference between the Röntgen ray photography of the early days and now, inasmuch as the apparatus has since been considerably improved. On the photographic plates a great deal more is visible to-day than there was formerly. A picture of the guinea pig is very instructing indeed. We observe in the first place the entire skeleton and in the thorax we can observe not only the bony, but also the cartilaginous parts. Muscles and bones vary, however, in the density of the shadow thrown. In the thorax the lungs appear particularly bright. In the middle of the light field the heart can be discerned. The diaphragm which separates the chest from the stomach is plainly visible. Under the left side of the diaphragm the strongly inflated stomach, can be seen, reaching to the last rib. In the upper part the rather dark liver can be observed. In about the middle of the abdomen the intestines can be seen in contours. At the left of the spinal column, about the height of the last rib a round spot might, according to form and position as well as color, be diagnosed as the left kidney. The successful operations on the animals make us very hopeful that the Röntgen process may turn out to be extremely useful with the increasing improvements of the technical details.

POWER TRANSMISSION.

TRANSMISSION AT RHEINFELDEN.[1]

BY E. RATHNAN.

As early as 1889 the Allgemeine Elektrizitäts-Gesellschaft investigated the advisability of power transmission at Rheinfelden. The investigating committee had to confer with the various states surrounding the district, and the most interesting condition was the demand of leaving in the bed of the river a quantity of water at any time of at least 50 cubic metres. According to the report of Professor Intze, who was retained as consulting engineer, the effective horse-power did not exceed 13,800 at the turbine; this being a low and satisfactory estimate the "Transmission Works Rheinfelden" were founded with a capital of four million marks.

Twenty turbines of 840 horse-power each were planned, and at the end of the upper canal a corresponding number of chambers are constructed to serve for the motor installation. These chambers are 5.5 metres wide, 10 metres long and are separated by walls 1.25 metres thick. Arrangements are made to absolutely remove water from these chambers if repairs or inspections require it. The dynamo rooms will have a width of about 10 metres and a length of over 150 metres, thus extending over all turbine chambers. Rails and wagon paths lead from the dynamo room to the shore on one side and a bridge will be built across the river to connect the two shores.

The Francis turbines, Fig. 1, have two working wheels and

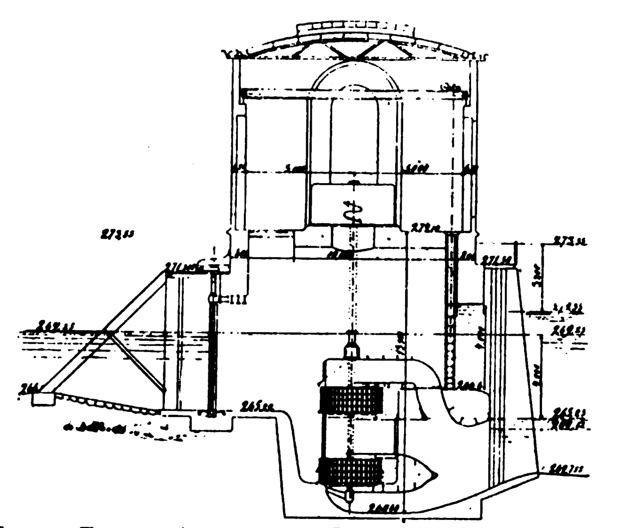


FIG. I.—TURBINE ARRANGEMENT, RHEINFELDEN TRANSMISSION.

two guide buckets, but inasmuch as the water runs out in two directions from every working wheel, they might as well be considered as quadruple turbines. In consequence of direct coupling of the dynamos to the shafts of the turbines, instead of toothed gearing transmission as was first proposed, and owing to the better introduction of the water through the upper canal, the gain in useful energy will be about 2,000 horse-power. It should be mentioned that the maximum efficiency can only be expected if the fall is considerable, while when the river runs high the somewhat greater amount of water used cuts no figure.

The turbines used consist of two pairs of wheels of 2,350 mm. opening, and 1,240 mm. high. The turbines are reaction wheels, each working section containing 32 and each conducting section containing 36 buckets. The mean distance between two turbines is 3,370 mm. The turbines have an efficiency of 75 per cent.

The electrical part of the installation was given most careful study. The problem was to distribute over a considerable distance with small losses and cheap distributing network; the various consumer's premises had to be independent and the current system had to be such as to serve for lighting, heating, electrolytic work and power transmission. Since no such ideal system exists, it remained to choose between the direct current, single phase and multiphase.

After long considerations it was decided to adopt three-phase current at 50 periods per second, since with that number drop due to self-induction may be kept low. For transformers, motors and incandescent lamps this method is well adapted

[1] Abstract of a paper read before the Verband Deutsch Elektrotechn.

and also permissible for arc lamps, if the requirements for steadiness are not exaggerated.

To determine the most suitable voltage many investigations had to be made. On the assumption of a network of 20 kilometres radius and considering cost of generators, transformers, measuring and regulating apparatus, 16,500 volts was considered the most suitable.

Since the demand for electrical energy grows only gradually, it was decided to work in the beginning with 6,800 volts, which is the voltage of the generators. The type of generator used, Fig. 2, has revolving pole pieces, because these machines allow of the adoption of a great many poles of comparatively small diameter, and the generation of the field without too large a mass of copper. In principle these machines consist of two stationary, mechanically and magnetically connected armatures; they are built up of laminated iron sheets and carry on their projecting teeth the spools which have micanite insulation.

The induction ring which consists of five sections is connected with the shaft by means of a spider and has 55 poles on its circumference, the ends of which consist also of laminated iron sheets, and which close the magnetic circuit between the two armatures so that during the revolution of the pole piece the section of highest magnetic density travels along the surface of the two armatures, thus acting inductively on the armature spools. In order to relieve the weight of the shaft, oil is introduced under pressure. Magnetic leakage is avoided as much as possible by the introduction of sections of bronze.

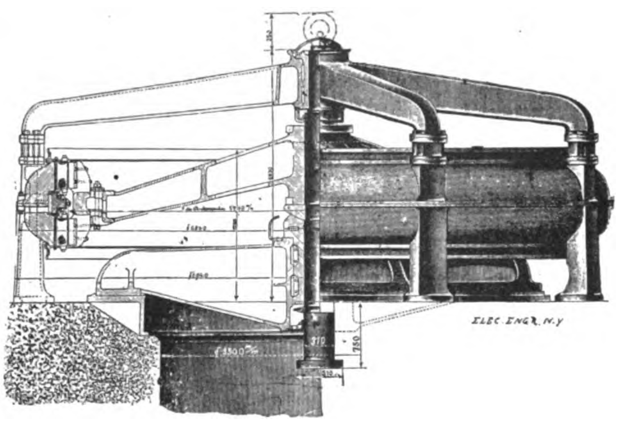

FIG. 2.—THREE-PHASE DYNAMO, RHEINFELDEN POWER TRANSMISSION.

The normal capacity of each dynamo is 63 amperes with 3,800 volts per phase, and thus furnishes 720 kilowatt. Under an assumed lag in consequence of the motors up to cos. b = .8 this capacity would be reduced to about 580 kilowatts, thus requiring about 840 horse-power at the shaft.

The total efficiency is above 92 per cent. Although no dangerous overheating is expected, considerable attention has been paid to ventilation. Since lighting and power service will be permanently kept apart, four dynamos will be used for the first and fourteen generators for the latter; half of these will be devoted to the chemical industries. In case of exceptional consumption, in which the two reserve dynamos are not sufficient, the lighting and power circuits may be combined.

The transformers, which are to raise the voltage to 16,500 will be put up in a separate room later on. Three rectifiers will be installed to generate direct current for the charging of a small plant of accumulators which is to do service on Sundays.

The scale of prices commences with 40 pfennig per kilowatt hour, and the rebate goes as high as 80 per cent. for large consumers. For power the price per kilowatt hour will be 1.6 pfennig (.4 cent.).

POWER FROM THE NIAGARA RAPIDS.

It is announced that there is every prospect of a new power company being incorporated at Niagara to develop the power of the Rapids from the current along the Gorge Road. The company owning this road control the New York State bank of the lower river for a distance of over six miles, along the full extent of which there is a rapid current.

While the franchise now held by the company does not empower them to develop and sell power an incorporation might be formed having such power. Already two attempts at developing the power of the current have been made and both plants, of a crude nature, were swept away by high water.

A ROTARY FIELD MOTOR FOR LECTURE PURPOSES.[1]

BY ALBERT F. GANZ, M. E. INSTRUCTOR IN APPLIED ELECTRICITY, STEVENS INSTITUTE.

Description of Motor.—A general view of this motor, which was briefly mentioned in the last number of the "Indicator," is shown in Fig. 1. It was constructed in the electrical laboratory of the Institute, with a view of obtaining a simple piece of apparatus for illustrating the principles of rotating magnetic fields, as embodied in commercial induction motors. The model has proved so generally useful that a brief description of it, together with a simple explanation of the theory involved, may be of interest[2].

The model consists essentially of a laminated ring electromagnet of square cross-section, having a mean diameter of 27.5 centimeters and sectional area of 18.4 square centimeters. This ring is divided into twelve equal parts by radial flanges, and each part is wound with 140 turns of No. 14 B & S wire; the ends of each coil are brought to separate binding posts on the base of the model. By this arrangement the coils can be grouped in any manner desired.

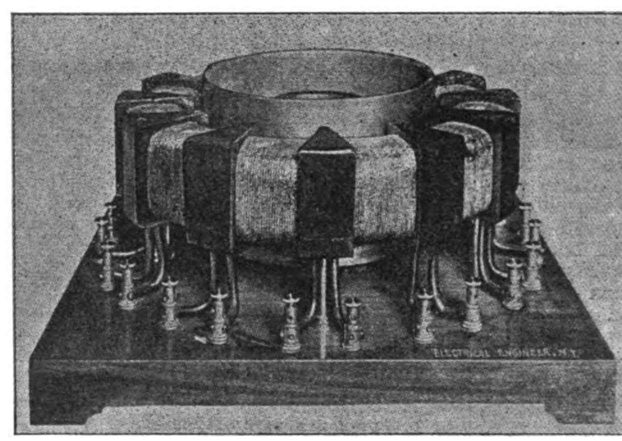

FIG. 1.—ROTARY FIELD MOTOR FOR LECTURE PURPOSES.

In the center of this ring, and just below it, is a brass disc free to rotate. Fig. 2 shows a cross-section of the bearing; it consists of a vertical steel shaft (A) running in a brass bearing (B), together with a pair of steel discs (C) separated by steel balls placed in suitable grooves and forming a horizontal ball bearing. The brass disc (D) is a sort of turntable upon which the masses of metal, armatures, or rotors generally, with which we wish to experiment, may be laid or suitably fastened. The weight of the rotating mass is thus supported by the steel balls, reducing friction to a minimum[2].

Production of Rotating Fields.—The simplest rotating field is produced by revolving an ordinary horse shoe magnet about an axis pasing midway between the poles. By taking a number of magnets, with their poles alternately N and S, we can produce a multipolar rotating field. If a disc of copper or iron is pivoted in the axis of rotation and placed near such a magnet, it will be dragged around with the rotating field, due to the eddy currents induced in the disc. Such rotations have long been known under the name of Arago's rotations.

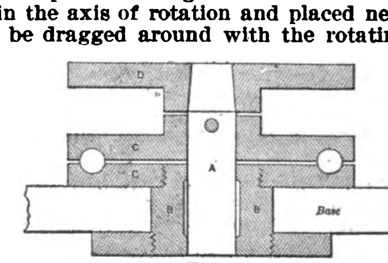

FIG. 2.

Such traveling poles can also be produced by the proper combination of alternating currents, differing from each other in phase. At least two such currents are necessary, in which particular case the phase difference should be 90 degrees. Such are the ordinary two-phase currents, graphically represented in Fig. 3. One method of connecting the coils for two-phase currents is shown in the diagram, Fig. 4. At one particular instant, marked 0° in Fig. 3, the current in A is a maximum, and that in B zero, so that the resultant magnetization is that

1 "Stevens Indicator."

2 For a complete analytical treatment of the subject see "Polyphase Electric Currents," by S. P. Thompson.

due to A alone. If the ring were cut in two across a diameter C-D, coils G, on one half of the ring, would produce the poles n and s; coils H, on the other half, the poles n' and s'. When both coils are active, as they really are, the ring can be joined again and the resulting poles will be at N and S. The general direction of the lines of force at this instant is shown in Fig. 5.

One quarter-period later, marked 90° in Fig. 3, the current in A is zero and that in B a maximum, so that the magnetization at this instant is that due to B alone, bringing the resultant poles to N' and S'. At a time half-way between these two, marked 45° in Fig. 3, both set of coils are equally active. G

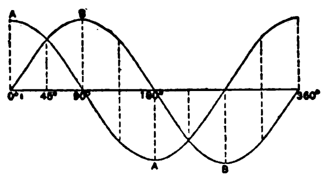

FIG. 3.

and H tend to produce poles at N and S, while C and D, such at N' and S'. The resultant poles will therefore be midway between or at E and F. The same reasoning would show that at any intermediate time the resultant poles would be at corresponding intermediate points.

One half-period after the first instant considered, marked 180° in Fig. 3, the current in B is zero and that in A has reversed and is again a maximum; the poles will therefore be N and S reversed. Another quarter-period later the poles are N' and S' reversed, and at the end of a complete period the poles have made one complete revolution.

In fact, if the two currents are of equal period and amplitude and differ by exactly quarter of a period, the resultant field has a constant value, and rotates with a uniform angular velocity. Three equal currents, differing by 120 degrees, applied to three coils placed symmetrically will also produce a resultant constant rotating field[3]. Or, in general, any number of equal currents of as many phases may be applied to as many symmetrical coils with the same result. A pivoted magnet placed inside of this ring would be dragged around in synchronism with the revolving poles, and would make a synchronous multiphase motor.

The paths of the lines of force for one instant are shown in Fig. 5; they are seen to stream across the interior of the ring, and, as explained above, this system of magnetic lines rotates about the axis of the ring at a rate corresponding to the frequency of the alternating current.

Suppose now that we place a mass of metal inside of the ring; this is usually known as the rotor; the lines of force, rotating about the axis, evidently cut this mass of metal and set up in it electromotive forces, and these in turn produce currents. The general direction of these currents is found by applying Fleming's three-finger rule, using the right hand; it must be borne in mind that we have to assume the rotor to revolve and the lines to remain fixed when applying the rule. The general direction of currents at z will be towards the reader, and at w away from the reader perpendicular to the plane of the paper; now these currents

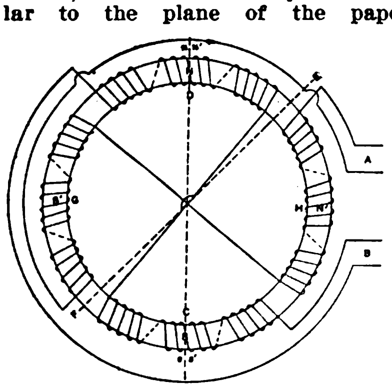

FIG. 4.

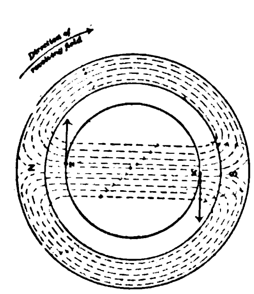

FIG. 5.

are in a magnetic field, and consequently the rotor, carrying the currents, experiences forces tending to move it. To find the direction of these forces, we apply Fleming's three-finger rule for motors, using the left hand; it will be found that these forces at z and w are in opposite directions, and produce a couple in the direction of the rotating magnetic field. If our rotor is pivoted it will be set into rotation in the direction of the revolving field. Very good results were obtained with an ordinary iron pulley, shown in the illustration, Fig. 1.

[3] For an analytical proof of this see "Polyphase Electric Currents," page 63.

The magnitude of the couple varies as the square of the number of lines of force; for, if this number is doubled, the current induced in the metal is also doubled, so that the force between the two is quadrupled. For a given magnetizing current, the flux depends directly on the goodness of the magnetic circuit; and since the space inside of the ring always forms part of this circuit, the flux will be increased by introducing iron into this space.

The currents induced depend upon the rate of cutting of the lines of force; this rate is greatest when the rotor is fixed, and decreases as it begins to revolve, finally becoming zero if its speed of rotation should become that of the magnetic field. The difference between the angular velocities of field and rotor is called, by S. P. Thompson, the slip; the cutting of lines, and therefore the induced currents, are due to this slip; and since the rotation is produced by these induced currents, there must always be some slip. That is, such a motor cannot run in synchronism with the rotating field.

Instead of producing simply two traveling poles, we can so connect our coils as to produce a number of such poles. The diagram, Fig. 6, shows the connections for producing six traveling poles by means of two-phase currents. The capitals N and S indicate the positions of the poles at one instant when the current in B is a maximum; one quarter-period later these poles have shifted to the positions indicated by the small letters n and s—that is, through 30 degrees. We thus have a multipolar rotating field, the number of rotations of the field being equal to one-third the frequency of the alternating-current supply. This method of connecting therefore affords a means of obtaining slow speeds. By increasing the number of poles, we decrease the number of revolutions of the rotor in the inverse ratio.

Closed Coil Armatures.—So far we have only spoken of

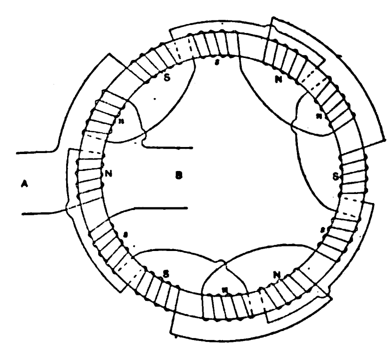

FIG. 6.

masses of metal to be used as rotors; the general direction of induced currents in such masses of metal will be as has been shown above. But some of the currents will not flow in the proper direction to help produce motion, and such currents will be wasted. To avoid this waste, we must restrict the induced currents to flow in directions in which they can do useful work, which direction is parallel to the axis. This is accomplished by winding conductors upon a core and so connecting these conductors that the current flowing upward near one pole returns downward near an opposite pole. In the case of the bi-polar type this would be across a diameter; in the six-pole winding mentioned, the span would be 60 degrees. A number of closed circuits would thus be established in which the induced currents would flow in directions proper for producing rotation. Another very common form of connecting these conductors together is that known as the squirrel-cage construction. This consists in connecting together all the conductors on each end by means of a ring. Such an armature will run in any rotary field. For our model we constructed a squirrel-cage armature by making a cylinder of sheet copper and cutting into this a number of slots parallel to the axis of the cylinder.

The core is ordinarily made of soft iron, laminated in a direction perpendicular to the axis. At the moment of starting, the induced currents are very large; the effect of this is to partially neutralize the magnetizing effect of the field coils, which will then draw very large currents from the supply. To avoid this a starting resistance is introduced. Since the secondary circuits have inductance, there is always a lag between the secondary currents and induced electromotive forces, and consequently also between the primary and secondary currents. This is an important matter in the design of these motors.

Several other uses of the model may be mentioned as matters of curiosity. The field magnet by itself can be used as a static transformer, with a variety of ratios. S. P. Thompson's method of phase transformation can also be illustrated; for this

purpose all coils are connected in series. If two phase currents are supplied to four symmetrical points on this series, three-phase currents can be drawn from three symmetrical points on the series; or vice versa. This is a very striking experiment.

Besides the few methods of connection for producing rotary fields, already mentioned, a number of other methods may be used, some of which will readily suggest themselves.

Reversing Induction Motors.—It has been shown that the rotor follows the direction of rotation of the revolving field. So to reverse the direction of the rotor we must reverse the rotation of the magnetic field. In the two-phase system this is effected by interchanging the wires of one circuit, so that, if continuous currents were used, the direction of the current would be reversed in one set of coils. In the three-phase system, using three wires, the reversal is effected by interchanging any two of the three wires.

ELECTRICAL TESTS OF POWER REQUIRED BY WOOD-WORKING MACHINERY AT THE NAVY YARD, WASHINGTON, D. C.[1]

In the case of the following tests, the mechanical horse-power delivered by the motor was determined by tests made under the same conditions as the previous power tests. This was necessary, as in many cases long leads were run to the motor and the drop was large. In other cases it was necessary to use a rheostat in series with the armature to obtain the required speed. Under these conditions the efficiency of the motor was a very variable factor, and a separate test was made in each case to determine the output of the motor. The column of mechanical output is therefore the proper one to use in determining the motor required, and the electrical horse-power to be delivered by the generator.

The work done is the heaviest that will be required of these particular machines:

Circular rip saw, 28 inches diameter; speed, 1,200 revolutions per minute, or 8,800 lineal feet per minute. Arbor pulley 5¼ inches diameter by 8½-inch face; hand feed; motor belted to saw shaft: Motor and saw, idle, 3.4 e. h. p.; ripping seasoned heart oak, 7⅝ inches thick; feed, 10 feet per minute, 19.3 e. h. p.

Circular rip saw, 24 inches diameter; speed, 1,500 revolutions per minute, or 9,429 lineal feet per minute; hand feed; motor belted direct to 7-inch pulley on saw shaft: Motor driving saw, idle, 3.2 e. h. p.; ripping seasoned heart oak, 6 inches thick, 10 feet per minute, 12.8 e. h. p.; ripping seasoned white pine, 6½ inches thick, 15 feet per minute, 9.4 e. h. p.; ripping seasoned yellow pine, two inches thick, 45 feet per minute, 10.7 e. h. p.

Circular rip saw, 14 inches diameter; speed, 2,200 revolutions per minute, or 8,067 lineal feet per minute; Arbor pulley, 3 inches diameter, 5 inch face; hand feed; motor belted to saw shaft: Motor, idle, .96 e. h. p.; motor and saw, idle, 2.7 e. h. p.; ripping seasoned heart oak, 3½ inches thick, 12 feet per minute, 6.3 e. h. p.

Circular rip saw, 12 inches diameter; speed, 2,200 revolutions per minute, or 6.914 lineal feet per minute; hand feed; belt pulley 3½ inches diameter and 3-inch face; motor belted direct to 3½-inch pulley on saw shaft; saw set to wabble for cutting grooves: Motor, idle, .96 e. h. p.; driving saw, idle, 2.2 e. h. p.; cutting groove in seasoned walnut, ⅜ x ⅞ inches, 12 feet per minute, 3.6 e. h. p.

Band saw pulleys 72 inches diameter; speed, 160 revolutions per minute, or 3,017 lineal feet per minute; belt pulley 30 inches diameter, 8-inch face, power feed; motor belted to saw shaft: Motor and saw, idle, 12.1 e. h. p.; ripping seasoned ash, 10¾ inches thick, feed 6 feet per minute, 16.1 e. h. p.; ripping seasoned white pine, 16½ inches thick, feed 10 feet per minute, 16.1 e. h. p.; ripping yellow pine, 12 inches thick, 20 feet per minute, 18.8 e. h. p.

Band saw, pulleys 42 inches diameter; speed 350 revolutions per minute or 3,850 lineal feet per minute; belt pulley 16 inches diameter, 5-inch face; hand feed; motor belted to saw shaft: Motor, idle, .96 e. h. p.; Motor and saw, idle, 2.9 e. h. p.; ripping seasoned oak, 12 inches thick, feed 3 feet per minute, 5.7 e. h. p.; cross-cutting seasoned oak, 8 inches thick, feed 5 feet per minute, 5.7 e. h. p.; ripping live oak, 10 inches thick, feed 3.2 feet per minute, 5.7 e. h. p.

Band saw pulleys, 28 inches diameter; speed 480 revolutions per minute, or 3,520 lineal feet per minute; belt pulley 12 inches diameter, 3½-inch face; hand feed; motor belted to saw shaft: Motor, idle, .96 e. h. p.; motor and saw, idle, 1.7 e. h. p.; ripping seasoned oak, 3 inches thick, feed 2½ feet per minute, 2.3 e. h. p.; ripping seasoned pine, 3 inches thick, feed 4 feet per minute, 2.3 e. h. p.; cross-cut seasoned oak, 3¼ inches thick, feed 4 feet per minute, 2.3 e. h. p.

Daniel's planer, machine bed 2 feet 5 inches by 21 feet 6 inches; belt pulley 13 inches diameter by 5¼-inch face; speed 350 revolutions per minute; speed of cutting edges of tool 10,400 feet per minute; power feed 12 feet per minute; motor belted to countershaft: Motor, idle, .96 e. h. p.; driving machine, idle, 3.9 e. h. p.; planing seasoned oak, cut 3-16 inch deep by 20 inches wide, 12 feet per minute, 6.2 e. h. p.

Hand cylinder planer or jointer, size of machine 24 inches; belt pulley 4 inches diameter, 5-inch face; speed 3,200 revolutions per minute; speed of cutting edge of tool 4,000 feet per minute; hand feed; motor belted to shaft of tool: Motor, idle, .96 e. h. p.; driving machine, idle, 2.40 e. h. p.; planing white pine, cut 11-100 inch deep by 18 inches wide, 25 feet per minute, 4.80 e. h. p.

Cylinder planer, size of machine 24 inches; belt pulley 5 inches diameter, 5-inch face; 2,250 revolutions per minute; speed of cutting edges of tool 3,105 feet per minute; power feed; motor belted to shaft of tool: Motor, idle, .96 e. h. p.; driving machine, idle, 2.40 e. h. p.; planing pine, cut 1-16 inch deep, 18 inches wide, 11 feet per minute, 3.6 e. h. p.; planing oak, cut 1-16 inch deep, 6½ inches wide, 11 feet per minute, 3.6 e. h. p.

Boring machine, speed of bit 375 revolutions per minute; hand feed; motor belted to bit shaft: Motor, idle .96 e. h. p.; driving machine, idle, 1.7 e. h. p.; Boring, 4-inch hole in seasoned oak, 9 3-5 feet per minute, 2.3 e. h. p.

Boring machine, belt pulley 8 inches diameter, 3-inch face; speed 750 revolutions per minute; hand feed; motor belted to machine shaft: Motor, idle, .96 e. h. p.; driving machine, idle, 1.9 e. h. p.; boring 1-inch hole in oak, feed 3¾ inches in 5 seconds, 2.2 e. h. p.; boring 1⅝-inch hole in oak, feed 1 inch in 7 seconds, 2.2 e. h. p.

Pattern makers' lathe, speed 888 revolutions per minute; motor belted direct to lathe: Motor, idle, .96 e. h. p.; driving lathe, idle, 2 e. h. p.; turning seasoned poplar, 12 inches diameter, ½ inch cut, 3.2 e. h. p.

Carver and molder, speed of tool 5,236 revolutions per minute; motor belted direct to tool shaft: Motor, idle, .96 e. h. p.; driving tool, idle, 2.8 e. h. p.; cutting groove, circular sector, 2 inches wide, ¾ inch deep, 3½ feet per minute, in white pine, 3.9 e. h. p.

[1] Reported by Prof. O. G. Dodge, U. S. N.

MONSTER ELECTRIC ELEVATOR AT ALLEGHENY, PA.

Electricity is to be used to furnish motive power for a monster elevator which it is proposed to erect in the lower part of Allegheny. The only way the people have of getting from McClure avenue to California avenue is by a one and one-quarter-mile trip, and yet these two points are separated from each other by a distance of only 150 feet. A company is now being organized to build an elevator from McClure to California avenues. It will be sufficiently large to carry several wagons and a number of passengers at once. It will be run by electricity. At the head of the scheme are Lewis Mathews, of McClure avenue; John Wall, of the Wall Manufacturing Company; Christopher Becker, a butcher of McClure avenue, and John Rising, a druggist on the same street. It will cost about $25,000 to construct the elevator.

AN ELECTRIC SWUNG BRIDGE.

The new highway bridge across the Connecticut River connecting Middletown with Portland, Conn., is now swung by electricity. The electrical equipment consists of four G. E. 800 horse-power motors. Two of these are connected with the swinging mechanism, one working and the other being held in reserve. Of the other two, one is located under each end of the turning span, to raise it from the fixed piers before the third motor begins to swing it. The bridge span is 450 feet long, the longest single-span highway bridge in the world. Previous to the installation of this electrical equipment by the General Electric Company, fifteen men were required to start the bridge and eight men to swing it.

ELECTRICITY IN NAVAL WORK.

At the recent meeting of the Institution of Naval Architects in Berlin, Herr Dietrich, Constructor-in-Chief of the Imperial Germany Navy, read a paper on the development in design and construction of German men-of-war. He thought England might with advantage copy Germany in employing electricity as much as possible instead of steam. The German Admiralty found that the only way to get rid of the heat from numerous steam pipes was to do away with them. By the use of electricity the conducting wire took the place of the steam pipe, and the ships were rendered more healthy as well as safer in action. All new German warships have electricity as the motive power for ventilating fans, turning gear of gun turrets, ammunition hoists, coaling winches, and such purposes. In the discussion which followed it was noticeable that Herr Dietrich's paper had made a great impression on the English

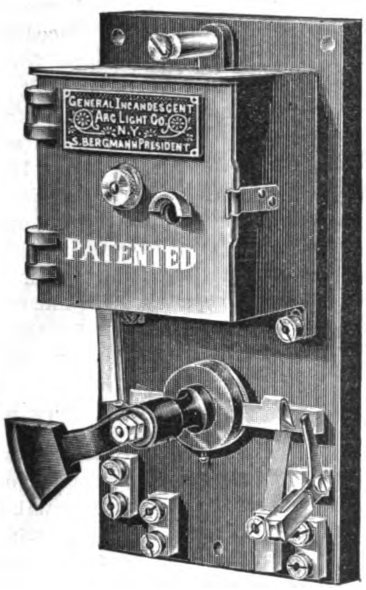
part of his audience, and there was a desire felt that his remarks on the further employment of electricity should be recommended to the notice of the English Admiralty.

LETTERS TO THE EDITOR.

CLOCK SWITCH FOR LOW TENSION ARC LAMPS.

We are interested in an article published in your edition of July 15, reprinted from the London "Electrical Review," entitled, "Public Art Lighting on Motor Generator and Battery System," which calls attention to the desirability of a clock switch for low tension arc lamps.

We desire to state that we have been manufacturing such clock switches for some time. These switches, which are illustrated in the accompanying cut, operate automatically both to turn on current at whatever hour of the day the dial



CLOCK SWITCH FOR LOW TENSION ARC LAMPS.

is set for, and also to cut it off again at any desired time. The trimmer attends to the setting of the switch and winding of the clock at the same time that he trims the lamps, and second and third trips for switching the lamps on and off are saved by its use.

These clock switches have been in regular use on the municipal arc light circuits of the Edison Electric Illuminating Company of Brooklyn for some time, and have recently been installed for the same work of the Edison Electric Illuminating Company of New York, and a number of them are in use by companies in other cities; but the companies first named will be sufficient reference regarding the success attending their use and that the saving in operating expense is considerable and amounts to more than the first cost each year.

GENERAL INCANDESCENT ARC LIGHT CO.

New York, July 22, 1896.

THE SOUTH HAVEN, MICH., MUNICIPAL PLANT.

In your issue of July 29 there appeared an article headed "Mistakes of Municipal Control," with a footnote as follows: "Facts and figures presented to the citizens of St. Joseph, Mich., by Mr. W. Worth Bean, President St. Joseph and Benton Harbor Electric Railway and Light Co. (After thorough investigation the municipal plant idea was abandoned and a contract made with the company.—Eds. E. E.)"

It is not my desire or intention to enter into a controversy with the author of that article or anyone else on the merits or demerits of municipal ownership of electric lighting plants,but I feel that the article in question does an injustice to the business tact of our village officials, who are all responsible business men, and in a certain degree, to myself as electrician.

Mr. Bean is known as an enemy of the municipal ownership of anything, and electric light plants in particular, and would naturally desire under the circumstances which caused him to make that report, to make a poor showing for our plant. He took for the basis of his report the first six months from date of installation, which would, you will agree, be an unfair criterion. We have since that time substituted coal for oil, making thereby a reduction of nearly one-half in our fuel bill. We are carrying twenty amperes on our alternator, which is 2,000 volts primary and 1,000 light capacity, and forty-two arc lights on our 50 light machine.

Mr. Bean did not spend over five minutes in conversation with me on the subject of our plant, about the same length of time with the engineer relative to the waterworks, and possibly thirty minutes with the village president on both subjects. He did not examine the books of the village clerk to verify his statements regarding the number of customers, and his report is about as correct as could be expected from anyone giving the subject the same amount of time.

After returning to St. Joseph he wired our village clerk to this effect: "Write me giving expense account of operating your electric light plant, also receipt for same and I will tell you whether your plant is paying expenses or not." It is needless to say his telegram went into the waste paper basket.

In conclusion I will say if the Board of Public Works in St. Joseph decided to abandon the municipal plant idea on the strength of Mr. Bean's report of our plant, they certainly showed a nervous haste in so doing, and if they will send a committee here to make an impartial investigation, we will convince them that they made a mistake.

L. A. BRIDGES,

South Haven, Mich. Electrician and Superintendent.

NEWS AND NOTES.

USE OF ACCUMULATORS WITH ALTERNATE CURRENT.

The night load at the central station lighting Zürich being near the maximum output of the station, and the street mains, moreover, not being adequate for dealing with much heavier currents than those employed at the time, it was decided, when current was required for a large new music hall, to light the same by means of direct currents from accumulators, says the "Electrotechnische Zeitschrift." These accumulators are charged during the day by means of rectified alternate currents, so that, in addition to relieving the night load, the day load is increased, and thus much more favorable conditions obtained for the economical working of the station. The consumption of current at this music hall (the "Neue Tonhalle") is equivalent to 2,000 16-candle-power lamps. The plant is installed in the cellars of the Neue Tonhalle, and comprises a battery of accumulators, two current rectifiers, the switches, and measuring arrangements. Moreover, in view of the novelty of the arrangement, an alternate to continuous-current transformer was put in as a reserve.

CONDITION OF MOSCOW STUDENTS.

The reply of the students of Moscow to the invitation of the students of Glasgow University to take part in the Kelvin Jubilee, has not, says an exchange, received the attention from the press that it deserved, especially as the Russian youths requested their Glasgow would-be hosts "to do our letter as much as possible notorious." The communication is very quaint. Here, for instance, is a passage which shows the conditions under which learning is acquired in Moscow: "It (the 'common administration') raises against us the less civilized classes of the population as against men evil-minded and rioters, it surrounds us by spies, unseldom concealed under our 'academic dress,' sometimes even it sends in our middle provocators. We are even subjected to searches, the most active from us undergo administrative chastisements—they lose their liberty and sometimes for some years are send out from the cities having a university, what for many attracts the impossibility of ending their education and following the chosen career. Many intelligent and energetic men are perished by this police regime with all his discretion. . . . You see now, it is for us quite impossible to send any delegates; every person, sended by us, would undergo a too hard punishment. We salute, nevertheless, your professor, whose scientific merits are known to all the world, and we express our profound regret that we have no possibility of taking a more active part in the life of the Western intelligency, sympathy of which and the greatest possible connexion with which cannot but be to us very desirable." The letter, which had been sent under cover to Berlin, and there registered before being posted, is signed by the "Moscow Federative Council of the 45 United Zemljachestva of Moscow."

THERAPEUTICAL EFFECTS OF HIGH FREQUENCY CURRENTS.

THE therapeutical effects of high frequency currents are being investigated by D'Arsonval in a scientific manner which promises results whose accuracy will be of the greatest value. He has already demonstrated that currents of this nature have a powerful effect on organic composition, and in another column we print a preliminary report of some very exact experiments in this direction, which are being undertaken in Paris under his initiative. One noticeable point about these experiments is the extreme care which has been taken to secure accuracy in his results and to eliminate any possible source of error which might arise through the imagination of the patients. In his own words "every precaution was taken to give these observations a character of precision which should give them value." Another point of interest is the unusually large amount of current which was administered to the patients and which, it appears, produced no effect upon their sensibilities. In these experiments from 350 to 450 milliamperes were used, which is an amount unthought of in the case of the application of ordinary currents. The reason why such currents produce no effect on the sensibilities of patients is still a matter of conjecture, but D'Arsonval has proved very conclusively that it is not for the generally accepted reason that currents of this nature are distributed superficially over the body. On the contrary he believes that these currents penetrate the body deeply, as they operate noticeably on the vaso-motor centers. We must therefore look for some physiological reason to account for the harmlessness of currents of high frequency to the human body.

SAFETY FUSES AND MAGNETIC CIRCUIT-BREAKERS.

DURING the past few years much has been written on the subject of safety fuses for the protection of electric circuits carrying heavy currents and it may now be fairly taken to be the consensus of opinion among those who are entitled to speak on the subject, that, except for branch circuits of comparatively small carrying capacity, the safety fuse is not only inadequate but may even constitute an element of danger under certain circumstances. These dangers are due to two general causes: First, the lack of dependence to be placed on the fuse blowing at the current for which it is intended; and second, that due to the generally prevalent practice of designedly inserting fuses of greater carrying capacity than the circuit is intended to carry for the very purpose of enabling the circuit to carry an overload either temporarily or permanently, and thus to obviate the "trouble" of inserting a fresh fuse. To what extent the latter practice has spread not only here, but abroad, is made apparent by the recent prize competition instituted in Germany for a "non-interchangeable" fuse which shall make the insertion of an improper fuse impossible. These manifest defects of the fuse have recently led to a more general adoption of the magnetic cut-out or circuit-breaker. It is probably due largely to the excellent work of this type of protector in the railway field that its present employment in lighting is due, and the practice is to be commended in every

way. But recently another phase of this subject has forced itself to the front, which must be taken into account, and which affects directly the operation of central stations for lighting and power. This is the tendency and, indeed, practice of discarding altogether the use of safety devices in the station and trusting to luck, or, in the end, pocketing the loss of an armature burnt out. The justification for this procedure is found in the desire to prevent at all hazards an interruption of the service, such as would be caused by the blowing of a fuse or the tripping of a circuit breaker, some station managers believing it to be more economical in the end to repair an armature than to answer complaints of lights out and motors stopped. The question here raised is a nice one and as to whether the practice is worthy of adoption is one which each station manager will have to decide for himself. But is there not some method of operation which will prevent a burn-out and still maintain the integrity of the circuit? It would seem that there is, and that a proper relationship between engine and dynamo may indeed make the station safety device of minor importance. It is this method of attacking the problem that Mr. William Baxter, Jr., discusses in another column and which we think deserves the most serious consideration, not only from the standpoint of tne cut-out and interruption of the service alone, but from the general economy of installation and operation. It will thus be seen that the last word has by no means been said on the question of circuit protection within the station, and that it involves problems far beyond the mere choice of the type of protector. In view of the importance of the subject we shall be glad to open our columns to the expression of opinions by our readers.

THE FINANCIAL ASPECT OF THE ELECTRICAL BUSINESS.

EVERYONE connected with the manufacturing side of the electrical industry is fully aware that the financial results of the business have been very unsatisfactory in the case of almost all of the large manufacturing concerns; and this is in spite of the enormous growth of the business and the almost universal adoption of electrical machinery.

There have been a number of fundamental troubles, mostly of the nature of extravagance, which are slowly being eliminated from this business. A number of these troubles are pointed out in an article in the "Engineering Magazine," by Mr. B. E. Greene, who believes that a new order of things is about to be established, and that the business will shortly take its place among the stable and substantial industries of the country.

One of the most serious losses of money has been the cost of patent litigation. Mr. Greene states that in one year three of the leading companies spent $1,500,000 in this direction, an amount equal to five per cent. on their entire capital stock. We might add that but comparatively few of these patents have been sustained and of those which were, many have been put to illegitimate uses. Patents have been used to coerce customers into the purchase of all kinds of apparatus used in conjunction with patented articles, under threat of not furnishing the latter to be used with the accessories of any other manufacturer. Again, patents have been and are to-day carried on the books of some of the large manufacturing concerns at many times their value, if we take the value of a patent at what it would bring if sold in the market under foreclosure of the company. Insolvent concerns have made their finances appear in a satisfactory condition for the time being by arbitrarily adding any required amount to their assets under the item of patents. These uses of patents are neither legitimate nor honest, yet they have been practiced to the great detriment of the business.

Another point of extravagance in the electrical business, which has, however, been unavoidable heretofore, is the displacing of stock on hand by improved devices which made everything previously manufactured practically obsolete and worthless. New stock has often been sent to the scrap heap because of an improvement which rendered it antiquated and useless within a few months. Still another unavoidable expense has been the experimental work and researches for improvement in every direction.

As to the outlook, we venture to think patent litigation on the large scale will undoubtedly soon draw to a close, if not by agreement, then because of the gradual expiration of the fundamental patents. Systems and apparatus are now practically standardized and the rapid changes of the past have ceased to depreciate all the stock carried by a company. There appears to-day no reason why a turning-point in the trade should not be speedily reached, beyond which it will be possible to determine the selling price of apparatus upon its manufacturing cost, and at a decent profit.

THE N. E. L. A's WORK.

ONE of the most prominent speakers at the recent meeting of the Northwestern Electrical Association went to considerable length to demonstrate that the National Electric Light Association was an effete body that had long since outlived its usefulness, and was only maintained to gratify some people's personal vanity or to support a sinecure for some one. We denied these statements at the time and stated our belief that the N. E. L. A. had a mission to fill, and an important one, quite distinct from that of the State or sectional electrical organizations which have been formed. That we were not mistaken in our estimate of the value and vitality of the pioneer organization is shown by the interim report of Mr. Frederic Nicholls, the president of the N. E. L. A. This deals first with the relations between the central stations and the manufacturing companies. Judging from Mr. Nicholls' report, it would seem that the manufacturing companies are quite willing to lend an attentive ear to a word from the association, and that unfair competition can be suppressed when the oppressed party calls the association to its aid. This only proves once more the fact, long since apparent, that the central stations, far from being at the mercy of the "parent companies," now, in fact, dominate the situation; but this domination we are glad to believe will only be called into play to right a wrong or to secure a better quality and higher standard of manufactured product. Another good piece of work accomplished by the association since last May is the issuance of reliable data on the electric lighting of 400 cities in the United States, which will shortly be followed up by a supplementary list of additional cities. Besides this the collecting of information on the laws passed by State Legislatures affecting electrical companies has been taken in hand and promises to become a valuable feature of the association's work. We congratulate Mr. Nicholls on the energy he has displayed since his induction into office, and believe more firmly than ever that when his term of office expires, the association's critics will have no fault to find with its work.

MISCELLANEOUS.

ALTERNATE CURRENT TRANSFORMERS.[1]

BY DR. J. A. FLEMING, F. R. S.

THE ACTION OF THE TRANSFORMER.

In the last ten years the alternate current transformer has been developed from an experimental instrument into a practical appliance of immense utility. According to recent statistics, there are at present about 50 alternating current electric supply stations in the United Kingdom, supplying not less than 1,100,000 8 candle-power lamps. This amount of lighting requires the expenditure of 54,000 horse-power, or 40,800 kilowatts at full load, and hence there must be transformer capacity in the United Kingdom at the very least equal to 40,000 kilowatts. These transformers, as presently to be explained, all contain an iron core, which has to be magnetized and demagnetized 200 times a second, or 6,000,000 times a year. The total weight of iron cores in the whole of these transformers will be certainly not less than 400 tons, and it will require at least 400 kilowatts to maintain the magnetization of these cores. If these transformers are connected with the circuits only, on the average, 4,000 hours a year, it is very easy to see that the magnetization of the cores of the transformer will require not less than 1,600,000 Board of Trade units spent per annum in magnetism, and this means at least 16,000,000 lbs. of coal, or 8,000 tons. Hence, in the United Kingdom, we have buried away somewhere or other at least 400 tons of iron forming the cores of transformers, and these involve at least an expenditure of 8,000 tons of coal, costing some £6,000 sterling to maintain that magnetization. It is, therefore, easily seen that the study of the construction of the alternate

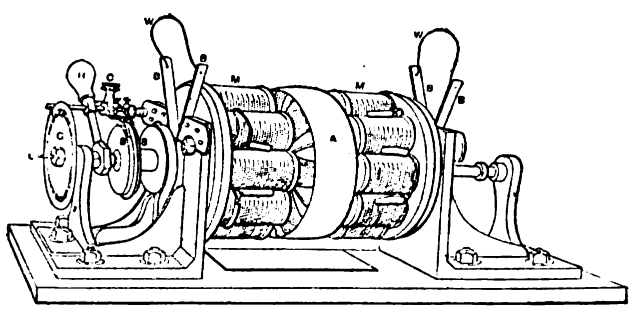

FIG. 1.—ALTERNATING CURVE TRACER.

current transformer, and its possible improvement, is one which is not at all unimportant, from an engineering point of view.

I propose to assume in these lectures that the majority of those present are acquainted with the principal facts connected with the flow of alternating currents of electricity in inductive circuits, and to address myself more particularly to the study of alternating current transformers from a practical point of view, discussing in the four lectures of this course the action of the transformer, the construction of the transformer, the testing of the transformer, and the employment of the transformer. You are all probably aware that an alternating current transformer in its simplest form consists of two circuits of insulated wire which are wound upon an iron core, and that this device operates to transform electric energy in such fashion that the flow of an alternating current through one circuit is made to produce another current in the second circuit, with an increase or decrease of current strength taking place at the expense of potentials. The transformer does no more than any lever, wheel and axle, or simple machine in transforming power from one form into another form. The general operation of the transformer or induction coil, in whatever form it may be taken, is then as follows:—Through one of the circuits, called the primary circuit, is passed an intermittent, interrupted, or alternating current. This primary circuit is interlinked with a magnetic circuit, and the primary circuit establishes in the magnetic circuit an intermittent, interrupted, or alternating induction; the magnetic circuit is interlinked with a secondary circuit, and the variation of magnetic induction in the core creates an electromotive force in the secondary circuit, which at any instant depends upon the rate of change of the total induction linked with the secondary circuit.

As the word "induction" will very frequently be mentioned during the succeeding lectures, it is exceedingly important there should be no ambiguity in your minds as to the meaning of this term. We may help ourselves by regarding the analogy of conducting circuits and magnetic circuits. Consider a conducting circuit in which an electric current exists. As long

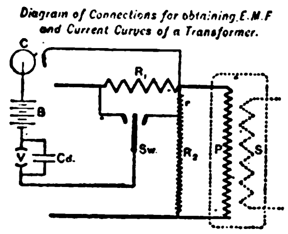

FIG. 2.

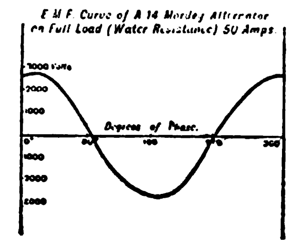

FIG. 3.

as the circuit is closed we recognize the presence of the current, either by heat produced in the conductor, or by electrolysis, and by various magnetic and dynamical actions in the medium round it. We select some one of these effects, say the electrolytic effect, and we base our quantitative definition of current strength upon it; thus, for instance, the accepted definition of an ampere is that it is a current which in one hour deposits, electrolytically, 4.025 grammes of silver. The cause, whatever its nature, producing the current is called the electromotive force. If we draw any line linked with or surrounding the conductor conveying the current, whether that line be included in a magnetic material like iron, or a non-magnetic material like air, we find a physical action taking place in that path which is called magnetic induction, and the immediate cause of this magnetic induction we speak of as magnetic force. We measure this induction by one of the effects it can produce, namely by the electromotive force which it can set up in another conducting circuit linked with the magnetic circuit when that induction is suppressed or reversed at a given rate. Faraday showed that the proper measure of the total magnetic induction linked with any conducting circuit was the total quantity of electricity set flowing in the circuit when the magnetic induction is suppressed or reversed. In practical work it is better to abandon the rather academic phrase, "number of lines of force" or induction, so much used, and to think of the induction as a physical effect produced in the magnetic circuit, its value being reckoned in webers, the induction being produced in the magnetic circuit by magnetic force, just as electric current reckoned in amperes is produced in the conducting circuit by electromotive force. Hence we have this definition of a unit of magnetic induction. A unit of magnetic induction, called one weber, is an amount of induction which, when linked or unlinked with a circuit of one turn, and having a resistance of one ohm, causes one coulomb of electric quantity to flow round the conducting circuit. Generally speaking, if induction is measured in webers (1 weber $= 10^8$ C.G.S. units), we have the following relation between the magnetic induction, the number of turns or linkages which the secondary circuit makes round the line of the induction, the resistance in ohms of the secondary circuit, and the total quantity set flowing in the secondary circuit reckoned in coulombs.

$$\text{Webers} \times \text{linkages} = \text{coulombs} \times \text{ohms}.$$

Since one weber is a larger amount of induction than is met

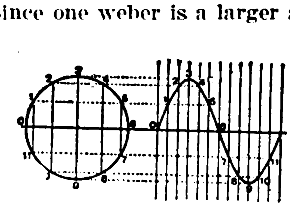

FIG. 4.

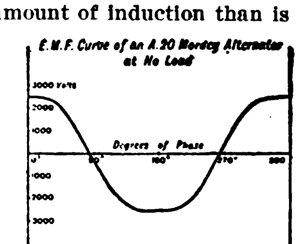

FIG. 5.

in any single transformer core or dynamo magnet, it is convenient to take the millionth part of this as the practical unit, viz., the microweber, and to commit to memory the following rule: Microwebers × linkages = microcoulombs × ohms, and to recollect that one microweber is equal to 100 C.G.S. units of induction, or what would commonly be called 100 lines of force. In order to measure induction, we require then a ballistic galvanometer as a practical instrument to measure electric

[1] Society of Arts Cantor Lectures.

quantity; and we can at once make a measurement of the induction in any magnetic circuit by determining the quantity of electricity set flowing in a circuit of a known number of turns which is linked with this induction, and then unlinked, by withdrawing the circuit or reversing the induction. As a practical illustration of these methods, it will be useful to make a measurement of the induction existing in this closed iron ring, when it is magnetised by a current flowing round it.

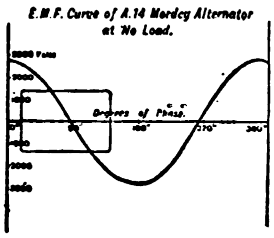

FIG. 6.

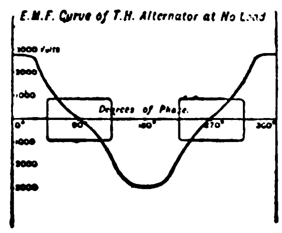

FIG. 7.

The ring, as you see, is wound over closely with one layer of wire, which we will call the primary circuit. If we measure the mean perimeter of the ring, and count the number of turns, it is a simple matter to obtain the number of turns per centimetre. If a current, measured in amperes, is set flowing through this current, then it can easily be shown that the magnetizing force acting upon the iron is equal to 1¼ times the turns of wire per centimetre, multiplied by the ampere current flowing through the circuit[3]. This magnetizing force produces in the iron a certain magnetic induction which is measurable in microwebers. In order to find out the magnitude of this induction, we put upon the ring a secondary circuit of a known number of turns. We then employ a ballistic galvanometer suitable for measuring electric quantity, and we must first calibrate this ballistic galvanometer to determine the excursion or throw of the needle, when a given quantity of electricity measured in microcoulombs is sent through it. This is most easily done by charging a condenser of half a microcoulomb by means of a standard cell having an electromotive force of 1.5 volts, and discharging this quantity of $1.5 \times .5 = \frac{3}{4}$ microcoulomb through the galvanometer. This produces a certain throw or excursion of the needle, and we may then assume that for any other throw of the needle the quantity of electricity producing it is proportional to the throw as determined by the above calibration. In order to measure the magnetic induction in the iron circuit, all that we have to do then is to connect the secondary circuit having a known number of turns, and the resistance of which, added to that of the galvanometer and connecting wires must be determined in ohms, and observe the throw of the galvanometer needle, which is produced when the primary current is reversed. Ascertaining from the previous calibration the electric quantity measured in microcoulombs represented by this throw, we multiply that number by the total resistance of the secondary circuit, including the galvonometer measured in ohms, and divide the product by the number of linkages or turns of the secondary circuit. This quotient gives us double the induction measured in microwebers existing in the iron core at the time when the steady current is flowing through the primary circuit, hence the induction is at once measured in microwebers.

Returning then to the alternate current transformer, we may classify transformers, converters, or induction coils as they are also called, according to their construction, and their use as

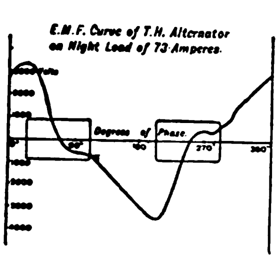

FIG. 8.

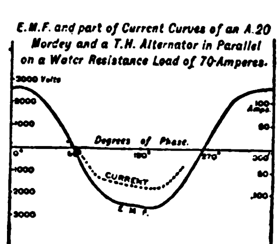

FIG. 9.

follows: Transformers may be (a) iron-core transformers, with a core wholly or partly of iron; (b) air-core transformers with a core or magnetic circuit wholly of non-magnetic substance. Iron core transformers may be (c) closed iron circuit transformers with a magnetic circuit wholly of iron (d) open circuit transformers with a core partly of iron. Transformers may be used (e) to transform a potential difference in a constant ratio, in which case they are called constant ratio transformers; (f) to transform a current strength in a constant ratio, in which case they may be called constant transformers. The transformers may be employed (g) to raise pressure or current, and they are then called "step up" transformers; (h) to lower pressure or current, and then they are called "step down" transformers. This is not an exhaustive classification, but it is sufficient for practical purposes. By far the most important member of the group is the constant potential closed iron circuit transformer employed with alternating currents taken from a constant potential primary circuit. This may be considered from its importance to be the chief of the clan, and to it, therefore, we shall pay most attention. In order to possess a complete knowledge of the operations and action of such a transformer, we require to know the nature of the operations going on in all parts of it at the same instant. We have seen that the broad general action of the transformer as employed with alternating currents is as follows: If an alternating primary current is passed through the primary circuit it acts upon the iron core with an alternating magnetic force, and creates in the iron core an alternating magnetic induction. If a secondary circuit is also wound round the same iron core, the periodic variation of magnetic induction in the magnetic circuit creates a periodic electromotive force in the secondary circuit, and if that circuit is closed, creates in it a periodic secondary current. The method which of late years has proved most fertile in adding to our real knowledge of the subject of the transformer is that of delineating graphically the various periodic quantities concerned, by a process which is called alternating current curve tracing. It is, therefore, necessary to study this process in some detail. Suppose that we have an alternating current dynamo or alternator in operation, we know that the potential difference between the terminals of this machine undergoes periodic variation, and that it passes from one maximum in one direction to another maximum in an opposite direction. At any instant the machine is producing an electromotive force which is called its instantaneous value. Suppose that the alternator terminals are connected to a condenser, the

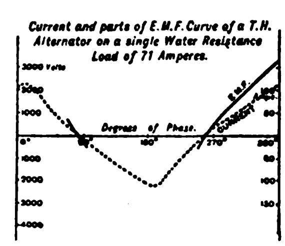

FIG. 10.

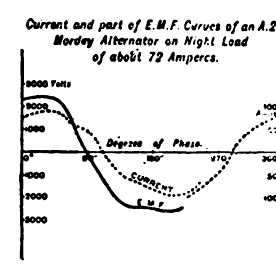

FIG. 11.

potential difference of these condenser plates follows the same law of variation as the electromotive force of the machine. If the condenser is removed at any instant, and the potential difference of its plates examined that will give us the potential difference of the terminals of the alternator, or the electromotive force of the alternator, at the instant when the condenser was disconnected. The practical arrangements made for doing this, which I have found it convenient to use, are as follows: A small alternating current motor (see Fig. 1) has its field magnets excited by a constant continuous current, and its armature traversed by a current coming from the alternator under examination. The shaft of this alternating current motor carries an ebonite disc, on which is placed a small steel slip. As the disc rotates, the steel slip passes at each revolution underneath two small steel springs, lightly touching the ebonite disc. The steel slip, therefore, electrically connects these springs (which are otherwise insulated) together, and this connection takes place at each revolution. The two springs are carried on an insulated bar, which is capable of being moved round an arc of a circle in such a manner that the instant when the springs are connected together can be altered and determined by the angular position of the rocking bar, carrying the two springs as read off on a scale. If this little alternating current motor is started in step with the alternating current machine it will keep in step with it, and will close the circuit of the two springs once during every revolution at an instant during the complete phase of the electromotive force depending on the position of the springs. These two springs, constituting the revolving contact breaker, are connected in series with a small battery of lithanode cells, B (see Fig. 2), and these again with an electrostatic voltmeter, V, across the terminals of which a condenser, C d, is joined This appliance may then be employed to determine the form of the curve of an alternating current, or an electromotive

[3] Vide "The Alternate Current Transformer," Fleming. New Edition. Vol. i., p. 23.

force, as follows:—Suppose it be desired to determine the curve of electromotive force of any alternator, the contact breaker is joined across the terminals of the alternator, and the reading of the voltmeter is taken as the rocking arm carrying the springs is moved round by steps through an angular interval corresponding to one complete period. At equal intervals during the movement, the electrostatic voltmeter is read, and in order to bring the readings within the best part of the scale of the voltmeter, a selected number of the cells of the battery, B, are placed in series with the voltmeter so as to add a known electromotive force to the electromotive force being measured[3]. By the employment of a revolving contact breaker of this form, a number of curves were taken from the alternating current machines in the City of London Electric Lighting Station at Bankside, some of which are shown in the accompanying figures.

Fig. 3 represents the electromotive force curve of a Mordey alternator on full load, the load being a water resistance. It will be seen that the curve of electromotive force is not very far from a simple periodic or simple sine curve, as shown in Fig. 4. Fig. 5 shows the electromotive force curve of a larger Mordey alternator at no load, and Fig. 6 shows the manner in which the electromotive force curve, at no load, is related to the position of the pole-piece represented by the rectangular line. The electromotive force curve of an alternator is, however, not by any means always so nearly a simple periodic curve. Fig. 7 represents the electromotive curve of a Thomson-Houston alternator taken at no load. The position of the field poles with respect to the electromotive curve being shown by the square rectangles in the figure. Fig. 8 shows the electromotive force curve of the same machine when working on a highly-inductive load of transformers. In order to determine the form and relative position of the current curve, all that it is necessary to do is to put in series with the alternator circuit a non-inductive resistance sufficient to carry without sensible heating the outgoing current. By connecting the revolving contact breaker and associated voltmeter with the terminals of this non-inductive resistance, we can delineate the curve of fall of potential down the non-inductive resistance, which is identically the same thing as the curve of current in the resistance.

In this manner have been determined the current curves taken from the above-mentioned machines, both on inductive and non-inductive loads. Fig. 9 shows the electromotive force curve and part of the current curve of a Mordey and Thomson-Houston alternator on a water resistance; and Fig. 10 shows the current curve and part of the electromotive force curve of a Thomson-Houston alternator, working on a water resistance. These diagrams show that when an alternator, having an electromotive force of 2,000 volts, is working on a water resistance, this load is an absolutely non-inductive load, the current curve being practically perfectly in step with the electromotive force.

This leads to the conclusion that in testing a high tension alternator for efficiency, it is quite sufficient to load up the machine on water resistance to measure the current going out of the machine as ordinarily measured on an alternating current ammeter, to measure the difference of potentials at the terminals of the machine, as measured on an alternating current voltmeter, and to multiply the values of the two readings together, and thus obtain the true power in watts being given out by the machine on the water load. There is no question of difference of phase in this case. If, however, the alternator is working upon an inductive load, such as a number of transformers lightly loaded, then the current curve lags behind the electromotive force curve by a definite amount at the

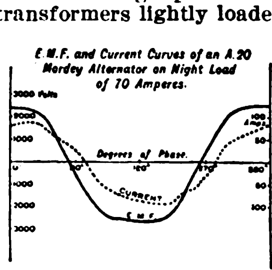

FIG. 12.

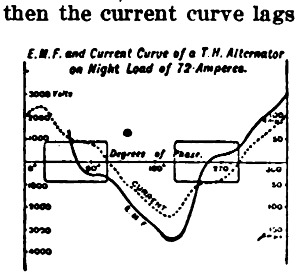

FIG. 13.

zero value. This is shown in curves, Figs. 11, 12 and 13, giving respectively the electromotive force and current curves of a Mordey alternator, and a Thomson-Houston alternator working on transformers lightly loaded. It will be seen that the difference of phase between the current and electromotive force curves is different at different parts of the curve; in the case of the Thomson-Houston alternator there is no difference of phase between the maximum values of the current and electromotive force, but a considerable difference between the zero values. In the diagram of the Thomson-Houston alternator the position of the field poles is shown by the square rectangles, which, therefore, indicate the manner in which the electromotive force curve is related to the field poles in the machine. It must not be supposed that the form of the current curve, or of the electromotive force curve, is a fixed attri-

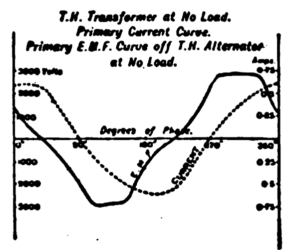

FIG. 14.

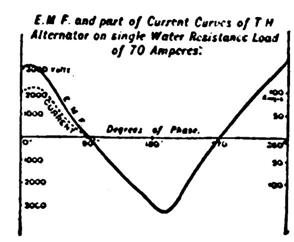

FIG. 15.

bute of the alternator, that is to say, we cannot speak of the electromotive force curve of an alternator as if it were something unchangeable and peculiar to that machine. It often largely depends upon the nature of the load. Thus, for instance, in Fig. 14, is shown the form of the electromotive force curve of a Thomson-Houston alternator when very lightly loaded, and in Fig. 15 is shown the electromotive force curve of the same machine when loaded on a non-inductive resistance to a fair proportion of its full load; whilst on referring to Fig. 13 we see the form of the electromotive force curve of the same machine when working on an inductive load, and it will be noticed how very different in form are those three curves.

[3] For further details see the "Alternate Current Transformer." Fleming, Vol. i. (new edition), p. 521.

THERAPEUTICAL EFFECTS OF CURRENTS OF HIGH FREQUENCY.[1]

BY A. D'ARSONVAL.

CURRENTS of high frequency act powerfully to increase the intensity of organic composition as I have demonstrated previously. I have thought for some time that this particular method of electrical energy would give good effects in the special class of diseases so long studied by my friend Prof. Bouchard, under the name of "Diseases due to Lack of Nutrition." Certain forms of surgary diabetes, gout, rheumatism, obesity, etc., are in this class. I instituted at the beginning of the year a series of clinical researches on this subject. The experiments were made at the Hotel Dieu by the medical staff directed by my assistant, Dr. Charrian, and were under his control from the medical point of view. The results obtained so far have so completely met my expectations that I am able to describe some of them now.

These are the methods instituted in these researches: I reject completely all the results depending upon the imagination of the patient, and take account exclusively of the physico-chemical modifications or exact clinical measurements. I eliminate in this way entirely the subjective changes which would be attributed to suggestion. Besides, positive results were obtained with animals and we can answer such an objection to start with in the case of patients.

The observations recorded by the author refer to two patients with diabetes and one with obesity. The variations of temperature were taken twice a day, as well as the arterial pressure, which was measured by the aid of the sphygmomanometer of Prof. Potain. The analysis of urine was made by Mr. Guillemonat and was carried out in the following manner: Each day from urine passed in twenty-four hours there was taken one-fifth for example of the total volume. Every five days an analysis was made. By this process we have a method which eliminates the causes of error due to daily variations. Precautions were naturally taken to prevent the decomposition of the urine. The urotoxic co-efficient of the urine, a co-efficient of which we know the great importance to-day, thanks to the work of Mr. Bouchard, was taken by Mr. Charrian in his laboratory. Finally, the application of current was made with the greatest caution under my directions by Mr. Bonniot, not connected with the staff, who was a pupil of Drs. Tripier and Apostoli. In a word, every precaution was taken to give these observations a character of precision which should give them value. The analysis of the gas of respiration as well as the radiation of heat from the patients was taken with equal care.

A word now as to the arrangement of the instruments per-

[1] From "L" Industrie Electrique."

mitting the production of currents of high frequency at the bed of the patient. I could not consider using the apparatus described in my previous communication for the reason that the Hotel Dieu is not connected to an electrical station. In order to periodically charge the condenser I had recourse to a Ruhmkorff coil, operated by storage batteries. Under the influence of the energetic current which traverses it the hammer very rapidly soldered itself to the anvil and this closing in short circuit led to the rapid deterioration of the coil and the accumulators, if constant care was not taken to prevent this action. To avoid this, I had made by Mr. Gaiffe the following modification shown in the accompanying illustration, Fig. 1. The anvil, instead of being fixed, was continually rotated by means of a small electric motor operated from a

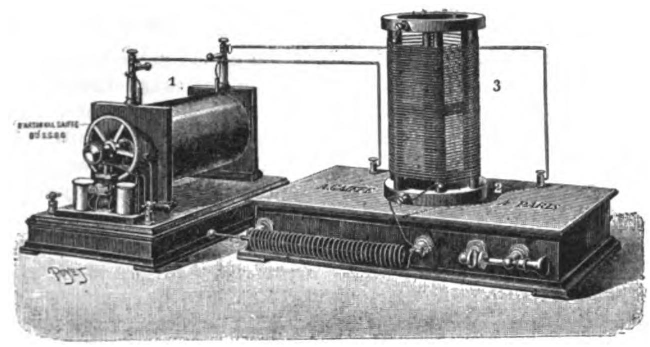

FIG. 1.

branch circuit from the accumulators. If the sticking took place it could not be maintained, and the interrupter thus acted without any watching. The coil charges the flat condensers connected in series, which are contained in the box situated alongside of the coil.

The current of high frequency was taken off as usual at the extremities of the solenoid. Its intensity was regulated by using a greater or less number of coils, and it was measured by the galvanometer, represented in Fig. 2, which is constructed to measure currents of high frequency. This is a thermo-galvanometer, composed of a fine wire, the heating of which is registered by variations in its length, and is indicated by a movable needle upon a scale divided experimentally in milliamperes on one side, and in volts on the other. This apparatus permitted us to pass through the organism currents of which the intensity was upwards of 500 milliamperes.

I have indicated already three principal processes for electrization by currents of high frequency. The first consists in bringing to the part of the body which one wishes to treat the currents which come from a solenoid, by means of con-

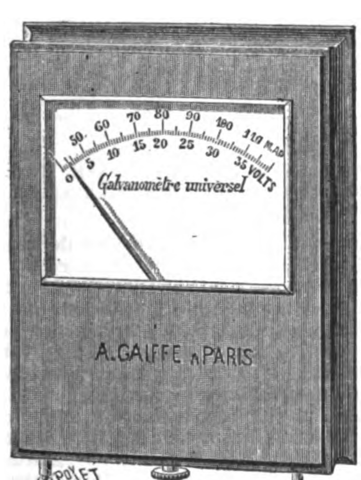

FIG. 2.

ductors with appropriate electrodes. The second consists in placing the patient in a solenoid which does not touch him, but which induces in his body currents of a similar frequency. This is the method of auto-conduction or induced faradization. In the third method the patient constitutes one of the armatures of a condenser charged statically by the solenoid as represented in Fig. 3.

In the observation here analyzed the first process was employed. The currents from the solenoid, traversed the entire body from the hands to the feet. One of the poles of the solenoid was connected with the water in a foot-bath, in which the patient placed both feet. The second pole was connected to both hands by a two-part conductor terminating in metallic handles. Under these conditions the current was distributed, and its intensity was varied between 350 and 450 milliamperes. The duration of treatment made daily was at first of six minutes and was lowered successively to five and to three minutes according to the sensitiveness of the patient. This current, I repeat, acted without the knowledge of the patients, so they submitted without repugnance to the operation.

The following observations are simply our conclusions: High frequency always acts powerfully on the circulation, and suggestion is not sufficient to explain the good effects of electricity, since the patients who had not benefited by the treatment had faith in it, contrary to precedent, and were astonished to find themselves no better. If this view opens new promise to therapeutics I wish to put it before doctors in a clinical point of view. I have shown experimentally that high frequency is a powerful modifier of organism.

I should add a word from the theoretical point of view. Why is it that these currents which act so powerfully make no impression upon the sensibilities? Physicians say that the cause is their superficial localism. I have shown by abundant proofs of a physiological order that these currents on the contrary penetrate deeply into the organism and operate notably on the vaso-motor centers. Physicians have not considered that their explanation only applies to bodies which are good conductors, like the metals. In the case where the conductors considered have only the conductivity of the human body (inferior to that of water in the ratio of 1 to 100), the same rules show that the division of the current should be sensibly uniform through the organism. It is easy to verify this, however, as I have done, with a cylinder of glass full of salt water, of which the dimensions were 70 centimeters in

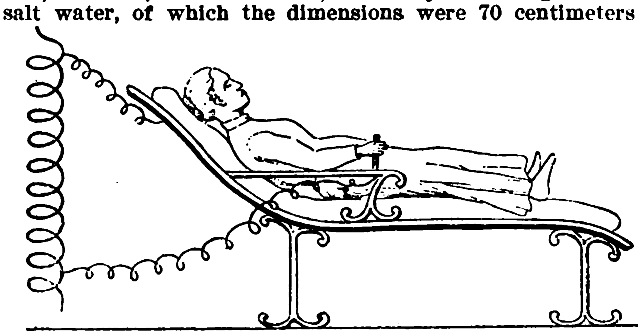

FIG. 3.

length and 25 centimeters in diameter. The density of the current whether at the center or near the outside did not vary at all in its value. The true explanation of the harmlessness of currents of high frequency is, therefore, of a physiological nature, in conformity with what I have stated on the subject.

THE ORGANIC MEMBRANES AS INSULATORS.[1]

BY SIR BENJAMIN WARD RICHARDSON, M. D., F. R. S.,

Up to the present time we have been content to look upon a membrane of the body, the pericardium, the periosteum, the capsule of the kidneys, and any structure of the kind, as a covering of the organ wrapped up in it, that holds the organ, as it were, in a mold, supports it in its place, allows it to glide, and by virtue of the fluid secreted, keeps it distinct and separate. There can be no question that these grand functions belong to the membranes, which have ever been to us structures of the utmost moment. I have watched the influence of many substances upon them; have noted their conditions during the various stages of life, and have examined their degenerations during disease and after death. But I have recently made observations on these structures—membranes—which, if I am right, give them a new value, or rather a value that has not before been appreciated. It seems to me they are electrical insulators, and by their presence confine and render useful the vital force that is developed in the organs they surround. My first observations leading to this conclusion were conducted on the nervous membranes—those that envelop the cerebral convolutions and the spinal cord; from these I passed on to the other membranous envelopes, to find that they all have a common quality.

I obtained an electrical battery consisting of 24 small cells, so arranged that one cell could be put on at a time, or the whole, or part of the whole, as might be required. I commissioned Messrs. Faraday, of Berners street, to construct for

[1] London "Lancet."

me a delicate galvanometer, the needle of which moved in a millimetre circle and certified, with accuracy, the force of the current transmitted. I fixed to one pole of the battery a conductor which was connected to the galvanometer, and from the opposite pole of the battery attached a platinum conductor of the same length and carried it also to the galvanometer. This last conductor I divided in the center and joined the end of the portion from the galvanometer to a platinum disk that was secured by its under surface to a porcelain slab. The other half of the conductor (from the battery) was allowed to remain free with a probe-like end, which could be used at any moment to touch the platinum disk and complete the circuit, or to touch any substance laid upon the disk that would either conduct or break the current. The apparatus, when complete, acted perfectly, and the minutest current could be detected. Sometimes I used the battery with a single cell, sometimes with more than a single cell, while, as a general rule, I used the whole power of cells—24 in number. When all was in order and the battery in action, the platinum probe was brought into direct contact with the platinum disk, and the current was proved by the deflection of the needle on the galvanometer. After this, the needle being steadied and set, a piece of some thin membrane was laid on the platinum disk, and its conduction or resisting power tested with the results to be described.

Dura Mater.—A disk was cut from the dura mater of a dead sheep, and, after being thoroughly cleaned, was laid on the platinum disk. The probe-like end of the conductor from the battery was then pressed upon it, when the current was found to be completely intercepted. The insulation was in fact, perfect. A piece of membrane covering the spinal cord at its upper part, stripped off and carefully cleaned, was laid on the platinum disk, and the probe end of the conductor was put upon it. It resisted the current as effectively as a layer of india-rubber or gutta percha or a fine slice of fatty tissue could have done.

Periosteal membrane.—From off a bone a bit of periosteum detached, cleaned, and laid on the platinum plate insulated perfectly.

Pericardial membrane.—This membrane was tested in the most careful manner and yielded the same result.

Endocardial membrane.—There was more trouble with endocardial membrane than with pericardial, for the structure is very fine and strongly adherent to the underlying substance. But when cleanly dissected out, it was found to be as perfect an insulator as the pericardium, so that the heart structure proper is apparently inclosed in two layers of insulating membrane. The endocardial lining of the arteries showed the same character; the valves of the heart cut out entire did not absolutely insulate, but the membrane covering them on either side did.

Peritoneal membrane. —Portions of peritoneal membrane were taken from various parts—from the liver, from the spleen, from the intestine and from the bladder. When the membrane was derived from any of those sources and scrupulously cleaned and spread out on the platinum disc, it resisted just as the other membrane had done, and proved itself an insulator.

Capsule of the kidney.—The readiness with which the capsule of the kidney can be detached renders it a good specimen for experiment, and it was freely used. It proved to be a perfect insulator, and we may consider that the kidney as it swings in its place is completely insulated.

Lining membrane of an egg.—The thin lining membrane of an egg detached from the inside of the shell, when tested, showed the same insulation.

It was a question whether mucous membrane in the same manner as serous membrane resists the current. To test this fact, mucous membrane was taken from the side of the tongue of a sheep, from the lining of the intestinal canal, and from the lining of the trachea. The membrane had to be carefully cleaned, with the greatest attention to detail, and when it was laid out in its pure character of membrane it also insulated.

In the above, physiological observations have alone been named, but there are pathological ones connected with the subject of equal moment. The absorption of water by membrane, water being a conductor, may interfere with insulation in the case of dropsies, and some deposits may also interfere, but these and other points remain for investigation.

HÜBNER STORAGE BATTERY PLATE.

A novel form of electrode has been invented by George Hübner, of Baden, in which the active material may be cast without any supporting grid, and which has a hard, porcelain-like finish.

In constructing these plates, there are melted together nitrated hydrocarbons, e. g., dinitrobenzol, mononitrobenzol, or bromonitrotluol, with nitrated cellulose, e. g., mononitrocellulose, cellulose meal, and lead oxids. The cellulose meal may be prepared by grinding cellulose. For cheapening the plates it is advisable to add tar or its derivations. The mixture, when cooled, forms a dense, hard, porcelain-like product. Before it cools it can be cast in molds, and be thus formed into plates, which without any support or other accessory are sufficiently rigid to be used as storage-battery plates.

Plates having about one hundred square centimeters area, constructed as described, may be charged with a current of from thirty to forty amperes without suffering in any way.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES—IV.

BY J. A. FLEMING, M. A., D. SC., F. R. S., M. R. I.

Leaving the further elaboration of these points, we must next notice some of the facts with respect to the magnetization of iron at low temperatures. Professor Dewar mentioned in a discourse on the scientific uses of liquid air some results obtained on cooling small steel magnets. These effects we have since again explored at greater length. Let me show you in the first place the effect of cooling a small steel permanent magnet to the temperature of liquid air. We will first take a magnet made of knitting-needle or ordinary carbon steel, and examine the effect of low temperature upon it. Placing the magnets behind the small suspended magnetic needle of a magnometer, we obtain a deflection of the magnetometer needle which is a measure of the magnetization of the magnet causing the deflection. On bringing up a small vessel of liquid air and immersing in it the magnet under test, we notice at once a sudden decrease in the deflection of the magnetometer needle. This indicates that a notable percentage of the magnetization of the magnet has been removed. On taking away the air bath and allowing the magnet to heat

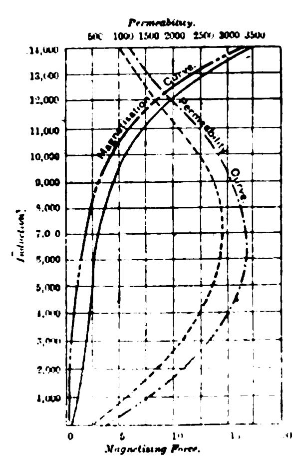

FIG. 10.—PERMEABILITY OF SOFT ANNEALED IRON. TWO OUTER CURVES AT 15° C.; TWO INNER CURVES AT 186° C.

up again we find that there is a still further decrease in magnetization. On cooling it again with liquid air the magnetization increases, and from and after that time the effect of the cooling is always to increase the moment of the magnet, and the effect of heating it up again always to decrease the moment of the magnet. Hence we see that the effect of the first immersion in liquid air was to give a shock to the magnet which deprives it permanently of a considerable percentage of its magnetism, but when once it has survived this treatment, then cooling it strengthens the magnet and warming it weakens it. This is not by any means always the case. If we take a magnet made of the 19 per cent. nickel steel, the peculiar characters of which were explained a few moments ago, we shall find a very different state of affairs. Here we see the first effect is, as before, to remove a very considerable percentage of the initial magnetization, but after that stage is passed, then cooling this nickel-steel magnet always weakens it still more and warming it up again strengthens it. The subsequent effect of cooling is therefore in the opposite direction in the carbon steel and in this nickel steel.

We have in this way examined the behavior of magnets made of a very large number of steels—chromium steels, aluminum steels, tungsten steels, silica steels, and nickel steels in various states of temper hard and soft. We find that in some cases there is no initial decrease of magnetism at all, and that

the steady state begins at once. Broadly, however, the results amount to this: a steel magnet when plunged into liquid air generally loses some fraction of its magnetization, but that after a few such immersions it arrives at a fixed condition, in which the effect of cooling it is in most cases to produce an increase of magnetic moment, but in a few exceptional cases to produce a decrease of magnetic moment.

In the technical use of magnets for instrumental purposes they have to go through a process called ageing to get rid of the sub-permanent magnetism. One of the best ways of ageing a magnet is to plunge it several times into liquid air. We have given a large amount of attention to a study of the changes taking place in the magnetic qualities of soft or annealed and also hard iron when cooled to very low temperatures. In the first place, we have examined the change in the permeability of iron at the temperature of liquid air. If a ring of iron is wound over with a coil of wire and subjected to gradually increasing magnetizing forces, this produces magnetization in the iron, but the magnetization does not increase proportionately with the force. It tends to a limit, and the curve which shows this variation is called a magnetization curve. The number which expresses the ratio of the magnetization to the magnetizing force is called the susceptibility of the iron. Instead

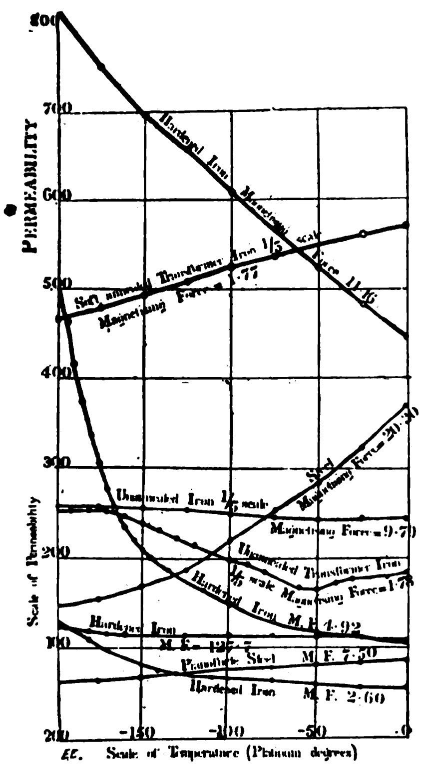

FIG. 11.

of considering the magnetization of the iron as one of the variables, it is often convenient to consider the induction in the iron, and the induction is defined as a quantity the rate of change of which with time measures the e. m. f. set up in a secondary circuit wound round the iron ring.

The ratio between the induction and the magnetizing force at any instant is called the permeability of the iron. By tedious experiments with the ballistic galvanometer, it is possible to draw out a complete magnetization curve of the iron, starting from the lowest induction up to the point at which the iron becomes practically saturated. Assisted by Mr. J. E. Petavel, who has given us most valuable help in these very tedious magnetic observations, as well as the subsequent reductions of them, we have made a large number of observations on the permeability of a carefully annealed iron ring made of very fine Swedish iron of the highest quality (Fig. 10). The result is to show, as seen from the curve (Fig. 11), that cooling the iron to —200 deg. slightly diminishes the permeability. In other words, it requires a greater magnetic force to produce a given amount of magnetization when the iron is at —200 deg. than when it is at the ordinary temperature. When, however, we began to study the behavior of hardened iron in this respect, we found ourselves in the presence of very curious effects. If pure iron which has been carefully annealed is twisted, knocked, bent, stretched or compressed, it passes into a state known as hard iron; and hard iron has very different magnetic qualities from soft iron. A very extended series of experiments with rings of hard iron have shown that hard iron, at least in certain cases, has its permeability greatly increased by cooling; and this change takes place with great suddenness. We can show you by a simple experiment that this is the case. If we take this hard iron ring, which has two coils of wire wound round it, and connect one of these circuits to a battery, we shall send a current through this primary coil and magnetize the iron ring. If the other or secondary circuit is connected to a galvonometer then at the instant of starting the primary current there is a transitory induced current produced in this secondary circuit. As long as the induction in the rion remains constant, no electric change will take place in this secondary circuit. If, however, we plunge the iron ring into liquid air, we find again a secondary current produced at the moment of cooling the iron. This indicates a sudden increase of permeability at the instant of cooling. If we bring the ring out of the liquid air we find it retains some of the increased permeability acquired on cooling, but loses a portion of it more slowly if it is heated up again to ordinary temperatures by plunging it into a bottle of alcohol. Owing to these changes we found it impossible to repeat again exactly any required magnetization curve in the case of the hard iron. The sudden cooling alters the magnetic qualities of the iron to such an extent that it is not possible to get it twice in exactly the same state.

ELECTROMAGNETIC WAVE DETECTOR.

In a recent communication to the Royal Society, entitled "A Magnetic Detector of Electrical Waves and some of its Applications," Mr. Rutherford investigates the effect of Leyden jar discharges on the magnetization of steel needles, and shows that the demagnetization of strongly magnetized steel needles offers a simple and convenient means for detecting and comparing currents of great rapidity of alternation. The partial demagnetization of fine steel wires, over which is wound a small solenoid, was found to be a very sensitive means of detecting electrical waves at long distances from the vibrator. Quite a marked effect was found at a distance of over half a mile from the vibrator. Detectors made of very fine steel wire may be used to investigate waves along wires and free vibrating circuits of short wave-length. Fine wire detectors are of the same order of sensitiveness as the bolometer for showing electrical oscillations in a conductor. This detector also has the property of distinguishing between the first and second half oscillations of a discharge, and may be used for determining the damping of electrical vibrations and the resistances of the discharge circuit.

WIND POWER.

A paper by Mr. E. O. Baldwin, published in the "Canadian Electrician," deals with the author's attempts to utilize the power of the wind for producing current. They are strong at windmills in Holland, where they use them for pumping purposes, but the difficulties in the way of getting a useful supply of current are much greater than when the only work required is to lift water a short distance and speed regulation is of no importance. Mr. Baldwin's regulating apparatus consists of an additional coil on the field magnets to act as demagnetizing coil, and an electro-magnet which attracts a pivoted iron arm against the resistance of a spring and throws the demagnetizing coil into the field circuit whenever the voltage rises above the desired point. There is a very rapid vibration of the arm, and Mr. Baldwin states that he can adjust the regulation so that lamps can be run directly off a dynamo belted to the windmill without any perceptible flickering. Normally, however, a storage battery is used.

ELECTRIC CURRENT IN THE AUDITORY NERVES.

In a communication to the Académie des Sciences, MM. H. Beauregard and E. Dupuy described some experiments carried out by them "On the Electrical Variation caused in the Acoustic Nerve by Sound." These investigators find that whenever a sound falls upon the tympanum, an electric current traverses the acoustic nerve and is proportional to the pitch of the note, though they have not as yet established the connection between the current and the volume of the sound. They point out that this discovery places in the hands of physiological investigators what they consider to be a very certain method of determining the limits of audibility in different animals.

WE have received a circular from Messrs. Moura, Deans & Co., 5 Rua do Hospicio, Rio de Janeiro, Brazil, offering their services as patent solicitors and as a general bureau of information for industry, trade and commerce of Brazil. Mr. A. Guimaraes, of 95 Broad street, New York, is the firm's correspondent in this country.

OLD HORSE CARS AS SUMMER HOUSES.

When the car horses throughout Connecticut cities were retired, a few years ago, with the coming of the trolley, people wondered what would become of the 600 cars that they had dragged so long. No one would have guessed then that a brisk demand for these old cars would spring up in one season and would almost completely exhaust the supply. Yet such has been the case this summer.

The cars have been sold for summer shelters in rural districts, for hunters' camps, for lodges by solitary lakes, for cabins on house boats, and, most of all, for the homes of campers on the coast of Long Island Sound and its islands. As a bicycle advertisement catch line reads, "You see them everywhere" this summer.

All along the Sound beaches from Larchmont to Watch Hill and even out on Block Island these cars are found, poised on breezy bluffs, by purling brooks, and on shining sands, some as annexes to pretentious cottages, some strung together like a vestibuled train, some painted in the most fantastic hues, but all doing duty as efficiently as before the day when the car horse became extinct. The happy idea of using the cars for summer camps has been so generally adopted that one finds a South Norwalk car unexpectedly confronting him at Black Rock Harbor, a lot of Waterbury and Bridgeport cars at Stratford and Merwin's Points, New Haven cars at Woodmont, Savin Rock, and Morris Cove, Hartford and Middletown cars at Branford Point, Double Beach, Guilford, and Saybrook, and Norwich cars and stages on the Thames River and on the Eastern islands. So extensive has the demand become for cars that Station Agent Hayward, at the Union station of the Consolidated road in New Haven, recently received a letter of inquiry from a woman inland, asking him for his lowest prices for passenger cars; also, for a list of styles.

A Norwich party at Scotchcap, on the Thames River, have arranged four horse cars in the form of a hollow square. A canvas awning covers the courtyard made by the cars, and a tall flagstaff rising from the center completes the pleasing establishment. One of the cars is used as a kitchen and workshop, and the others are lounging, sleeping, and reception rooms. Duncan De Wire, on Block Island, has five of the cars, arranged like the connected cars of a vestibuled train.

HORSELESS CARRIAGES.

From recent careful observation of the behavior of petroleum driven carriages, says the London "Electrical Review," it is surprising that many of the French people can run their vehicles at all. They appear to think that the engine needs no attention. Many carriages which in their hands have given difficulty, have been run by a well-known English expert without any trouble. One matter, however, seems to be proved as a consequence, viz., that unless the coachmen of the future are mechanicians, all motor carriages will have to be greatly simplified. Indeed, in certain quarters, much attention is now being given to this part of the subject, and in due course we hope to see a carriage of adequate horse-power and simple in the extreme. In the meantime the public should be warned against buying a good deal of rubbish which is being offered, and we therefore suggest that any would-be purchaser should insist upon the following test before he closes a bargain: He should see the vehicle travel up and down hill for not less than thirty miles at a stretch, and at the end of this trial run it should be seen that none of the parts have become too hot. The question of whether the mechanism is of the most approved type he must naturally leave to an independent expert. There are several carriages in this country about which much fuss is being made, but which we are confident could not perform the journey mentioned, although for short runs such as can be observed at the Imperial Institute, Crystal Palace, the Hurlingham Club, etc., success seems assured. There are many easily-led people who would eagerly purchase a horseless carriage on the strength of such seemingly perfect, though utterly useless, performances.

THE BIG COTTONWOOD POWER CO.

The long distance transmission plant of the Big Cottonwood Power Company, which our readers will remember was described in our pages some time ago, was started on the second of last June. They have since closed a contract with Salt Lake City to furnish three hundred 2,000 candle-power arc lights for street lighting, at $8.50 each per month. The contract is for one year and is based on the Philadelphia schedule.

They have also a ten-year contract with the Salt Lake and Ogden Gas and Electric Light Company to supply current, the minimum guarantee being 2,000,000 units annually.

HORSE POWER AND CRITICISM.

There is a critic who always has his jaundiced eye on our columns, whether to carp at ourselves or our correspondents. In his haste to get at our correspondent, Mr. Steavenson, however, he allowed his physiological ignorance to blind him somewhat. Mr. Steavenson referred to the power exerted by a horse at the moment of starting, and our critic animadverts upon this on the ground that a horse pulling against a resistance and not moving forward can be doing no work, there being no motion. This may be true of a steam-pressed piston, but it is not true of animal power. The horse must expend energy in keeping a stress upon its traces, and to attempt to draw strict mechanical parallels without brains is an erroneous proceeding, though possibly well suited to our critic's capacity. Let him try lifting himself in a basket. He may then perceive that, though he will be performing no useful work—a condition of things to which, no doubt, he is accustomed—he will, in keeping up a steady upward pull, be expending energy that would in time tire the strongest and longest arm.—London "Electrical Review."

ODD JOBS FOR NIAGARA.

The owners of the new Lewiston & Youngstown electric railway, which is to be known by the shorter title of the "Old Fort Route," expect to have the road in operation this week as far as the village of Youngstown at least. Cars have been run within the limits of the village of Lewiston. Power for this road will be supplied by the Niagara Falls Hydraulic Power and Manufacturing Company, it practically being a continuation of the Gorge road service.

Along the route of the Niagara Falls and Lewiston Railway the current of the lower Niagara is very rapid, and efforts to utilize it are likely to be made in the near future. This railway company controls the river bank for a distance of six miles, and could a good current motor be obtained there is no doubt but what it would profit largely by the possible development. Two men have already been ambitious enough to exhibit motors, but both plants were swept away by high water.

The Cataract Power Company, a Canadian concern, not identified with the Niagara development, has offered to run the beach pumping station of Hamilton, Ont., at a price which has led E. A. C. Pew, representing the Hamilton and Lake Erie Power Company, to write stating that he some time ago made a proposition to run the works for $25 per horse-power a year, at which rate he estimates the city would be saved $20,000 a year. Mr. Pew further calls the attention of Hamilton people to the fact that he has enlisted capital in the erection of a plant, and that it was on the strength of a resolution passed by the council that capital was led to invest in the projected electric plant, but the resolution in question was only a promise to consider the scheme.

LYONS, N. Y.—The Wayne County Traction Company has been organized with a capital stock of $60,000, divided into 600 shares of $100 each. The principal office is to be in Lyons, N. Y., the purpose of the company being to construct and maintain a trolley line between Lyons and Newark, N. J., as soon as a charter can be secured. The officers of this company are: President, A. C. Robertson, Athens, Pa.; vice-president, Orlando F. Thomas, Lyons; secretary, D. N. Johnson, Athens, Pa.; treasurer, F. K. Harris, Athens, Pa. Directors: F. N. Dean, Ithaca, N. Y.; Burton Hammond, Charles Taft Ennis, Clement R. Sherwood, all of Lyons, N. Y., and N. C. Harris, Athens, Pa.

THE HAZELTON BOILER COMPANY, New York City, report recent sales of boilers aggregating 2,450 horse-power, among which we notice the following. The Rochester Gas and Electric Company, Rochester, N. Y., 500 horse-power; the Bristol Electric Light and Railway Company, Bristol, Conn., 200 horse-power; the Canandaigua Electric Light and Railroad Company, Canandaigua, N. Y., 250 horse-power. The Hazelton Company report that nearly all of their orders now being received are for the earliest possible delivery, and that many of their recent sales have been made to old customers, who are now enlarging their plants. The original boilers sold to these customers have been in constant operation for from eight to ten years, without repairs, still carrying high pressure, and giving the same good results as when new. This, together with the fact that the Hazelton Company has made various improvements in the construction and setting of their boilers, increasing their efficiency and economy, and improving their appearance, makes it much easier for them to make sales now than formerly. These facts are not only gratifying to the company, but also seem a pretty sure indication of an improved feeling and condition in manufacturing business generally throughout the country.

Society and Club Notes.

ELECTRICAL CREDIT ASSOCIATION FOR CHICAGO.

A meeting of the representatives of the electrical trade of Chicago was held on July 30, to consider the advisability of organizing a credit association, somewhat similar to those existing in Boston, New York and Philadelphia. The following firms were represented:

Washburn & Moen Manufacturing Company, J. A. Roebling & Sons Company, Central Electric Company, Electric Appliance Company, American Electrical Works, Anchor Electric Company, Bryant Electric Company, S. F. B. Morse, American Circular Loom Company, Standard Underground Cable Company, Geo. Cutter, Chicago Edison Company, Western Electric Company, Osburn Bros., Dearborn Electric Company, Chicago General Fixture Company, Chas. E. Gregory Company, Sunbeam Incandescent Lamp Company, Lescoen, Macomber Whyte Company, J. M. Hill, Wagner Electric Manufacturing Company, Columbia Lamp Company, New York Insulated Wire Company.

A temporary oganization was effected by the election of Mr. F. Overbaugh chairman, and Mr. Jas. Wolff secretary. The discussion of a permanent organization was carried on at considerable length, and many valuable suggestions were made. The following committee was appointed to draw up by-laws, etc., for a permanent organization: Mr. W. H. Carpenter, of the Western Electric Company; Mr. C. A. Brown, Central Electric Company; Mr. W. N. Anthony, Chicago Edison Company.

The officers of the temporary organizations will act as ex-officio members of said committee, and a meeting will be held August 11, when it is expected a permanent organization will be established.

The organization of an association of this kind in the West for the protection of the supply houses is one that is greatly needed when the nature of some of the recent failures is taken into consideration, and its permanent establishment should be welcomed by all who believe in transacting business on a sound basis.

EXCURSION OF THE GENEVA INTERNATIONAL CONGRESS OF ELECTRICIANS.

In connection with the Electrical Congress held in Geneva this month, an excursion has been projected through Switzerland, during which the principal electrical installations in that country will be visited. The excursion will last six days, beginning Monday morning, August 10, and ending Saturday evening, August 15. The following itinerary has been prepared:

Monday: Leave Geneva at 7 a. m. Stop at Lousanne to visit the electric railway installation. Stop at Fribourg to visit the electrical and hydraulic plants of the Administration of the Waters and Forests, and the Jurasimplon railroad, the cars of which are lighted by storage batteries. Arrive in the evening at Neuchâtel, passing by Morat and the lake of Neuchâtel.

Tuesday: Excursion to Noiraigue to visit the electric and hydraulic installations at Val-de-Travers. Visit to the elevator works of the Chaux-de-Fonds at Champ-du-Mulin. Visit to the works of Combe-Garrot, supplying Chaux-de-Fonds and Locle. Visit to the works of the city of Neuchâtel, having monophase and polyphase currents. Leave for Berne.

Wednesday: Visit to the municipal plant of Berne. Leave for Langenthal. Visit to the works of Wynau, using triphase current. Arrive at Aarau.

Thursday: Visit to the electric plant at Aarau, using diphase and continuous currents. Leave for Bremgarten. Visit to the works of Zufikon, which supplies triphase current to the manufacturers of Zurich. Arrive at Lucerne. Visit to the electric works at Thorenberg.

Friday: Voyage on the lake of the Quatre Cantons, in chartered boat. Excursion to Stanserhorn—altitude 1,900 meters—by a cable road run by electricity. Visit to the works of Rathausen. Arrive at Zurich.

Saturday: Visit to the electrical plants of Zurich and neighborhood: Oerlikon, Baden, etc.

MEETING OF THE SOCIETY OF THE MILITARY TELEGRAPH CORPS AND THE U. S. OLD TIME TELEGRAPHERS.

The Society of the United States Military Telegraph Corps and the Old-Time Telegraphers' association, will meet in Pittsburgh September 9, 10 and 11 next.

Among the members expected at the meeting are Thomas A. Edison, Gen. T. T. Eckert, president of the Western Union Telegraph Company; A. B. Chandler, president of the Postal Telegraph and Cable Company; J. D. Reid, Andrew Carnegie, Thomas M. King, H. W. Oliver, David McCargo and Robert Pitcairn.

The chairman of local committees are as follows: Arrangements, C. M. Schaefer; transportation, W. D. Vincent; reception, John A. Munson; entertainment, Samuel T. Paisley; press, W. C. Connelly, Jr. Mrs. S. A. Duncan, chairman of the ladies' committee, will look after the reception and entertainment of the ladies.

The Old-Time Telegraphers' association will hold a business meeting Wednesday, September 9 at 10 a. m. at the Monongahela House; at 2 p. m. the business meeting of the United States Military Telegraph Corps will be held at the same place. At 8 p. m. there will be a lecture by A. B. Chandler, Esq., president of the Postal Telegraph Cable Company. Thursday, September 10, an excursion to prominent industrial establishments will be followed by a banquet at the Monongahela House. Friday, September 11, the members will visit the glass works, parks and other points of interest around Pittsburgh.

Educational.

CURRY UNIVERSITY ACQUIRES THE KEYSTONE ELECTRICAL COLLEGE.

The Keystone Electrical College, Pittsburg, has combined with the Curry University electrical department. Dr. Leon Le Pointois, who will be its head, is the electrical engineer of the Baltimore and Ohio Railroad. Associated with him in the new electrical faculty are Charles Hyde, M. E., Victor Bentner, M. E., Prof. J. A. Calderhead, C. E., and Morris W. Mead as lecturer on applied electricity. The course of the institution is to be strictly technical.

Obituary.

SIR WILLIAM GROVE.

The death is announced of Sir William Grove, at the age of 85. He was educated at Oxford, where he proceeded to the degree of M. A. in 1833. Two years later he was called to the bar at Lincoln's Inn. Being temporarily prevented by ill-health from following the legal profession, he turned his attention to the study of electricity, and in 1839 invented the powerful voltaic cell which bears his name.

He was Professor of Experimental Philosophy at the London Institution from 1840 to 1847, and he took an active part, as a member of the Council, in the business of the Royal Society, particularly in the reform of its constitution, effected, after a severe struggle, in 1847. Mr. Grove became a Q. C. in 1853. He first promulgated the doctrine of the correlation of physical forces in a lecture in 1842.

Personal.

PROFESSOR J. P. BARRETT has retired from the presidency of "The Electrical Journal" and from the field of electrical journalism.

THOS. F. CLOHESEY, Electrical Engineer, has completed plans and specifications for an underground cable system for the Fire Department wires at Cincinnati.

MR. ALBERT F. MADDEN, who has been so long associated with the invention and manufacture of storage batteries, has joined the forces of the Electric Storage Battery Company.

MR. JAMES E. KEELYN, president of the Western Telephone Construction Company, of Chicago, will be at the Astor House, New York, arranging important business extensions during the last two weeks in August.

MR. M. N. FORNEY, mechanical engineer, has opened an office in the Taylor Building, 41 Cortlandt street, as a designing, constructing and testing expert, and as a consultative and representative purchasing agent. Mr. Forney's high standing and distinguished ability are known to everyone in the railway and mechanical world, and we do not hesitate to commend his professional services warmly. Mr. Frank J. French will be his business manager.

NIAGARA FALLS.—The Niagara Falls and Lewiston Railroad Company, the "Gorge Road," have purchased a plot of ground 232 feet square between the New York Central tracks and the edge of the bank and are clearing it preparatory to erecting a fine brick and iron car shed, 200 feet square. The building will be 20 feet in the clear, and will stand close to the point where the tracks of the road reach the top of the river bank.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Central Stations:

FRANKFURT ON THE MAIN ELECTRICITY WORKS.—Abstract of annual report.—"Elektrot. Anzeiger," July 23, '96.

COMBINED LIGHT AND POWER PLANT.—The lighting and power supply for Rome is illustrated and described. Tivoli, 12 miles from the city, furnishes the water power. An auxiliary plant is at Rome, the latter being a steam plant. Several interesting illustrations accompany the description part, as, for example, diagram, showing energy transmitted and absorbed in the combined power and light station, load diagrams. Diagram of transformer stations, section of tramway, etc.—Lond. "Engineering," July 24, '96.

Dynamos and Motors:

COMPOUND DYNAMOS IN PARALLEL.—By A. O. Dubsky and P. Girault. A short discussion of the requirements, especially with reference to railroad service.—"L'Ind. Elec.," July 25, '96.

Thermo-Electricity:

THERMO-TROPIC BATTERY AND A NEW METHOD OF DEVELOPING ELECTRICAL ENERGY.—By C. J. Reed. Writer considers that Dr. Jacques' battery is not a galvanic, but a thermo-electric, cell. He furnishes experimental proof and gives also a definition of the difference between galvanic and electrolytic action.—"Elec. Eng'r.," Aug. 5, '96.

Electro-Chemistry:

COMMERCIAL OZONE.—By E. Andreoli. On the various methods of producing azone for practical purposes.—"L'Electricien," July 25, '96.

ELECTRIFIED VAPORS.—By G. Schwalbe. This paper deals with the behavior of the electrified vapors rising from fluids.—"Ann. der Phys. u. Chem.," July, '96.

Electro-Physics:

THE ELECTRO MAGNETIC THEORY OF DISPERSION.—By H. von Helmholtz. Translated with notes from Wiedemann's Ann. by James L. Howard, D. Sc., in Lond. "Elec.," July 24, '96.

ATMOSPHERIC ELECTRICITY.—By C. Chree, D. Sc. Paper read before the Roy. Soc. Some observations made at the Kew Observatory.—Lond. "Elec.," July 24, '96.

POLARIZED FLUORESCENCE.—By L. Sohucke. A contribution to the Kinetic theory of solids. This paper does not deal directly with electricity, but is mentioned here on account of the imporatnce of the subject in connection with Röntgen rays.—"Ann. der Phys. u. Chem.," July, '96.

ON THE DAMPING OF ROTATING DIELECTRICS IN A MAGNETIC FIELD.—By William Duane.—"Ann. der Phys. u. Chem.," July, '96.

ORGANIC MEMBRANES AS INSULATORS.—By Sir Benjamin Ward Richardson, M. D., F. R. S., in the London "Lancet." Quite a number of the membranes of the different parts of the body show considerable electrical resistance.—"Elec. Rev.," July 29, '96.

Lighting:

THE KINCAID ARC LAMP REFLECTOR.—A reflector consisting of four semi-parabolas arranged so as to throw light in four distinct directions at street corners.—"Elec. Eng'r.," August 5, '96.

SERIES GROUPING OF INCANDESCENT LAMPS.—Description of several high voltage systems.—"L'Ind. Elec.," July 25, '96.

Magnetism:

EXPERIMENTS OF MAGNETICALLY SOFT AND HARD BOTTLES.—By Alfons Kohn. An exhaustive study with experimental researches.—"Ann. der Phys. u. Chemie." July, '96.

Measurements:

TRUE RESISTANCE.—By Rollo Appleyard. Author holds that "true resistance" has no proven right in equations concerning the arc, since the word resistance is a conception derived from our experience of homogeneous metallic conductors.—Lond. "Elec." July 24, '96.

INDUCTANCE IN CABLES.—By A. Davidson. A few experiments illustrating the value of inductance as a negative capacity in submarine cables.—Lon. "Elec. Rev." July 24, '96.

A NEW FORM OF QUADRANT ELECTROMETER.—By F. Dolezalek and W. Nerust. Charging one electrometer needle from an outside source is overcome by introducing a small pile on a suspension inside of the instrument.—"Zeitschr. f. Elektrochemie." July 5, '96.

RESISTANCE MEASUREMENT OF ELECTROLYTES.—By F. Kohlrausch. In response to an attack author shows that measurements of electrolytes by means of an alternating current and a dynamometer can be made with a very high degree of accuracy.—"Ann. der Phys. und Chemie." July, '96.

UNIT SPOOLS OF SELF-INDUCTION.—By Max Wien. Author has constructed some standard spools which are practically independent of temperature and time.—"Ann. der Phys. u. Chem." July, '96.

Railways:

THIRD RAIL CONDUCTORS.—By Leo Daft. Some experiences with third rail experiments in the early days of the development of the electric railway.—"Elec. Eng'r." Aug. 5, '96.

RETURN CIRCUITS OF ELECTRIC RAILWAYS.—By Chas. Hewitt. From the "Journ. of the Franklin Inst." A general discussion of the subject.—"Indust. and Iron." July 24, '96.

Telephony, Telegraphy, etc:

TELEPHONES IN RUSSIA.—The aggregate of subscribers for the empire was, in 1895, 9,007 on companies, and 6,111 on Government systems.—Note in Lond. "Elec. Eng'r." July 24, '96.

BURGLAR ALARM.—A jewelry house in Chicago has attached a large bell on the outside of the building, which can be set ringing from many different places in the store.—"Western Elec." Aug. 1, '96.

TELEGRAPH MONOPOLY.—By Prof. Frank Parsons. One of a series of articles in which the telegraph monopoly in this country is being discussed.—"The Arena," July '96, see previous and subsequent issues.

Power Transmission:

NIAGARA-BUFFALO TRANSMISSION LINE.—An illustrated description of the new three-phase pole line and insulators.—"Elec. Eng'r." Aug. 5, '96. "Elec. Rev.," Aug. 5, '96.

COMBINED ELECTRIC LIGHTING AND TRACTION PLANTS.—By Hesketh and Rider. See Synopsis July 29, '96; also for paper in full "Elec. Rev." July 29, '96. Lond. "Elec." July 24, '96.

UTILIZATION OF THE ENERGY OF THE RHONE.—By E. Boistel. Description of the power transmission plant, with sections of the canal and the position of the generating plant.—"L'Electricien." July 25, '96.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED AUGUST 4, 1896.

Alarms and Signals:—

ELECTRICAL FIRE-ALARM SYSTEM. Charles D. Tisdale, Boston, Mass., 565,053. Filed Aug. 27, 1895.

Consists of a core wire of metal fusible at a low temperature, and an insulating material covering said wire, a second wire wound around said insulating material and an outer covering of insulating material surrounding the whole, said insulating coverings being readily destroyed by heat.

FIRE-ALARM SIGNAL BOX. George F. Milliken, Boston, Mass., 565,086. Filed April 20, 1891.

Non-interfering signal box.

TRAIN DESPATCHER'S CHART BOARD. John T. Williams, Brooklyn, N. Y., 565,150. Filed April 30, 1896.

A chart board having arranged thereon a miniature duplicate of the tracks controlled and miniature trains moving upon the chart in accordance with movement of trains on the regular track.

AUTOMATIC ELECTRIC FIRE-ALARM. Charles D. Tisdale, Boston, Mass., 565,188. Filed July 11, 1895.

Consists of two wires, one of which is made of fusible material that will fuse at a desired degree of heat, running side by side around the rooms, but not in contact with each other; an open electric circuit and a sounding device.

COMBINED TELEPHONE AND DISTRICT ALARM SYSTEM. F. Drake, San Francisco, Cal., 565,202. Filed Sept. 26, 1894.

Details of construction.

ELECTRICAL FIRE-ALARM SYSTEM. J. D. Gould, Brooklyn, N. Y., 565,410. Filed Aug. 27, 1895.

Similar to above.

Secondary Batteries:—

ELECTRODE FOR SECONDARY BATTERIES. George Hubner, Gernsbach, Germany, 565,140. Filed June 24, 1895.

For description see page 160.

Conductors, Conduits and Insulators:—

SUBWAY FOR ELECTRICAL CONDUCTORS. William H. Hart, Brooklyn, N. Y., 564,994. Filed May 20, 1896.

Constructed of two series of sections arranged end to end.

ELECTRIC CABLE FOR FIRE-ALARM SYSTEMS. Henry A. Reed, Newark, N. J., 565,178. Filed Dec. 30, 1895.

Comprises a central wire of fusible metal, an electric wire wound around said fusible wire, an insulating material over the two wires, an electric wire wound upon the insulating material, and an insulating material covering the whole.

CABLE FOR ELECTRIC FIRE-ALARMS. Henry A. Reed, Newark, N. J., 565,217. Filed April 20, 1896.

Similar to above.

CONNECTING DEVICE FOR ELECTRIC CONDUCTORS. Howard Gilmore, Easton, Mass., 565,344. Filed March 7, 1896.

The combination of body portion, base, hook, and spring carried by the base, rosette and blade carried by rosette to make the shank of the hook a step for the blade.

Dynamos and Motors:—

COMPOUND-WOUND POLYPHASE GENERATOR. B. G. Lamme, Pittsburg, Pa., 565,284. Filed June 4, 1895.

Consists in producing by induction an independent secondary current corresponding to each phase of primary armature current combining and rectifying such secondary currents and exciting the field magnet coils therewith.

Lamps and Appurtenances:—

ELECTROLIER. N. L. Root, C. L. Reed and D. C. Hale, 565,092. Filed March 13, 1895.

The combination with telescoping stationary and movable members of a helical spring connecting said members to form an extensible electrical conductor.

GLOBE FOR ELECTRIC ARC LIGHTS. S. Heimann, New York, N. Y., 565,269. Filed Feb. 29, 1896.

A glass chimney, a metal ring surrounding the lower end of said chimney, a cylindrical metal frame in the lower end of which said ring fits snugly and a series of glass tubes, held longitudinally and side by side in said cylindrical frame.

Miscellaneous:—

ELECTRO-THERAPEUTIC APPARATUS. Henry E. Waite, New York, N. Y., 565,056. Filed April 2, 1894.

Comprises a room having a series of rods arranged about the walls, a series of devices adjustably mounted on the rods and carrying electrodes, and detachable connecting-bars for electrically connecting the rods.

ELECTRIC SAD-IRON. F. H. Date, J. Heffron, B. H. Scranton and J. Scudder, Detroit, Mich., 565,136. Filed May 31, 1895.

Current is automatically cut out when not in use.

ELECTRIC SOLDERING IRON. F. H. Date, John Heffron, J. Scudder and B. H. Scranton, Detroit, Mich., 565,137. Filed July 18, 1895.

Similar to above.

ELECTROLYSIS. Henry Blumenberg, Jr., Wakefield, N. Y., 565,-324. Filed Jan. 10, 1895.

Relates to the production of an oxysalt or chlorate from the corresponding haloid salt or chlorid by electrolysis.

MEANS FOR DESTROYING INSECTS OR MICROBES ON PLANTS. Jean Fuchs, Porto Ferrajo, Italy, 565,384. Filed Jan. 17, 1896.

A needle provided with a binding-post and inserted in the plant and connected to a conductor connected with a source of electricity and a rod buried in the earth and connected by a conductor to a source of electricity.

Railway Appliances:—

RAIL-BOND. Frank E. Buxton, Worcester, Mass., 564,968. Filed Nov. 29, 1895.

A bond wire with terminals diminishing in cross-section.

DEVICE FOR SUSPENDING AND SUPPORTING TROLLEY WIRES. Charles H. Fisk, Washington Court House, O., 564,984. Filed Feb. 23, 1895.

Consists of two main divisions and a washer, so formed that in connection with a means to tighten the collar on the washer the device will tightly grasp the wire.

CONDUIT FOR ELECTRIC RAILWAYS. Charles D. Mattison, New York, N. Y., 565,085. Filed Feb. 23, 1892.

A sectional conduit system supplying automatic contacts.

ELECTRIC RAILWAY. Henry Brandenburg, Chicago, Ill., 565,102. Filed May 16, 1895.

Conduit system.

ELECTRIC RAILWAY. Henry Brandenburg, Chicago, Ill., 565,103. Filed Aug. 28, 1895.

Provides a sub-conduit to receive débris passing through the conduit proper.

ELECTRIC MOTOR. J. Conner, J. R. MacMillan and A. J. Fuller, Philadelphia, Pa., 565,155. Filed Sept. 17, 1895.

A device for preventing lateral movement of the motor-frame.

TROLLEY-WIRE SUPPORT. Louis McCarthy, Boston, Mass., 565,-174. Filed July 20, 1894.

The wire is held by a yielding support which permits it to respond to vibrations.

UNDERGROUND-TROLLEY SYSTEM. R. E. Sherman and D. E. Kenyon, Chicago, Ill., 565,240. Filed Nov. 12, 1895.

Comprises a slotted conduit, a housing therein containing longitudinal slotted tubular openings for the conductors of the line and a bifurcated trolley device.

ELECTRIC LOCOMOTIVE. R. Eickemeyer, Yonkers, N. Y., 565,-407. Filed Dec. 30, 1889.

Especially adapted to be operated by storage batteries.

Regulations:—

ELECTRICAL GOVERNOR. Mark A. Replogle, Cedar Falls, Ia., 565,032. Filed Jan. 26, 1894.

Details of construction.

DISTRIBUTION AND REGULATION OF POWER. Horace B. Gale, San Francisco, Cal., 565,138. Filed June 17, 1895.

Consists in coupling, with each prime motor to be regulated, a dynamo electric machine arranged to absorb superfluous energy from the motor and to supply energy when deficient.

METHOD OF AND MEANS FOR ELECTRIC REGULATION OF POWER. Horace B. Gale, New York, 565,139. Filed Jan. 15, 1896.

Similar to above.

Switches, Cut-Outs etc.:—

CIRCUIT-BREAKER. W. B. Tobey and H. W. Smith, Pittsfield, Mass., 565244. Filed Aug. 28, 1895.

Consists of spring-actuated normally closed shutters of insulating material, contact plates in their contiguous surfaces, a blade acting as a wedge for forcing apart the shutters when brought into engagement with the contact-plates, said shutters being adapted to close when the blade is withdrawn.

Telegraphs:—

COMBINED TYPEWRITER AND TELEGRAPHIC TRANSMITTER. C. E. Yetman, Oak Park, Ill., 565,128. Filed Sept. 7, 1895.

Designed to unite an ordinary typewriter machine having a series of finger-keys to actuate the type-bars, with an electric code-transmitter governed from the same keys.

Telephones:—

TELEPHONE SWITCHBOARD. Alfred Stromberg and Androv Carlson, Chicago, Ill., 565,046. Filed Oct. 29, 1895.

Details of construction.

TELEPHONE SUBSTATION APPARATUS. A. De Khotinsky, Boston, Mass., 565,080. Filed May 23, 1896.

Relates to apparatus used at a subscriber's station in a telephone system in which the telephone transmitter and signal-sending device have a common source of current supply.

TELEPHONING FROM CARS. Manious Garl, Akron, O., 565,385. Filed Jan. 10, 1896.

Embodies a portable pole provided with curved arms, in combination with a portable telephone and fixed telephone.

TELEPHONY AND TELEGRAPHY.

THE TELEGRAPH IN ITALY.

According to the official returns of the Italian Ministry of Posts and Telegraphs, the number of messages sent over the wires during the last half-year of 1895 was 22,002,206. This includes dispatches on the Red Sea line (Massowa and Assab).

THE TELEPHONE IN RUSSIA.

It has been determined that the telephone line which was put up between St. Petersburg and Moscow on the occasion of the recent coronation festivities shall be allowed to remain, and shall be available for use by the general public. On the subject of the development of telephonic communication in Russia, the "St. Petersburger Zeitung" says that the introduction of the telephone exchange system dates from 1882, when concessions were granted to a company for the establishment of telephonic systems in St. Petersburg, Moscow, Warsaw, Odessa, and Riga. There were several concessions to companies or private undertakers in the succeeding years, and in 1884 the first government system was established at Kieff, though there had been previous installations in connection with the St. Petersburg palaces. After that progress was rapid, so that by 1895 forty-one additional town systems had been established, and at present all the larger towns of the empire are provided with a properly-equipped exchange. As to subscribers, the list is naturally headed by St. Petersburg, with 2,230 in July, 1895; but as the number the year before was 1,977 there has probably been a considerable increase by this time. Such places as Baku and Nishni-Novgorod have 502 and 367 subscribers; the smallest is Berdiansk, with 30 only. The aggregate for the empire was, in 1895, 9,007 subscribers on companies' and 6,111 on government systems, while the corresponding figures for the previous year were 8,004 and 3,958. This shows a considerable augmentation, and there has been a corresponding increase in the length of lines during the year. Trunk-line work is naturally more backward, since the distances in Russia are so much greater than in other European countries. The trunk lines between Rostoff and Taganrog and Odessa and Nicolaieff may be mentioned. Besides all that have been referred to above, there are, of course, a quantity of purely private telephone installations serving factories and so on, but not connected with any central exchange.

BELL TELEPHONE STATEMENT.

The statement of the Bell Telephone Company for the month ending July 20, and from Jan. 1 to July 20, compares as follows with the report for the corresponding periods in 1895:

Month.	1896.	Changes.	
Gross output	12,584	Dec.	1,253
Net output	2,094	Dec.	4,230
Jan. 1 to July 20:			
Gross output	126,678	Inc.	27,782
Net output	73,011	Inc.	21,236

Total number of instruments under rental on July 20, 1896, was 747,987, against 634,281 in 1895.

H. STEVENS SONS COMPANY, of Macon, Ga., are making the conduits for the Atlanta Telephone Company's underground work. The specification calls for 4 and 6 three-inch hole conduits in 30-inch length with dowell pins for coupling them together. The conduits are made of clay, salt glazed.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

THE G. E. IMPROVED "M" AND "K" ARC LAMPS.

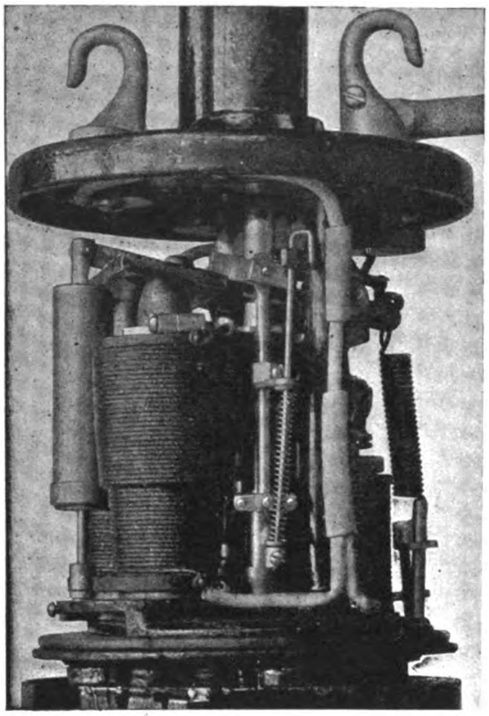
THE best arc lamp is that which gives the most and steadiest light at the least cost. Hundreds of men have tried their skill at designing lamps, but few have met the conditions stated above. The items whose sum makes up the cost of a lamp are: First, the original investment and the interest; second, the cost of current; third, the cost of carbons; fourth, the cost of trimming; fifth, the cost of inspection and repairs.

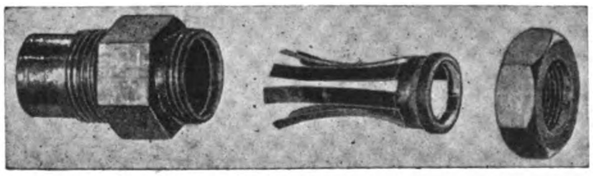
Assuming then that all series arc lamps give the same candle power for an equal current in the arc, we have five varying quantities to consider in judging what lamp to purchase and operate.

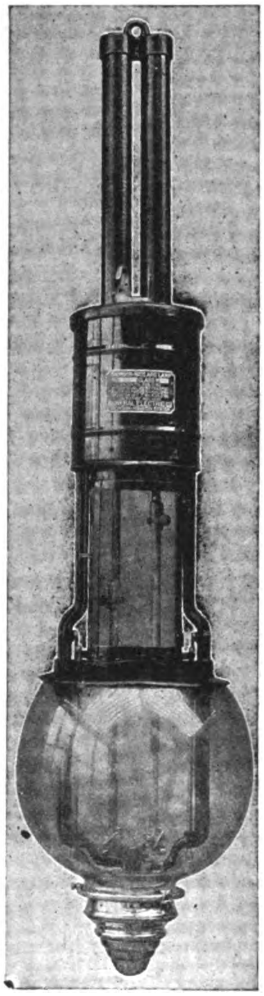
marked advantage over a poorly adjusted one. A lamp which can be supplied with the ordinary sizes and lengths of commercial carbons will prove cheaper in the end than one requiring special shapes and sizes.

Fourth. A large item in the cost of series arc lighting is often found in the expense of trimming. The time required to remove old carbons and insert new ones, to clean the globe, etc., varies widely with different makes of lamps. The ease of trimming also affects the third item of expense, as trimmers will not use special care in saving carbons when the shapes are different at top and bottom, but will throw away longs stubs that might otherwise have been used up profitably.

Fifth. The expense of keeping a lamp in good order is large or small, depending on the quality and design of the frame and mechanism. A simple arrangement of magnets and clutches enclosed in a water-proof case and with a frame which will not drop the globe is the ideal lamp, and the one which costs the least to keep in good running order.







THE G. E. IMPROVED "M" AND "K" ARC LAMP.

First. The original cost of a lamp is not a large item, and as a lamp higher in price may be more efficient and cheaper to operate than one of less cost, the price should not be the deciding feature.

Second. The cost of current for a lamp is not alone for that which passes between the carbon points, but includes all consumed in the magnets, the wiring, or in any part of the mechanism. The greater the lamp losses, the higher must the voltage be at the lamp terminals, and the greater the horsepower or kilowatt output of the generator. The starting current, when a whole circuit of lamps are thrown on together, is a serious matter with some lamps and stations, as it may be large enough to cause an excessive load on the machine with resultant stretching of belts, etc., or may make it almost impossible to start the whole series together.

Third. Carbons, while costing the same per inch for different lamps, may not cost anywhere near the same per candle power hour, the conditions of the feeding of the lamp and the accuracy of adjustment causing wide differences. A lamp that picks up quickly and feeds accurately will show a

The breakage of globes might almost be included under trimming expenses, as a majority of broken globes can be laid to the dropping of them by the trimmer, simply because the frame and globe holder construction makes it almost impossible to avoid such accidents.

The questions of expense are, however, not the only ones which affect the purchaser of arc lamps. The appearance of the lamp often has a considerable amount of influence. The external design of the lamp should harmonize with the place where it is installed; for general street use a plain unornamented frame is best in keeping with the poles, brackets and line construction generally employed. It is absurd to place highly ornamental lamps in situations where they can gather dust and dirt that will never be wiped off. Neither is it practical to attempt to adopt one ornamentation to all places, no matter what the character of the other decorations. An arc lamp should be taken for what it is, and should not be distorted in shape or lavishly carved and ornamented at a sacrifice of efficiency to style. Many makers of lamps have looked more to external than to internal characters, and have

produced extra short, extra narrow, or otherwise extraordinary lamps, whose chief merit is that they are cheap in first cost, and hence not expensive to scrap.

There are probably in use at present nearly 400,000 arc lamps, and three-quarters of them certainly are of the clutch type with smooth cylindrical carbon rods. Illuminating companies are not wholly blind to their own interests, and the preponderance of this type of lamp indicates that their preference is for the clutch feed lamp. Whatever the theoretical disadvantages of the clutch, it certainly works well in practice, and has been in use long enough to outlive various rack, chain and ribbon feed lamps which have been offered as improvements. When this lamp is properly constructed, the trimming and adjustment are simple and easy, and the heat losses in the lamp, wiring and mechanism are small. Clutch feed lamps seem to work in all weathers as well as, or better than, more complicated types and no lamp should be exposed to all of the inclemency of the weather without suitable hoods, protectors or covers.

The length of the clutch type lamp has sometimes been urged as an objection, but when we consider the adavntages in operation over other types and the fact that the majority of these are installed out of doors, this objection loses its force. A double carbon standard lamp burns for sixteen hours without retrimming, and if a shorter lamp is needed, a double lamp to burn eight hours is readily obtained. Most installations, however, now combine arc and incandescent circuits, and clutch arc lamps adopted for 100 or 150 hours run on incandescent circuits can be had at a low price.

There are a lot of imaginary difficulties in clutch lamps and a great number of real troubles with some other types. There are good rack feed lamps, but they are not adapted for series circuits. Certain makers propose to do away with the sliding contact on the carbon rods, but introduce worse features in the way of flexible conducting cords or chains which make the feed sluggish and unsteady. The carbon rods themselves are denounced as needlessly long and entirely unnecessary, yet it is believed that no series lamp has been commercially successful without them. The needs of series lighting require that a lamp feed shall respond instantly to any changes in current, and only an extremely simple and free working feed can do this.

Instead of trying new devices, one company has devoted its attention to perfecting the original clutch type lamp, and has recently introduced several improvements in series lamps of this type. These improvements are shown in the accompanying illustrations, and will be found of interest to all concerned in series arc lighting. These improved lamps operate on either 6.8 or 9.6 ampere circuits without change in adjustment. That is, the same lamp may be used for 1,200 candle-power or 2,000 candle-power. This improvement is gained by a special winding on the combination magnets, and an entirely new "bridge contact" which is sensitive and positive in action, and free from destructive sparking. It makes the lamp pick up instantly and does away with sputtering and hissing carbons.

The feeding clutch will immediately attract the attention of lamp users. It is light, durable and may be adjusted without removal from the lamp. This is done by means of an adjusting screw easily reached by a screw-driver and locked by a check nut. The clutch tension spring is insulated and thus protected from annealing, which sometimes occurs in springs subjected to the passage of current.

The combination magnets may be removed quickly from the lamp by unscrewing a strap which forms a part of the rocker frame. Other parts of the mechanism need not be removed in the operation. All moving parts, except the carbon rods, are nickel-plated. This gives a very clean cut appearance to the interior of the lamp, and is thorough protection from corrosion.

The lamp is made dust-proof by the enclosing cylinder, which has an internal shoulder fitting snugly against the base plate. The side springs for holding the cylinder in place have been discarded. The top of the lamp has been made water-proof by tightly fitting chimney base. The lower frame is adapted to an improved globe lowering device, and the shadows cast by the frame are reduced materially. The dust pan has been done away with, and a dust cup takes its place at the lowest point of the globe holder. This catches all dust, and may be removed readily from the lamp. It is much easier to keep lamps clean with this device than ever before.

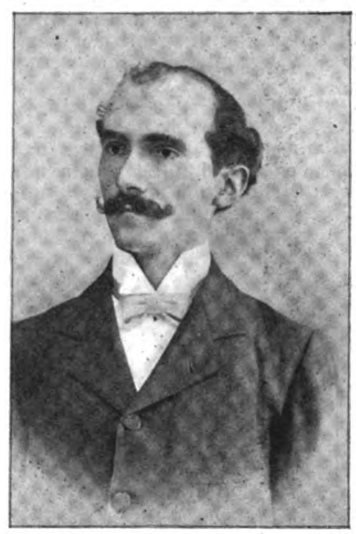
One of the greatest improvements in these lamps, and one which will appeal strongly to the trimmer and to the one who pays for broken globes, is the globe lowering device. By means of this the globe is lowered with the greatest ease to a point several inches lower than on earlier styles of lamp, and is held securely in this position while the lamp is being trimmed. In its normal raised position it is held firmly in place by a simple latch which cannot be lifted to release the globe until the globe itself is raised slightly from underneath. This insures a support from below at the time when the latch is withdrawn, and prevents the globes from being accidentally dropped and broken. The simplicity and reliability of this device together with its great convenience appeal at once to the practical trimmer.

No change in the size of carbons has been made, but in the full length double lamp, lower carbons may be used, the extra length projecting through the lower carbon holder into the dust cup from which it is electrically protected by suitable insulation. At the second trimming, these carbons may be raised, and the stubs used for the next run. The weight of the single carbon lamp is 25 lbs., and of the double carbon lamp, 30 lbs.

In bringing out these improvements, care has been taken to make each new part interchangeable with the corresponding part of the old lamps of the same make. This is an excellent point, as it allows those who have the earlier style of lamps to introduce into them such of the improved parts as they desire instead of having to abandon entire lamps for the sake of obtaining the improved features of the new.

These lamps, which are manufactured by the General Electric Company, have been designated the improved "M" and "K" respectively, and correspond to the former double and single carbon lamps of the same company.

MR. V. J. MIRANDA.



Mr. V. J. Miranda.

The first lecture and demonstration of the X-rays given in South America was by Mr. V. J. Miranda on July 5, at the Government Theatre at Pará, Brazil. The fluoroscope was also presented for the first time in that country at this lecture. Mr. Miranda is a graduate of Columbia College, electrical department, and afterwards worked in the shops of the Thomson-Houston Company, at Lynn, Mass.

He installed the electric lighting plant in the Government Theatre, Pará, Brazil, which has been in operation for the last three years. The two dynamos and all the electrical material were of the Western Electric Company's make, and the plant is driven by two MacIntosh & Seymour engines. Mr. Miranda now has a contract for the equipment of the new theatre at Manaos on the Amazon river. The plant will contain 2,000 incandescent and sixteen ornamental arc lights. Western Electric dynamos and Armington & Sims engines will be used.

X-RAY APPARATUS.

Mr. J. A. Le Roy, 143 East Thirteenth street, New York City, is supplying complete outfits for X-ray photography, including fluoroscopes. The action of the heart has been plainly seen with the instruments he furnishes, also the bones of the body, the liver and the denser organs have been readily traced. Owing of these facts the demand for the very best apparatus has become imperative.

This apparatus is fully tested before shipment, and is guaranteed in perfect working order, and it does not need an electrician to operate it. Mr. Le Roy publishes in his catalogue a number of testimonials in regard to his apparatus from well-known physicians and professional men.

ELECTRIC LIGHTING IN GUATEMALA.

We are informed by Messrs. Morehouse & Morril, engineers, of Quezaltenango, Guatemala, that they have taken a contract to furnish a complete hydraulic and electric plant for the lighting of the city of Antigua, close to Guatemala city. The contract price is $70,000. Mr. Morehouse has left for San Francisco, where he will purchase the supplies, machinery, etc., for this work.

THE SCOTT & JANNEY ELECTRIC & MFG. CO. are meeting with good success with their new alternating desk and ceiling fans.

THE NATIONAL ELECTRIC HEADLIGHT.

The most important recent application of the electric headlight manufactured by the National Electric Headlight Company of Indianapolis, Ind., is on Dr. Seward Webb's private car and engine, Ne-ha-sa-ne. He speaks in very complimentary terms as to the successful operation and value of the electric headlight.

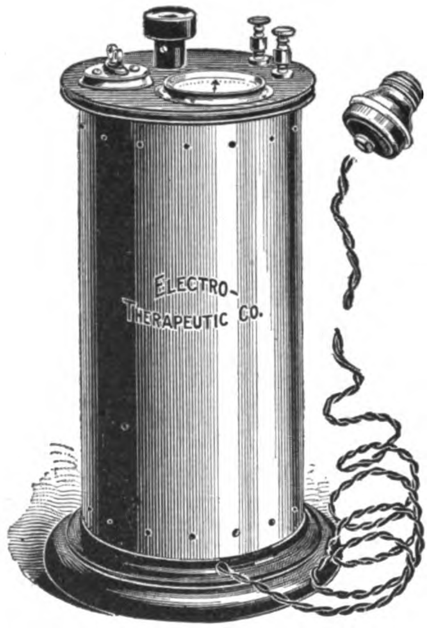
Perhaps the most ambitious railroad man in these times is Mr. E. H. Greene, the only son of Mrs. Hetty Greene, of New York. Mr. Greene is president and general manager of the Texas Midland R. R., a short road of 53 miles. The rolling stock of his road consists of the very finest that can be bought. He now has five of these electric headlights.

The company have established a branch office in the Monadnock Building, Chicago, with Mr. R. C. Vilas as the sole dealer and Mr. Mark A. Ross, late of the National Tube Works, St. Louis, as his sales agent. They have all the business they can attend to and have lately made a 100 per cent. addition to their working force.

THE WHEELER FRACTIONAL VOLT-SELECTOR.

THE G. M. WHEELER fractional volt-selector has become recognized as one of the standard apparatus for all cataphoric operations because of its capacity for controling the electric current so as to preclude all danger from painful shocks of any degree, even when the electricity is applied to the most sensitive parts of the body. It is being used by eye, ear and throat specialists, by dentists and others with entire success; either with the 110 volt street circuit or with a battery, proving in all cases a practicable and scientific instrument.

The principles involved in the administration of medicines, and of producing anaesthesia, by cataphoresis, have been known for many years, but their adoption and use by surgeons, dentists and physicians generally, has been delayed until very recently, because the instruments and apparatus for applying electricity without giving the patient a painful



THE WHEELER VOLT-SELECTOR.

shock have not been available until the fractional volt selector was constructed.

By it the current is permitted to flow over the patient's circuit only as the operator of the instrument may think necessary under the conditions which are offered by the patient: and so minute is the increase of the pressure of the current that the patient can feel no pain.

There are some features in this fractional volt selector which are similar to those of ordinary rheostats used in electro-therapeutics, but it is not a mere rheostat for it possesses powers and involves principles which remove it far beyond the definition of a rheostat. The illustration shows its external appearance, with its various parts and connections. Its weight is only about five pounds, and withal it is an attractive and valuable apparatus. The instrument is manufactured by the Electro-Therapeutic Company, 120 West Forty-fourth street, New York, who also make a variety of electro-therapeutic apparatus.

THE RAINBOW BELT.

The Peerless Rubber Manufacturing Company, 16 Warren street, New York City, are manufacturing a line of belting, the composition of which is practically the same as that of their Rainbow packing compound. It is made in an entirely

different manner from the ordinary rubber belt, inasmuch as it is composed entirely of but one piece.

This belt is intended particularly for electrical, saw mill and paper mill service, and is constructed with a view to running very true, which is particularly necessary for these classes of work. It is constructed in a mould, and afterwards pressed in a special machine.

WESTERN NOTES.

THE ELECTRIC APPLIANCE COMPANY have taken the general Western agency for the Boudreaux dynamo brush, and are carrying a complete stock in Chicago. These brushes are used almost exclusively by the United States Government, and by the largest manufacturers of electrical machinery in the United States.

THE CALLENDER TELEPHONE EXCHANGE COMPANY, of Brantford, Canada, whose highly ingenious system of automatic exchange apparatus was illustrated recently are now fully prepared to undertake contracts for the installation of their system. As soon as the demand warrants it the company will establish a factory in the United States. By the Callender system, it will be recalled, all operations at the central office are performed automatically, no operators being necessary.

THE AULTMAN & TAYLOR MACHINERY CO., of Mansfield, O., have issued a pamphlet containing a report of tests on the Cahall boiler which they manufacture. The tests were carried on by Mr. Thomas Pray, Jr., of Boston, upon a boiler belonging to the plant of the Armstrong Cork Company, of Pittsburg, Pa. The boiler in question was a Cahall patent vertical water tube boiler, in connection with which was a Hawley down draft furnace. The tests showed the efficiency of the boiler performance in percentage of the theoretical value of the coal consumed to be 85.862 per cent. The company will be pleased to furnish the pamphlet containing the report to anyone interested in boiler performances.

NEW YORK NOTES.

MR. ELIAS E. RIES, formerly of Baltimore, has opened an office as consulting electrical engineer at 4 West 115th street.

BREWSTER ENGINEERING CO. have booked some very large orders this week for the Belknap woven wire brushes. They are also compelled to run their electric moulding factory over time in order to keep up with their orders.

MR. W. C. ARMSTRONG, for many years a well-known figure in the line of open arc lamps, has realized the great advantages of enclosed arc lighting for various uses and has lately connected himself with the sales department of the "Pioneer" lamp concern. His offices are with the Electric Arc Light Company, 687 and 689 Broadway, where he will be glad to show his friends the new wonder. He reports good sales and a cordial reception for the "Pioneer" in all circles.

PHILADELPHIA NOTES.

VALLEE BROS. & CO. report the largest sales last month of any month since their company was formed.

MESSRS. MANSFIELD & BAIN, agents for the Walker Co., have removed from the Betz Building to 748 Drexel Building.

THE DIAMOND STATE HARD FIBRE CO. of Elsmere, Del., have recently increased their plant and are running to their full capacity.

Department News Items will be found in advertising pages.

THE

Electrical Engineer.

Vol. XXII. AUGUST 19, 1896. No. 433.

MISCELLANEOUS.

ELECTRICAL FEATURES OF THE GENEVA EXPOSITION.

WHILE it does not appear likely that the General Electrical Congress will have much effect on the course of events by its work, it is at least consolatory to know that the electrical exhibits at the Swiss National Exposition, at Geneva, this year, have made a very favorable impression on the visitors to that interesting display of Swiss ingenuity and resources. The Exposition, though not small, lays no special claim to admiration on the score of its bigness; but in tastefulness of arrangement and in the high quality and excellence of its exhibits, it has certainly never been surpassed. In electrical machinery, as in all that pertains to hydraulics and horology, Switzerland stands in the front rank, and the brilliant exemplifications afforded at Geneva this year, in these various fields, furnish much pleasure and instruction to every visitor.

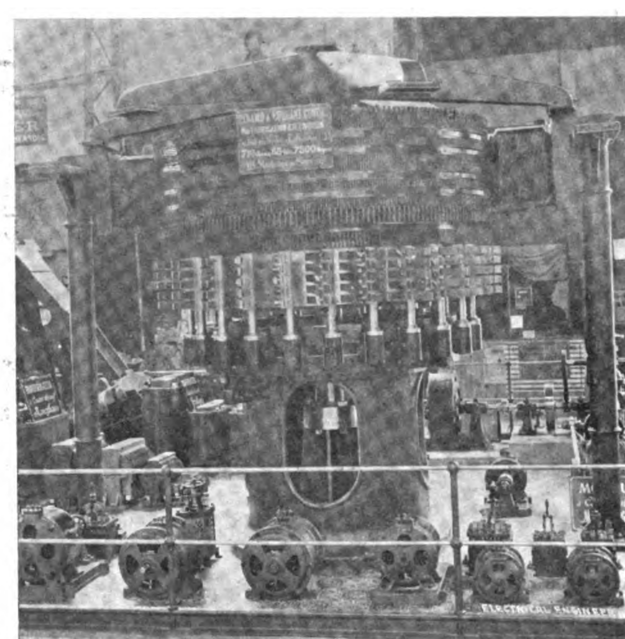
Theodore Turrettini.

For electrical engineers it will suffice to say that the president of the Exposition is Colonel Theodore Turrettini, Mayor of Geneva, the distinguished engineer whose name is associated alike with the utilization of the energy of the Rhone at Geneva and with the recent work at Niagara. Since 1894, the destinies of the Exposition have been in his hands, and the results are most satisfactory. With him have collaborated as directors and officials leading Switzers in all professions, the various committees for the 47 groups comprising no fewer than 600 persons of prominence and influence. The Exposition itself occupies a large stretch of ground on the southwestern side of the city adjoining the Boulevard de Plainpalais, and covers about 450,000 square metres, all told. It is bisected by the rushing and sparkling Arve on its way to join the Rhone just below the city; and it is reached very conveniently from the city by trolley cars that deposit the visitor right at the Plainpalais gates.

It is needless here to describe all the features of this Exposition, and the intention is to refer only to one or two of the more striking electrical elements of the show. In the first place it may be noted that as at all modern expositions of the first rank, the lighting is done by electricity, although entrance at night time is restricted to one or two buildings and to the beautiful and idyllic Swiss village. Outside the Fine Arts Palace, near the entrance, is a fine fountain so arranged as to be illuminated electrically with fine effect from beneath. There is a track contact electric railway making a circuit of the grounds, and an electric tower 165 metres high, furnished with two electric elevators and with an American bar at top and bottom. The main feature, of course, electrically considered, is the machinery hall, but the distribution of power by means of motors is on a very large and impressive scale.

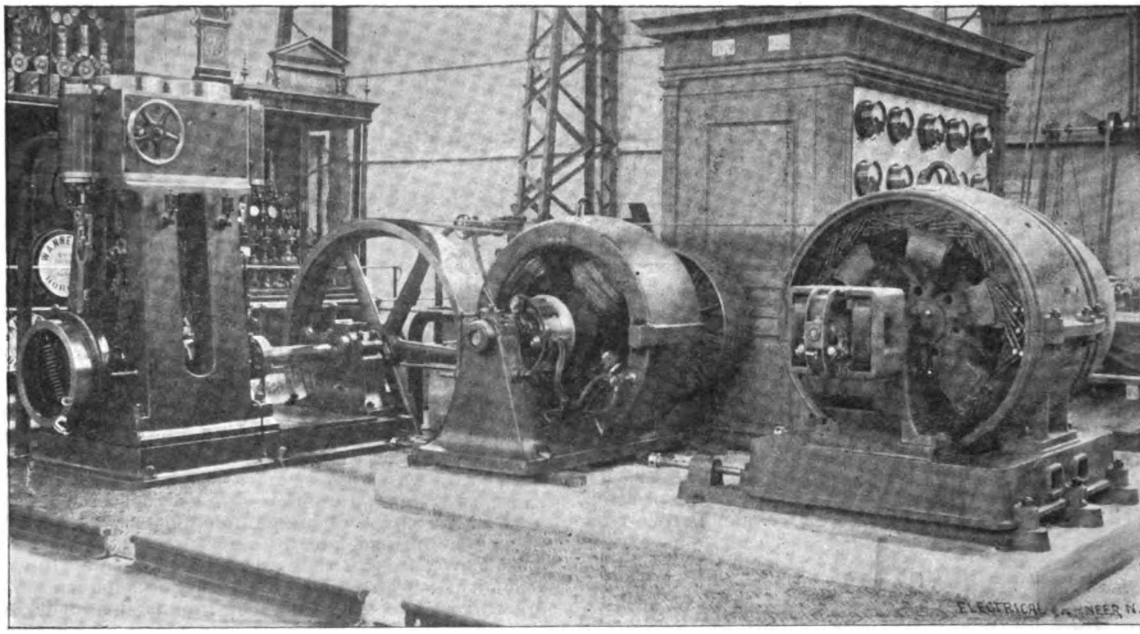
Exteriorly, the machinery hall is not beautiful, resembling a railway station with its circular or dome roof, but inwardly it is admirable. It is the most important of all the exposition buildings and was designed by Mr. E. Phelps, architect, the contractors being Theodore Bell & Co., of Kriens. It is built almost wholly of steel. The length is 150 metres and the width 88. It is divided into three naves, the central one being 35 metres in width, while the two others are each 25 metres. A very large part of this building is occupied by the electrical exhibits, embraced in group 38, the heavy apparatus for light and power being flanked by water power machinery and by street cars and light railways, while on another side are to be found smaller apparatus in the shape of lamps, telephones and telegraphs, batteries, push buttons, etc.

It is well known that an extensive use of the power of the Rhone has been made by the city of Geneva. The electrical apparatus is of the Thury continuous current design, to which reference has frequently been made in these columns; and a fine exhibit is made of it not only by the city, but by the manufacturers of it, the Compagnie de l'Industrie Electrique. This concern has supplied the Schuckert and Grazier arc lamps employed in lighting the grounds and for display work. It has also in operation a fine electric crane which travels the length of machinery hall and on which the public can ride if it pays a small fee, just in the same way as at Paris and Chicago. The pumps for the illuminated fountain are also driven by this company's motors, and in the very interesting pavilion of Raoul Pictet just back of the hall, a number of motors are driven, current being furnished by a 150 ampere series Thury generator. The exhibit includes also a compound wound street railway generator belt driven, and a two-phase synchronous motor wound so as to be able also to supply continuous current if run as a rotary transformer. It may be here noted in passing that the machinery in the hall is driven in various ways, there



OERLIKON GENERATOR WITH VERTICAL AXIS FOR ALUMINUM PRODUCTION.

being 145 horse-power of hydraulic motors, 450 horse-power of steam, and 500 horse-power of electricity, part of the current being derived from the city plant. It will be remembered that Mr. Thury has for many years made a specialty of continuous current long distance power transmission, and one familiar



Part of Oerlikon Exhibit at the Geneva Exposition.—Direct and Alternating Dynamos.

Interior, Machinery Hall, Geneva Exposition, Showing the Traveling Crane of the Compagnie De L'Industrie Electrique.

instance is that of Genoa. Another striking case is that of the transmission of 400 horse-power from Rondchatel to Biberist, a distance of 28 kilometres. When it is stated that the voltage in such work is carried up to 7,000 volts it will be seen that the insulation and general construction of the machines is necessarily of a very high type.

The exhibit of the Oerlikon Machine Works is remarkably fine, being at once large, representative and interesting. Although it includes continuous current apparatus, it may be said to demonstrate the success of the Swiss in alternating current work. The space occupied by the exhibit proper is no less than 365 square metres, but the works have motors scattered all over the exposition running machinery of different classes. Two illustrations are here given of some of the apparatus, one picture including a direct current generator of 80 horse-power, at 220 volts, and a 100 horse-power, 3-phase generator. The other cut shows a direct current generator for the production of aluminum. The shaft is vertical so as to be coupled to a turbine below. Each of these generators gives 710 horse-power (7,500 amperes at 65 volts) when running at 150 revolutions per minute. In the cut, some of the field magnets are seen removed from the spider, the object being to expose to view the construction of the armature. The Oerlikon works have made a specialty of this apparatus, and the number of orders received would imply that the quantity of aluminum made is greatly on the increase.

It is, however, as already noted, in alternating current apparatus that the works have made so fine a display. They have a single-phase alternator in the space of Escher, Wyss & Co., of 230 horse-power and 2,400 volts; also a triphase of 100 horse-power and 200 volts. There is also a triphase alternator of 20 horse-power at 110 volts, also coupled to an Escher & Wyss turbine. It is not generally known that the works build steam engines, but the exhibit includes an engine of vertical type driving a 4-pole continuous current generator; and part of the field magnet is shown of a dynamo which will constitute part of a direct coupled slow-speed unit. The Oerlikon motors are all over the place, and are also attached to a number of tools within the exhibit. A notable exhibit of weaving machinery in the Ruti exhibit is run by Oerlikon motors which can be run either by a generator driven by a Laval steam turbine or by the small 20 horse-power alternator driven by the Escher & Wyss turbine. The continuous current motors are driven by the two generators operated by steam engine, and the monophase and biphase motors used by a number of exhibitors take current from the power service of the exposition. The company's monophase motors range from one-twentieth up to 6 horse-power, and the triphase from one-third up to 36 horse-power. The motor driven tools in the company's exhibit are quite interesting and include a pivotal crane equal to lifting 5 tons; a horizontal ribbon saw operated by triphase motors; machines for cutting saw teeth; boring and drilling machinery for metal working; portable drill; boring machines for stone and coal cutting, driven by triphase motors; portable ventilators; planing machines, etc. In the exhibit of the Gotthardbahn (Gotthard Railway) are photographs of Oerlikon motor tools employed in its shops at Bellinzona; and the Swiss Military Department shows in the Military Park a movable projector for night operations.

Among other exhibits to be mentioned in passing are those of Alioth, of Basle, and the Société Suisse of Neuhausen, whose street cars are of interest. The Swiss Department of Posts and Telegraphs has a fine special exhibit in which every single detail of line construction and of operation is grouped and exposed, in a most instructive manner. Reference has already been made to the Pictet exhibit, where electrical machinery assists in the production of liquid air and extreme cold, and where electric light is seen in contrast with Mr. Pictet's acetylene gas. In the Agricultural Group also is to be found the alarm apparatus pertinent to the fire service, and the groups of instruction and meteorology also include much of interest to electricians.

The little electric railway that encircles the grounds is a modest affair, and on that score not to be harshly criticised. It is true there are no overhead wires, but it offers no really valuable suggestion as to a substitute. The car is a small one, and the light rails are supported on wooden insulating blocks. The current, at 100 volts, passes into the motor by one rail and back to the other rail, so that a dead short circuit would be an easy matter. The potential is only 100 volts, but it is said that the leakage on wet days will run up to 50 amperes, which should ordinarily be enough to run the car itself. Still, the road does its work very well and gets lots of patronage. The visitor who takes it as soon as he enters the gates gets at once an excellent idea of the disposition of the buildings and the main points of interest. It is, however, to the road up Mont Salève that the trip must be taken if one would see the boldness of Swiss enterprise in railway work. This road, on the third rail plan, climbs to an altitude of 4,000 feet, by means of single and double rack rails in the center of the track; and while one can look down northward on Geneva and Lake Leman the southward range of vision includes long terraces of snowy Alps and the huge white shoulders and peak of Mont Blanc itself.

ELECTRIC AND MAGNETIC RESEARCH AT LOW TEMPERATURES—V.

BY J. A. FLEMING, M. A., D. SC., F. R. S., M. R. I.

By subjecting a hard iron ring to frequent reversals of the same magnetizing force whilst it is cooled up slowly from the temperature of liquid air up to ordinary temperatures, we have been able to trace the gradual decrease of the permeability at any constant force throughout this range of temperature.

We have found, on the other hand, that unhardened steel pianoforte wire behaves like soft annealed iron.

We have, then, examined the hysteresis of iron at low temperatures (Fig. 12).

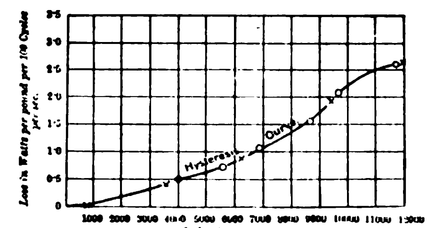


FIG. 12.

As the meaning of that term was very fully explained by the inventor of it in a discourse given quite recently, no time need be spent in an elaborate explanation of it. It is sufficient to say that when iron is magnetized and demagnetized or carried round a cycle of magnetization in which its direction of magnetization is first in one direction and then in the other, this process involves the expenditure of energy, and such dissipation of energy is spoken of as the hysteresis loss in iron. It would occupy too much time to attempt to explain in full detail the manner in which this dissipated energy can be measured. As a matter of fact, the method we adopted was the laborious but exact one of delineating a complete magnetization curve of the iron, by means of observations taken, with the ballistic galvanometer for various maximum values of the magnetizing force. In this way we were able, finally, to arrive at a curve which represented by its ordinates the value of the hysteresis loss in the iron in ergs per cubic centimetre per cycle, and the abscissæ the maximum value of the corresponding magnetic induction. When curves had been drawn out from all the many hundreds of observations for the case of the same soft-iron ring at ordinary temperatures and at the temperatures of liquid air, we found little or no sensible difference between them. The result is, then, that there is no appreciable change in the magnetic hysteresis loss of very carefully annealed soft Swedish iron when cooled to these low temperatures. With regard to the hard iron, although the permeability is increased, it is most difficult to say yet whether the hysteresis is increased or not, as every fresh reduction in temperature of the iron alters its physical state,

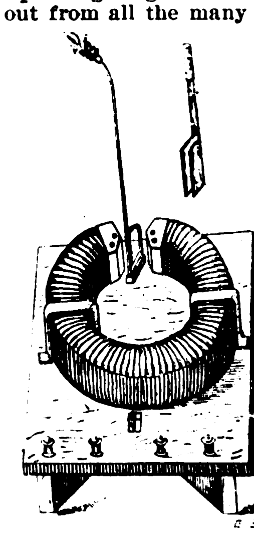

FIG. 13.

and makes it almost impossible to obtain similar repeated measurements.

It is natural to inquire how far accepted theories of magnetic action are able to reconcile the above-mentioned results. Some of them undoubtedly are in accord with deductions from received hypotheses.

It is generally considered that the facts connected with the magnetization of iron indicate that each molecule—or, perhaps, small groups of molecules—of the iron are complete micro-magnets, and that in the unmagnetized condition of the iron these molecular magnets arrange themselves in groups or in closed circuits; so that for each little group the external magnetic action or magnetic moment is approximately zero. Magnetization consists in arranging the members of some or all of those groups so as to collineate the direction of more or less of the molecular magnets and produce an external resultant magnetic moment.

Let us, then, consider one such little group by the aid of a model made of small magnets (Fig. 13), such as Ewing has suggested and used. Suppose the members of this group to be at a certain distance from each other, and we apply a given magnetizing force which is just sufficient to open out the group and co-lineate the magnetic axes of the several members of it. Next, suppose we cool this iron; this would result in bringing the members of the group into closer contiguity. The result of this will be an increase of the interpolar magnetic forces of the different members of the group, and as we can see from the behavior of the model, it would require a greater magnetic force to effect the same amount of collineation of the molecular magnets. This, however, corresponds with what we find to be the case on cooling soft iron to very low temperatures. Professor Dewar's experiments have shown that the tensile strength of iron and steel is increased to about double on cooling to —182 deg. C., and it is quite reasonable to suppose that this result is in part at least due to an approximation of the molecules.

As regards the behavior of magnets when cooled, it is highly likely that when the groups of molecular magnets have been opened out more or less that some of these are in a condition of instability, in which bringing the members of the group nearer together will have the effect of making them close up again into magnetic circuits of no external action. Hence, if this is the case, the first effect of the sudden cooling will be to effect the change. These half-hearted groups of molecular magnets constitute the sub-permanent magnetism which it is our desire to get rid of in ageing a magnet. Then, as regards the effect of temperature changes on the magnet when the stable condition of affairs is reached. In order to explain this, I think we must consider the action of the molecular groups upon each other. The approximation of molecular groups will in general, after the magnet is aged, have the effect of collineating more completely the different members of the groups, and hence increase the magnetic moment of the magnet, whilst the separation of the molecular groups and the reverse effects ensue on heating. The action of the low temperatures upon soft iron and upon magnetized steel would be explicable if we may legitimately make the assumption that lowering the temperature approximates the molecular groups and also the members of each group. The result of this in the case of existing permanent magnetization is to close up more or less those groups which are in an unstable condition, but it increases the collineation in those groups in which the magnetic moment exceeds a certain value. Hence, in the case of the permanent magnet the first effect of sudden cooling is a compound effect; it consists in a great reduction of the magnetic moment of certain unstable groups, but in an increase of moment of others. After this initial stage is past the normal effect is an increase of magnetic moment of the groups by bringing them closer together and a diminution by increase of distance.

There remains, then, to be explained the anomalous behavior of nickel steel and hardened iron, but the attempt to throw an inner light upon the results attained with these substances cannot possibly be successful until we have explored far more thoroughly at low temperatures the changes in their mechanical as well as magnetic qualities. However much we may be tempted to speculate upon the causes of these various changes in the properties of matter at very low temperatures, a much more important duty at the present time is the collection of facts and the completion of accurate quantitative measurements. The experimental difficulties of this low-temperature research are very great, but both Professor Dewar and I have been chiefly anxious in this particular work to prosecute preliminary explorations into as many regions of it as possible, these pioneering experiments enabling us to ascertain in what direction further inquiry will be profitable. Every step forward opens up fresh suggestions for investigation and, I may add, fresh difficulties. In the light of the results, however, thus ascertained we shall have additional means of testing and judging existing electrical theories, and the facts themselves when built into the fabric of scientific knowledge will serve to broaden those foundations on which we may profitably erect new hypotheses of electric and magnetic phenomena, which, even if they cannot dissipate entirely that mystery which enshrouds even the most familiar facts, will serve as a continual stimulus to thought and work in days and years that are yet to come.

ELECTRIC LIGHTING.

ELECTRIC LIGHTING IN BELFAST.[1]

BY VICTOR A. H. McCOWEN.

The Belfast Corporation, being the owners of the gasworks, and justly proud of the reputation they had gained of having their thoroughfares well lighted by gas, and the undertaking being also a paying concern, had no intention of allowing private companies to occupy the field. No fewer than seven of the latter in 1882 served notice of their intention to apply for provisional orders for power to supply electricity within the city. All these applications were successfully opposed; the Corporation remained in possession, and for seven years no further active steps were taken.

The Gas Committee was led to consider the question of the introduction of electric lighting. In September, 1889, they reported that in their opinion the time had arrived when the Council should obtain powers to supply electricity for lighting purposes, etc., within the city, and they also recommended that authority should be given to apply to the Board of Trade for a provisional order for that purpose. The Gas Committee were authorized to pay £50,000 out of the surplus profits of the gas undertaking towards the establishment of the electric light.

It was decided to obtain the assistance of a consulting engineer, and Prof. Alexander B. W. Kennedy, F.R.S., of London, was appointed. On account of the saving in capital cost, and other circumstances of the case, he recommended the system about to be described.

Area supplied.—The area at present supplied with electricity in Belfast, comprises probably the best part of the city. It includes first-class shops and offices, hotels, clubs, theatres, and churches; and of Howard street and College Square private houses.

As shops and offices together form a large percentage of the total consumption, the shape of the load curves depends greatly on their hours of closing. The distance of the farthest lamp from the station is as yet only about 800 yards, as the present area supplied with electricity is only a small part of the city.

Mode of Distribution.—The system of distribution is what is known as the three-wire low-tension. The current is supplied to consumers at 110 or 220 volts pressure. The distributing mains are connected up in a network, and fed at seven points by feeders from the generating station. The feeders deliver the current at the feeding points of the distributing mains at a pressure of 220 volts. The drop in the feeders at full load is 10 per cent. The pressure between the middle wire, and the positive or negative is 110 volts. Pilot wires are connected from the feeding points to voltmeters in the generating station, so that the switchboard attendant can always see what the pressure is at these points, and keep it constant by due regulation.

Charges and Pressures.—The charge for current for lighting is 7d. per Board of Trade unit, with discount ranging from 2½ to 17½ per cent. according to consumption; the maximum discount reduces the price to 5.77d. per unit. The charge for current for motors, heating, etc., in daylight hours, is 4d. per unit with the above discounts, of which the maximum reduces the price to 3.3d. per unit. Meter rents range upwards from 2s. 6d. per quarter, according to size. Installations containing over fifty lamps of 8 candle-power are wired either with single 220-volt lamps, or with pairs of 110-volt lamps in series, or on the three-wire system. Motors of over one horse-power are supplied with current at 220 volts. The meters in use are those of the Ferranti type.

Station.—The generating station is situated between Chapel Lane and Marquis street, within 250 yards of Castle Place, which is practically the center of the city; it is therefore a good position from which to distribute the supply. In the selection of the site, the question of convenience for delivery of coal, removal of refuse, etc., had not to be considered. The buildings were designed by Mr. C. Stanley Peach, of London. The shape of the site is rather irregular, and the space available has been made use of to the best advantage.

The engine room occupies the central and larger portion of the site, and measures 85 feet long by 33 feet wide at the east

[1] Abstract of a paper read before the Belfast Meeting of the Institution of Mechanical Engineers, July, 1896.

end and 44 feet at the west end. A 6-ton overhead traveling crane is provided, all the motions of which are actuated from below by means of ropes. The switchboard platform is raised about 4 feet above the floor level, and runs the whole length of the west wall of the engine room. The battery room, measuring 28 feet square, is situated between the engine room and the offices, on the same level; it contains four rows of stands for the cells, and is provided with ample means of ventilation. The offices occupy the west end of the site, with frontage to Marquis street. The meter-testing room and store room are above the offices on the first floor. A fitting shop and driver's room are placed at the east end of the building; and above them is the cooling tank, measuring 34½ by 12½ feet and 4 feet 2 inches deep.

Engine Room.—The plant in the engine room consists of the following engines and dynamos. Four 120 indicated horse-power tandem double-acting horizontal gas engines, running at 160 revolutions per minute, and driving, through eight ⅞-inch diameter cotton ropes, four 57.6 kilowatt dynamos of 240 amperes and 240 volts at a speed of 600 revolutions per minute. Two 60 indicated horse-power single-cylinder double-acting horizontal gas engines, running at 160 revolutions per minute, and driving through eight ¾-inch diameter cotton ropes two26.4 kilowatt dynamos at 750 revolutions per minute. Two 150 indicated horse-power four-cylinder single-acting high-speed vertical gas engines, running at 380 revolutions per minute, coupled direct to two 72 kilowatt dynamos of 300 amperes and 240 volts.

Switchboard.—The switchboard consists of five slates, each about 7 feet high; the center one is 36 inches wide, and the others 32 inches. All are bolted to an iron frame work, fixed on the switchboard platform about 4 feet from the engine room wall. The center slate carries the feeder and omnibus-bar voltmeters, the battery instruments and regulating gear, and the middle-wire ammeter and connections. The other four slates carry the feeder and dynamo instruments, switches, etc.: the two on the left hand are for the positive side of the system, and the two on the right hand for the negative side.

The machine and feeder bars, which are the vertical bars on the outer slates, are fixed on the front, and each is provided with three holes, through which a plug can be inserted to make connection with any one of the three omnibus bars that are fixed horizontally at the back of the board.

The automatic switches are arranged to break circuit should the current from the machine fall below 10 amperes. The shunt change-over switch is placed above the automatic, and connected with it by an interlocking lever. An ampere-hour meter is connected in the circuit of each dynamo, and registers the work done during a run, the readings being taken at start and finish. The voltmeters are Kelvin multi-cellular electrostatic, and are provided with multiple-contact switches. The feeder voltmeters show the pressure at any feeding point between the middle wire and the positive and negative wire. The bar voltmeters show the pressure between the positive and negative omnibus bars, and also between the middle wire and any of the omnibus bars. The dynamo voltmeters are used for showing the voltage of the machines before putting them on to the circuit.

The batteries are connected through their ampere-hour meters, polarized ampere meters, and emergency switches to the top omnibus bars. The usual practice at full load is to have all the machines and feeders plugged in parallel on this bar; but should it be necessary to run any particular pair of feeders at a different voltage, this can be done by plugging that pair of feeders and a machine on the bottom omnibus bar. As a a matter of fact, it has never been required to run a separate machine on a separate pair of feeders, as a very even drop all round is obtained.

The link connections are in the circuits of the small machines and are used for connecting them in the following different ways:—(a) As balancing machines on either side of the system; (b) as a special charging circuit for the batteries; (c) in parallel with the large machines across the system. The starting resistances and the shunt resistances are fixed in the cellar beneath the switchboard. The shunt regulating switches are fixed on the hand rail of the switchboard.

Battery.—The battery consists of 126 cells of the Electric Power and Storage Company's 34 K or heavy discharge type: sixty-three cells for the positive side of the system, and sixty-three cells for the negative. The capacity of each cell is 500 ampere hours, at a discharge rate of 100 amperes; the battery will, however, give a much higher rate of discharge for short periods. The plates are contained in lead boxes which are supported on wooden stands, being insulated from the latter by means of glass oil insulators. There are also eight hospital cells(which can either be used for assisting weak cells, or be put in series with the main battery. The connections from the battery in the regulator and switchboard consist of bare copper rods, supported by oil insulators suspended from the roof.

The method of regulating the battery is different from that usually practised, by cutting in or cutting out end cells. The regulation here is accomplished by putting the cells at the middle-wire end of the positive battery in parallel with those at the middle-wire end of the negative battery, the other ends of the batteries being connected through ammeters and emergency switches to their respective omnibus bars. The regulator is placed in the battery room, and is worked from a hand wheel on the switchboard by means of a rack and pinion. A reversible ampere-hour meter, which registers both charge and discharge, is connected in each battery circuit.

Dynamos.—The dynamos are by Messrs. Siemens Brothers, double-pole with drum armature and shunt-wound. The rope-driven machines are provided with heavy fly-wheels, and the larger ones have three bearings. The two small 26.4 kilowatt machines have double-wound armatures, each winding connected to a separate commutator. By means of a plug-board the armatures can be put in series or parallel, so that the machines can be run at 110 to 120 volts for balancing, or at 220 to 240 volts across the system. The voltage can also be increased to 270, if required. The rope-driven machines are placed close up to the back end of the back cylinder, to save floor space; and backward driving has been adopted, in order to get the slack of the ropes at top.

Gas Engines.—The six horizontal gas engines were manufactured by Messrs. Dick, Kerr & Co., Kilmarnock, under Hartley and Kerr's system. The four larger are double-cylinder double-acting, with the cylinders working tandem and the two pistons on the same rod, which is connected through cross-head and connecting rod to the crank. The bore of the back cylinder is 13¾ inches, and of the front 13½ inches; the stroke is 20 inches. The fly-wheel and driving wheel, one fixed on each end of the crank shaft, are each 8 feet 5 inches diameter, and weigh 37 cwt. and 29 cwt. respectively; the driving wheel is grooved for eight ⅞-inch ropes. These engines run at a speed of 160 revolutions per minute and indicate 120 horse-power; the number of explosions per minute is 320, or two per revolution.

The two smaller engines are single-cylinder double-acting; the cylinder is 13½ inches diameter and 20-inch stroke. They run at 160 revolutions per minute, and indicate 60 horse-power. The number of explosions per minute is 160, or one per revolution. The fly-wheel and driving wheel are each 7 feet diameter, and each weighs 57 cwt.

The cyclical variation in the speed of the tandem engines is very small, owing to the number of explosions, their low initial pressure, and their even distribution, the number of explosions being as 4 to 1 in comparison with a single-cylinder single acting engine.

There are four complete Otto cycles in two revolutions; and this work is continued right through the whole range of the engine load.

Governing.—The method of governing is different from that usually adopted of missing an explosion. With these engines the impulses are continuous, and are graduated according to the load.

With the tandem engines very steady working may be attained without running at a high speed. These engines were originally intended to work down to one-third of full load without missing an explosion; and it was thought that at lighter loads an explosion might be missed, and still sufficient steadiness be maintained. It was found, however, that the missing of an explosion at light loads affected the steadiness too much; and the adjustment of the engines was then taken in hand under the immediate personal supervision of Mr. Hartley, with the result of obtaining finely-graduated impulses, such as the writer believes have previously been unknown in gas engines. The engines are now capable of working from 20 per cent. overload down to no load, without missing an explosion. The word explosion seems here somewhat misapplied, when one considers the extremely low steady pressure all through the stroke.

Graduation of Explosions.—The difficulty to be overcome was the prompt ignition of the charge without initial shock, and under the difficult conditions of a rich charge varying down to an extremely poor one, and also to reduce the terminal pressure by more complete combustion in the cylinder. The charge ignites promptly and without shock, and the low terminal pressure shows that the charge is also utilized to the best advantage.

The quantity of air supplied to the cylinder is practically constant, the quantity of gas only is varied; and hence the difficulty of ignition. It is well known that a poor mixture of gas and air ignites slowly. The method adopted in certain experiments appears to indicate that stratification actually takes place in the gas engine cylinder, and that for certain purposes

it may be rendered of great use. The regularity of the ignition was attained by admitting gas to the cylinder later and later in the charging stroke; and even at full power a considerable quantity of air is drawn into the cylinder before gas is admitted. At light loads this results in the cylinder being almost full of air immediately following the piston, with only a small portion of rich and explosive mixture near the ignition chest. The ignition is controlled by a timing valve, which opens always at the same point of the stroke.

The gas charge is varied by a novel device, which is controlled by the governor. The gas valve is worked by an expanding cam, which may be described as an ordinary gas cam divided into three leaves in planes at right angles to the axis of the cam shaft. These three leaves are capable of being spread or closed by a sliding key, which slides in a keyway cut in the cam shaft, and is controlled by the governor. A helix upon the key engages the leading leaf of the cam; and when the key is moved longitudinally along the shaft in either direction by the governor, the cam is spread or closed as the case may be. The third leaf is fixed on the shaft, the middle leaf being loose on the shaft and having a slot in which works a pin fixed on the leading leaf. The key and cam are held in position by a detent driving the opening of the gas valve, but immediately it is fully opened the detent is released, leaving the cam again under the control of the governor. A Buss governor is employed, and the gas valves are gridiron slide valves; all other valves are of the mushroom type.

Ignition.—The method of ignition is by hot tubes, which are of ordinary wrought iron, nickel steel, and porcelain. The economical life of the wrought iron tubes is found to be rather short; after about fifteen hours the tube gets partially choked up, and gives late firing.

Lubrication and Packing.—The cylinders are provided with valve lubricators opening inwards; the oil is drawn in during the charging stroke. Asbestos packing is used for the piston-rod glands, and no trouble has occurred with hot rods, notwithstanding the high temperatures to which they are exposed; they are as bright and clean as those of a well-kept steam engine. The lubricant is ordinary gas-engine oil.

Cooling Water.—The cooling water from the overhead tank is circulated by means of small centrifugal pumps driven by belt from the crank shaft of each engine. The evaporation is made up through a ball cock valve connected with the tank, and supplied by the town water supply. The town water can also be mixed in any required proportion with the tank water. Separate connections are made to the cylinder cover and jackets; and regulating cocks are supplied for the necessary adjustments. When returned to the tank the water is discharged into a long timber shoot provided with a number of holes, by which is broken up into a shower, thus presenting a larger surface to the atmosphere, whereby the cooling is accelerated. This plan has been found of distinct advantage; and on few occasions has water been required from the town supply, even when running four or five engines together. The capacity of the tank is 10,700 gallons at 4 feet depth.

Gas Supply.—The gas is supplied through an 8-inch branch from the Corporation gas mains, brought into the station at the Chapel-lane end, and connected to three 500-light dry meters; the three are connected in parallel, and each is provided with a by-pass. The gas is conveyed from the meters through an 8-inch main, which runs the whole length of the engine room, supported by brackets on the columns. Each engine gets its supply from the main through a 3-inch branch pipe, provided with a valve and gas bag. The ignition gas is supplied through a separate pipe and meters. The horizontal engines each deliver their exhaust gases through 6-inch branch pipes into a common 18-inch exhaust main. A silencer is connected between the main and the uptake.

High-Speed Engines.—The high-speed vertical engines, which were manufactured by the Acme Gas Engine Company, of Glasgow, have four single-acting cylinders arranged in two lines of two in tandem, working on to opposite cranks. The pistons in the bottom cylinders form guides in the usual manner. The piston rod, connecting the top and bottom pistons, passes through a water-jacketed cylinder, the packing being ordinary Ramsbottom rings on the rod. The gas valves and mixture valves are of the mushroom type, actuated by means of cams. The piston valves, which control the exhaust and time the ignition, are worked from a small crank shaft fixed on the same level, and are parallel to the main crank shaft, being geared from it in the ratio 1 to 2 through steel spur and pinion. The cam shaft is also worked from this, through an upright shaft gearing with both.

These engines being of the closed-in type, the base forms an oil chamber in which the crank shaft works. The bottom pistons and the bottom piston valves are lubricated by the splash from the cranks. Lubricators are provided for the top cylinders only. The engine base is extended to take the dynamo, and the crank shaft is coupled direct to the armature shaft. A fly-wheel of 3 feet diameter is fixed on each end of the crank shaft, the one at the dynamo end weighing 28½ cwt. and the other 24½ cwt. Each cylinder is fitted with a stop valve, so that the engine can be run on one or more cylinders as desired. Each cylinder is provided with an ordinary pendulum type of governor; and the usual method of governing, by missing an explosion, is employed. Ignition is obtained by means of the hot tube. When the engine is running at full load, at its normal speed of 380 revolutions per minute and no explosions missed, 190 impulses per minute are obtained in each cylinder, or a total of 760 per minute in the engine. This, aided by the heavy fly-wheels, gives a very steady running.

The engines are provided with a separate silencer and exhaust pipe for each line of cylinders. The cooling arrangements are practically the same as with the horizontal engine. Tank water is circulated by means of a centrifugal pump; and there is also a direct connection from the town water mains. Cooling pipes are also fitted to the crank chamber. This kind of engine is specially suited for steady driving, high speed being attained without knocking, all parts being in constant thrust; this is obtained by having a high compression (about 90 lbs. per square inch) in one or other of the cylinders at every up stroke. When the bottom right cylinder is exhausting, the top right is compressing, and vice versa. The same operation occurs in the left line of cylinders, and by cushioning at the top of the pistol-valve cylinder the piston valves are also kept in constant thrust. Where economy of floor space is a consideration this kind of engine is very suitable. An engine of 150 indicated horse-power requires a floor area of 6½ feet by 5 feet, or 32½ square feet over fly-wheels, and the combined plant, engine and dynamo of 72 kilowatts, necessitates only an area of 62½ square feet.

Starting Arrangements.—The engines can be started either electrically or by compressed air. In the electrical starting the dynamo is run as a motor off the omnibus bars, pulling the engine round until it begins to explode. First the machine is plugged on to the omnibus bar, the machine automatic switch being left open. A starting resistance is then plugged into the machine circuit, the resistance switch being on the off contact. The field of the machine is next excited from the omnibus bar, by closing the shunt switch on the top or bar contact. An initial start is given to the engine by the driver, and the current is switched on gradually through the starting resistance. As soon as the dynamo is up to speed, the starting current is cut off. The voltage is then regulated by the shunt resistance, and the dynamo switched on to the circuit by closing the automatic switch. The closing of the automatic switch actuates the shunt switch, changing it over from the top to the bottom contact, and the dynamo then runs as a shunt machine. The electrical starting is worked from the switchboard by the engineer in charge.

In starting by compressed air, the engine has first to be turned by hand by the driver into the correct starting position. The stop valve admitting the compressed air is then opened, and is again closed as soon as a few explosions have taken place. The dynamo is then run up to speed and its voltage regulated; and it is put on to the circuit in the ordinary way.

Compressed-Air Starting Apparatus.—The air compressor has two water-jacketed single-acting cylinders of 4½ inch diameter and 8-inch stroke. The pistons are driven by opposite cranks. The admission and delivery of air are regulated by slide-valves moved mechanically. The crank shaft carries on one end a fly-wheel and on the other a mortice wheel, which gears with a steel pinion on the motor shaft. The power is supplied by a 6 horse-power electric motor, running at 800 revolutions per minute, and taking its current from the mains at 220 volts pressure. The air receiver is 12 feet long by 4 feet diameter, made for a working pressure of 100 lbs. per square inch, and tested up to 200 lbs.; it is provided with safety valve, pressure gauge, etc. A 4-inch air main from the receiver runs the whole length of the engine room, with a 2-inch branch pipe to each engine.

In the tandem engines the connection is made to the back end of the back cylinder. The compressed air is admitted during the impulse stroke of that end—by a valve actuated by a cam, thus giving an impulse every second revolution. The gas is cut off from the back cylinder while starting. As soon as an explosion occurs in the front cylinder, the compressed air is shut off, the starting cam put out of action, and the gas turned on, letting the back cylinder take up its part of the work.

In the single-cylinder double-acting engines the arrangement is the same, with only the difference in working that the gas is admitted to the front end of the cylinder, while starting, but not to the back end.

POWER TRANSMISSION.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST MILLENIUM EXHIBITION.—IV.

BY ALFRED O. DUBSKY

Synchronous Series Motors.—These motors are of the same construction as the series direct current motors; they have stationary field winding and a revolving drum armature. They start under full load, the number of revolutions diminishing with the increase of the load. The commutator brushes are made of carbon and no sparking is visible at normal load. Fan motors of the same type are manufactured. A noticeable quality of these motors is that their current can be reversed without the use of any rheostat. The flow of current is greater on reversing, of course, but it does no harm to the motor, which changes almost immediately the direction of its running.

In the foregoing description I have mentioned the alternating current single-phase machinery at the exhibition at Budapest. I will now give a further description of the polyphase plant, which contains some very interesting and very little known apparatus.

Three-phase Machinery.—There are two three-phase generators exhibited, each of 200 horse-power capacity, at 250 revolutions per minute. The distribution of the three-phase current is made at the pressure of 300 volts between two conductors,

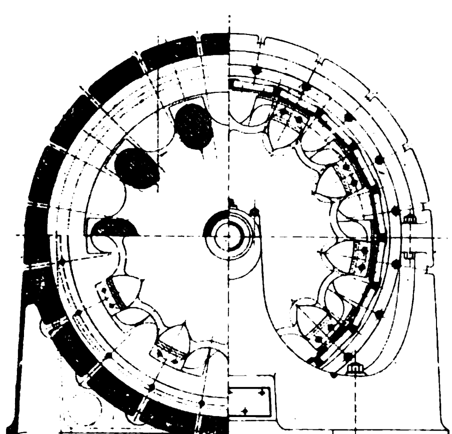

FIG. 18.

and the motors are wound directly for this voltage. One of these dynamos works at this same pressure, so its current can be used, therefore, directly for power distribution. The other generator is wound to give 3,000 volts, and several step-down transformers provide the low tension network with current. The number of periods is always 42 per second. As even the smallest motors never have less than 4 poles, the highest number of revolutions at the motor shaft is only about 1,200 per minute.

Figs. 18 and 19 give two vertical sections through this generator. There are no revolving conductors, as the revolving part consists of a star wheel made of cast steel, with projecting poles composed of laminated iron, shown in Fig. 20. There are ten such poles on each side of the machine. In this way the generator has two distinct armatures, each provided with an independent winding. The exciting coil is coaxial with the generator shaft, and by sending a continuous current through this coil a magnetic flux will pass through the winding of both armatures, according to the momentary positions of the projecting poles of the revolving part. These projections have a relative displacement on the two sides of the generator, and this displacement is equal to half the width of two projections. It will be quite apparent that the induced e. m. f.'s in the two distinct armature windings will have a relative difference of phase of exactly 90 degrees. By using now the well-known arrangement proposed by Mr. C. F. Scott, it is quite easy to obtain three equal electromotive forces with a phase difference of 120 degrees. For this purpose one armature is wound directly for a tension of 300 volts between its two terminals. The other armature has a number of turns 0.867 times less than the former armature, and as the sections of iron are exactly equal in both armatures, there will be an equal magnetic flux passing through the bobbins of both windings, the tensions will be therefore, in the ratio of the number of turns. We now connect the terminal of one armature (with the smaller number of turns) to the middle of the winding of the other one and the three remaining terminals will allow the commutation of three-phase currents.

There are great advantages to be obtained by using this ar-

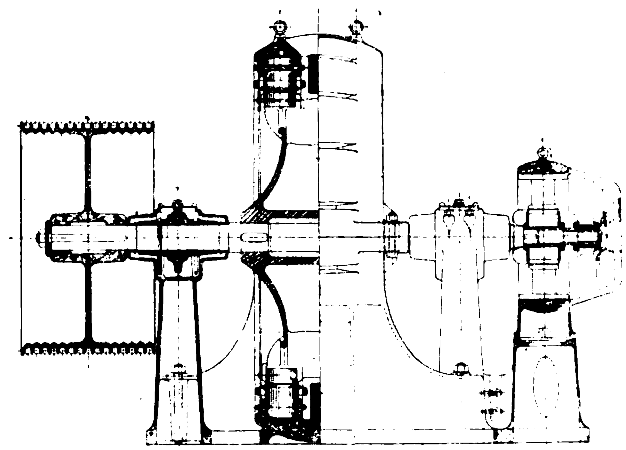

FIG. 19.

rangement. If there should be three distinct series of coils to generate the three-phase current the machine would be far more complicated and expensive. In this way the costs of punching and the number of coils are less, for the number of poles is only twice as large as the number of the pole projections. Moreover, the crossing of the connections is completely avoided, which is a great advantage for high-tension work. Most of the three-phase generators manufactured by the different firms have just this latter fault. In the present construction the bobbins are wound quite separately and are slid on the several armature poles. They are held in their places by the use of wooden wedges; the insulation of the iron parts of the machine is made of thick sheets of micanite.

The further construction of this generator is clearly demonstrated in Figs. 18 and 19. The continuous current exciter is connected directly on the generator shaft in such a way that the complete armature is built on a sleeve, which latter is keyed on the shaft without the use of any external bearing. The complete machine with its exciter, as shown in the exhibition, is illustrated in Fig. 21. This machine is driven by ropes from its steam engine, the other mentioned three-phase generator of the same size is coupled directly to its steam engine.

All these machines work with a magnetic flux more consider-

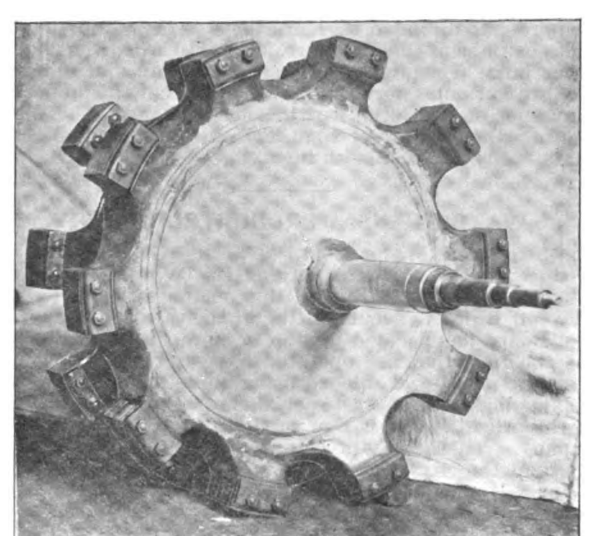

FIG. 20.

able than the special lighting generators. Without changing anything in the exciting current the drop of voltage between no load and full load on motor circuits never exceeds 15 or 20 per cent.[1] These machines are constructed for the use of mo-

[1]The short-circuit current is about 4.5 to 5 times larger than the current at full load.

tor circuits; for lighting purposes it is always more advantageous—for reasons of security—to employ dynamos having more copper and less iron in the armature.

The special construction of these generators renders it possible to obtain also single-phase currents from them. One armature always generates single-phase currents, for it is only by the combination of both armatures that three-phase currents are produced. One 200 horse-power, three-phase dynamo at the exhibition has been charged with 90 kilowatts in one armature and is still employed at times to supply single-phase lighting current. Moreover, single-phase and three-phase currents can be produced at the same time by these dynamos. It would be then a true "monocyclic" installation, with the difference, that one entire armature is employed distinctly for the services of the "teaser coil."

The current produced by these generators drives the different

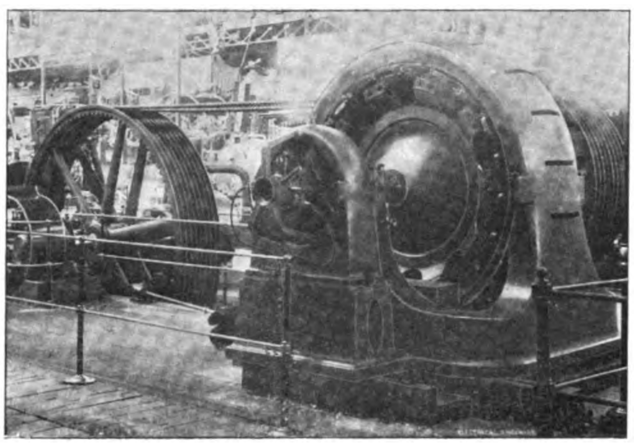

FIG. 21.

three-phase motors, distributed over one part of the exhibition. They are used for driving various machine tools, such as printing machines, looms, pumps, etc.

All these motors are of very different sizes. The smaller motors up to 8 horse-power have a rotor with a short-circuited armature and are switched directly on the circuit. The starting current under full load is about three times the current used when remaining at full load, and the starting torque is somewhat larger than the torque at normal running. The larger motors, those above 8 horse-power, are of a different construction. In order to diminish the starting current and increase the starting torque, the inductors revolve and the induced armature is stationary, the latter having a diphase winding in order to diminish the variations of the torque in the different positions of the armature. A fluid rheostat is used to introduce large resistances during the starting and these resistances are cut out afterwards from the circuit in proportion as the number of revolutions of the motor increases. These motors are suited to direct high-tension work, and an efficient plant is easily obtained with them.

WATER FANS A PROHIBITED LUXURY.

The Street and Water Board of Jersey City has determined to reduce the cost of maintaining the Water Department to the lowest possible figure, and thus enable the city to pay the heavy bill which is accumulating at the rate of $1,000 a day.

The Board has decided to stop in stores, restaurants and saloons the fans that are operated by water motors. There are 110 stores, shops and saloons using these fans, and water has been supplied to them at a special rate, which is less than one-half the price the city is now paying to the East Jersey Water Company. These motors consume a large volume of water daily, and the city is losing a considerable sum by continuing the special contracts, which were made when the city was pumping its own water. There is now a good chance to sell some electric fans in the city.

BUFFALO, N. Y.—Mr. H. H. Pratt, electrical engineer and contractor, Builders' Exchange, Buffalo, writes us: "I am a regular reader of your paper, and in each issue find much useful information for one in my business. I thank you for giving the trade so valuable a publication." Mr. Pratt has just bought the material for a municipal plant at Mayville, N. Y., but is in the market for quotations on other construction materials for work in view.

ROENTGEN RAYS.

CHARACTER OF ROENTGEN RAYS.

The Rede lecture at the University of Cambridge was given by Prof. J. J. Thomson, who took as his subject the Röntgen rays. After describing the properties of these rays as far as they have been discovered by experimenters, he stated that to sum up we may say that though there is no direct evidence that the Röntgen rays are a kind of light, there is no known property of these rays which is not possessed by one or other of the forms of light.

One of the most remarkable phenomena connected with these rays is the way in which the absorption depends upon the density of the body; if we measure the transparency of a series of bodies, we find that the order of opacity is the same as the order of their density. No other factor in the constitution of the body seems comparable in importance with density. In this respect, the relation between the opacity and the other properties of a body in the case of the Röntgen rays is simpler than that for luminous waves or electric waves. There seems no simple relation between the density of a body and its transparency to visible radiation or electrical vibration; in the case of the Röntgen rays, however, it seems the greater the density the greater the opacity. This appears to favor Prout's idea that the different elements are compounds of some primordial element, and that the density of a substance is proportional to the number of the promordial atoms; for if each of these primordial atoms did its share in stopping the Röntgen rays, we should have that intimate connection between density and opacity which is so marked a feature for these rays.

There seems considerable evidence that the energy associated with these waves is small. I am not acquainted with any effects produced by them which involve the expenditure of an amount of energy comparable with that emitted in a second by a candle. They do not produce any appreciable rise in temperature when they fall on the thin metallic strips of a bolometer. Mr. Skinner has found that they exert no appreciable effect on the combination of hydrogen and chlorine, though this is a good test of the intensity of very faint light; and, what is more unfortunate, they do not exert any of those deleterious effects on bacteria which are fortunately associated with ultra-violet light. Some of the other effects exerted by ultra-violet light seem to be associated with these rays; thus some observers who have had undue curiosity about their bones, and have in consequence exposed their hands frequently to these rays, have found that the hand so exposed became sunburnt. There seems considerable evidence, too, that these rays are not good for the eyes, though it is difficult to disentangle and distinctly injurious effect due to the rays from the bad effect that may be produced by the straining of the eye in the endeavor to see only a faintly luminous object.

There is one property of substances which seems peculiarly suitable for testing if these rays affect the substance through which they pass: it is the property of transmitting electricity. When we investigate the effect of the Röntgen rays on this property, we find the remarkable result that bodies which, when shielded from these rays, insulate to all appearances, perfectly allow electricity to pass through them when exposed to the action of these rays.

Experiments were then shown to prove that a gas, which is ordinarily the most perfect insulator of electricity known, will permit considerable leakage of current when acted upon by these rays. Ebonite, paraffin and other solid insulators were also shown to be conductors under the action of the X-rays.

EXPERIMENTS WITH X-RAYS UPON GERMS.

Some experiments have been made by Dr. William Shrader, of the Missouri State University, to test the effect of the Röntgen rays upon various disease germs. In nearly every instance these are reported to have met with success and prove conclusively that the rays are invaluable in the treatment of these diseases. Among the first experiments were those made with the diphtheria bacilli; tubes were inoculated with the germs, one exposed to the rays and the other not exposed. In the former the germs were destroyed, while in the latter they lived.

Following these tests two guinea pigs were inoculated with a solid culture of diphtheria, prepared in the bacteriological laboratory of the university. These pigs weighed 210 and 185 grams respectively. One was exposed to the rays for four hours in a wooden box, having a rubber cover, and is alive today after eight weeks, and no trace of the disease can be found. The other pig, not exposed to the rays, died within 28

hours after the injection of the poison. The post-mortem examination showed that his death was due to the diphtheria germs.

X-RAY INVESTIGATIONS.

It is stated by the London "Electrical Engineer" that Messrs. Novak and Sulc have examined nearly 300 substances with a view to ascertain the absorption of the Röntgen rays by chemical compounds. Their method of investigation consisted in attaching rings of glass to a sheet of paper and placing uniform layers of the finely-pulverized materials in the different rings so that the thickness of the layer was 0.4 cm. in each case. The paper with the rings was then placed over a photographic p'ate, which was enveloped in black paper and exposed to the Röntgen rays for a period of 20 to 25 minutes. By comparing the photographic effect of the rays where the substances were interposed, the relative absorptions were determined. A great number of organic compounds containing only carbon, hydrogen, oxygen and nitrogen appear equally penetrable, and hence it is concluded that the absorption has no relation to molecular weight or the arrangement of the atoms. Organic halogen derivatives have been found to possess much greater absorption, which increased with the number of halogen atoms present. This effect increased with the atomic weights of the halogens, two atoms of bromine having a greater effect than six chlorine atoms, while iodine derivatives were entirely impenetrable under the condtions used in the experiments. It may be added that Mr. Edison has already made a similar series of investigations.

DISCHARGE OF AN ELECTRIFIED BODY BY MEANS OF THE TESLA SPARK.

In a communication to "Nature" Mr. Frederic J. Smith states that it has been shown that a body charged with electricity may be discharged by means of the rays from a Röntgen bulb. "I find, also, that an electrified body is rapidly discharged by the influence of a high-frequency spark, such as that produced by the Tesla apparatus. The discharging action was shown in this way. A high-frequency spark was produced between two rather blunt points, one inch apart in air, no bulb being used. A gold-leaf electroscope, placed far away from the influence of the spark, was used to test the electrical condition of the charged bodies—viz., a stick of sealing-wax and a rod of glass. The sealing-wax was rubbed, and the electroscope indicated that it was well charged. It was again rubbed, and then brought to within a foot of the points, and by means of a key in the battery circuit the Tesla coil was thrown into action for an instant. On testing the sealing-wax rod with the electroscope, it was found to be entirely discharged. A similar experiment was next made with a glass rod; the glass rod was entirely discharged by the Tesla spark. From a previous experiment, it was seen that the electrification of the rods was dissimilar. The influence, then, of the high-frequency spark is to discharge electricity of either sign."

ELECTRIC TRANSPORTATION.

TO PROPEL BOATS ON THE WACO LAKE BY THE TROLLEY SYSTEM.

Among the enterprises suggested by the new Brazos River dam the citizens of Waco, Tex., will build is one which two Ohio men say they will put into execution if they can get a franchise giving them the exclusive right of moving boats on the lake by electricity. Their plan is to put a turbine wheel in, below the dam, and convert the water power into electricity. They will propel their boats on the trolley system and will carry passengers at a high rate of speed along the shores both on the Brazos and the Bosque.

A railway, based on the Greathead system of tunnels, is now proposed for Brussels. It is to be worked by electricity and to run 50 feet below the surface. The first portion is to consist of a complete circle about four miles long, with double track, having 11 stations, and a future extension of a second circle of about two miles long, with four stations. The two tunnels for the different directions will be quite distinct from each other, and run almost entirely below the public streets. There is to be a two and a half minute service each way. The total cost of the first circle is estimated at $3,000,000, a less rate than the City and South London Line, which cost $1,000,000 per mile. The elevators are to be operated by hydraulic power and will hold 40 people. Why electric elevators are not used is a mystery.

THE UNDERGROUND ELECTRIC ROAD IN BUDAPEST.

THE city of Budapest now possesses an underground electric railway in addition to its 28 miles of electric conduit railway. The new underground road was installed with the object of providing a direct route from the center of the city to the park, in which the Millenium-Hungarian National Fair is being held, which is a distance of about two miles. A franchise for a surface road through Andrassy avenue, which is about 125 feet in width and is used as a speedway, has been several times denied by the authorities, so the idea of a tunnel was advanced. Careful estimates by government engineers

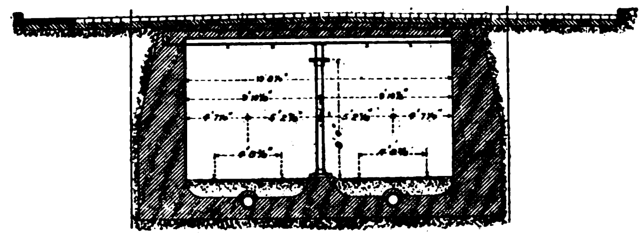

FIG. 1.

placed the cost at $656,000 per mile of double-track road complete, ready for operation. Assuming cars on five minutes' intervals from 6 a. m. to 11 p. m., 204 cars starting each way, the cars having a capacity of 50 passengers, 20,400 passengers can be carried per day. The schedule time from end to end is 18 minutes, corresponding to a speed of 12.5 miles per hour.

Ground was broken on August 13, 1894, the tunnel completed in December, 1895, and the railroad opened for traffic on May 2, 1896, the opening day of the fair. The work was done within the estimate. Nearly 25,000 passengers daily were carried during the first three days of operation.

The exact length of the tunnel is 10,467 feet. It connects with

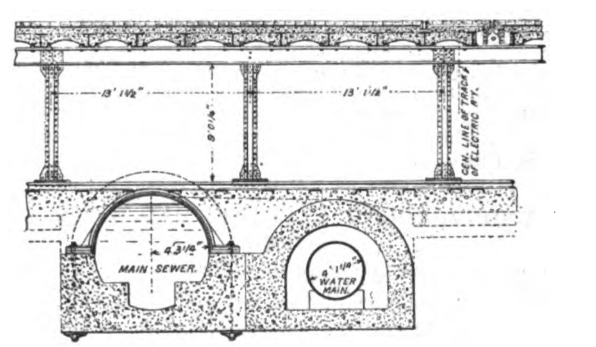

FIG. 2.

1,640 feet of surface lines in the park proper, making the total length, therefore, 12,107 feet and there are 11 stations. Nearly all of the earth was removed from the surface without tunneling. In the first three of the accompanying illustrations, taken from the "Railroad Gazette," Fig. 1 shows a cross section of the tunnel and Fig. 2 a longitudinal section. The steepest grade is 2 per cent; it occurs at the spot shown in Fig. 2, where the tunnel crosses over the main sewer and under the tracks of the surface electric conduit railroad. The shortest radius of curves is 131.25 feet. The bottom and the side walls of the tunnel are

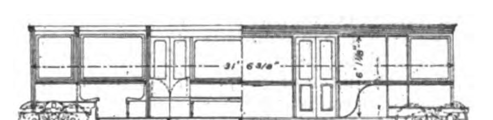

FIG. 4.

built of concrete, the latter were constructed first. The ceiling consists of concrete arches between I beams. These beams rest in the center of the tunnel on a stringer, which in turn is supported by columns, 13 feet 1½ inches center to center. The I beams were placed first, after that the stringer and the columns. The tunnel measures 9 feet 0.¼ inch from the top of the rails to the bottom of the beams, and is 19 feet 8¼ inches wide.

Fig. 3 represents the car, and Fig. 4 shows in detail the manner in which the tracks are attached to the car bodies. The body

is suspended between the trucks, and the bottom of the car is brought within 15¾ inches of the top of rails. The clearance between the car and tunnel wall is 7⅞ inches. The outside dimensions of the car body are: 31 feet 6⅜ inches long by 7 feet 6¾ inches wide by 7 feet 1⅛ inches high. There are two doors on either side of the car, 14¾ inches wide in the clear; those on the side of the columns remain closed, and seats, folding back sideways, are provided to utilize the space. The doors cannot

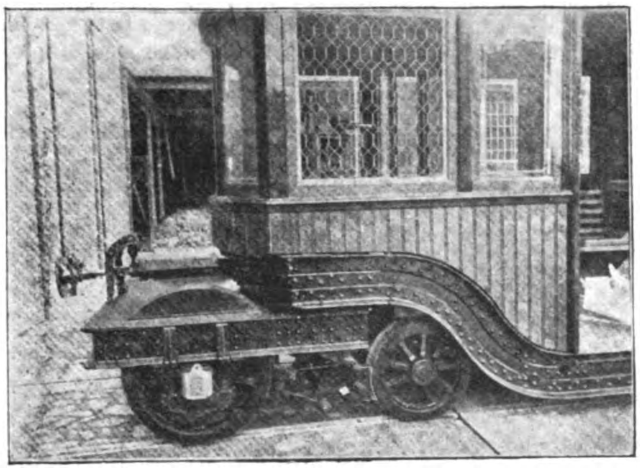

FIG. 3.

be opened until the current is turned off, nor can the current be turned on until the doors are closed. The cars seat 30 persons. The partitions shown in the drawing have been taken out, but the space over the trucks is partitioned off from the rest of car body for the motorman.

The current is fed in and returned through overhead wires; the rails are not in the circuit. Two 300-volt 100 horse-power generators for the tunnel were added to the existing power station.

The station platforms are from 10 to 16 feet wide and from 66 to 98 feet long. The station walls are covered with white glazed tiles. All iron parts throughout the tunnel are painted a silver color, which reflects the electric light and makes the tunnel as light as day.

NEW UNDERGROUND ELECTRIC RAILWAYS IN LONDON.

GREAT activity is being shown in London at present in planning underground street railways, and all of the roads under consideration are to be equipped with electricity by reason of the conspicuous success of the electric road already in operation.

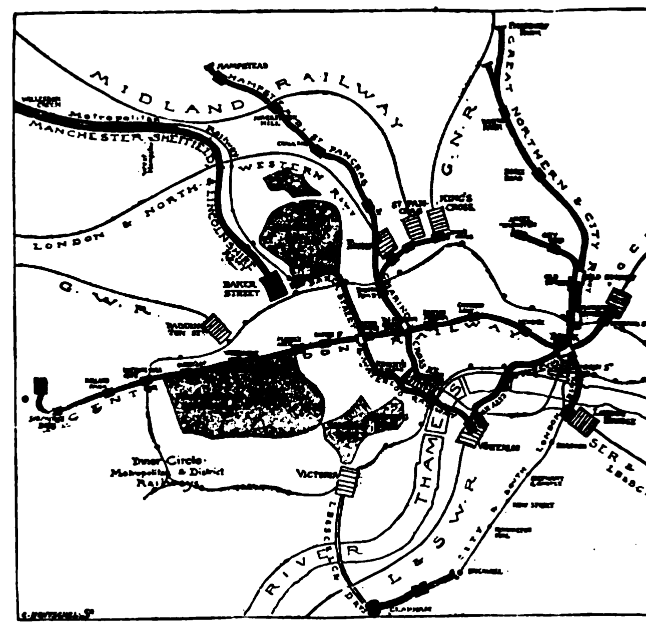
The railway referred to is the City and South London, opened in 1890. Here for the first time was tried that invention of Mr. Greathead's which, equally with electric traction, has helped to revolutionize urban railway construction. This contrivance, familiarly known to engineers as the "Greathead shield," is an air-lock system of tunnelling which enables work to be executed expeditiously at any depth, in perfect safety; and to be continued unhindered quite irrespective of whatever springs may be encountered while boring. The railways now under construction will be tunnelled in this manner at an average depth of sixty feet beneath the pavements of London, and no sign of their progress will be visible to those who use the streets, excepting only on the sites of proposed stations, where shops and houses are being demolished.

The accompanying map will serve to show the relations existing between the great trunk lines, with their outlying termini, and the Metropolitan and District Railways. To these are added the various electric railways authorized from 1891 to 1893, and the new trunk line, the Manchester, Sheffield, and Lincolnshire Railway is indicated.

There are no fewer than six lines authorized, two being at the present moment actively pushed forward. The Waterloo and City Railway is the shortest of all, and has but two stations, one at Waterloo and the other at the Mansion House. This particular line is, perhaps, the most urgently needed of all, and it is now rapidly approaching completion.

But public attention is attracted just now principally to the Central London Railway, which will run from Shepherd's Bush to Liverpool street, a distance of six and a half miles. Authorized in the sessions of 1891 and 1893, its construction has just been undertaken by the Electric Traction Company, who have let all the contracts and have already commenced pulling down the houses that occupy the sites of the fourteen stations along the route. Trains stopping at each station will be run at intervals of two minutes and a half, and will perform the journey from end to end, including all stoppages, in thirty-five minutes. The cost of construction and equipment, calculated at £500,000 per mile, brings the total cost to £3,500,000.

The rail level will not be less than 85 feet beneath the surface at some points on this line, and five hydraulic lifts will convey passengers to and from the trains, and subways will be con-



RAILWAYS IN LONDON.—NEW RAILWAYS SHOWN BY HEAVY LINES.

structed for foot passengers to cross from one side of the road to the other. The company expects to carry between fifty and sixty millions of passengers in the year, but the actual capacity of the line is 85,000,000. The boring of the two tunnels, which will be circular, lined with iron, and but 11 feet 6 inches diameter, will be proceeded with from each station simultaneously. By December, 1897, this work will have been completed.

It will serve to give some idea of the magnitude of these combined railway enterprises when it is considered that the number of new stations they will involve will reach a total of forty-five.

THE MEANING OF GRASS IN THE STREETS.

It used to be regarded as extremely discreditable to a city to have it truthfully said that grass grew in the middle of its streets, and the person who made the remark was regarded as an enemy from a rival town. The remark has lost its sting now, and people point with pride at the blades of grass struggling in the chinks between the paving blocks. It is an evidence of progress, and proof that the people of the place are hustlers. Conditions have changed in the last six or seven years in nearly every city in the country. Grass could not have grown in the middle of the busiest thoroughfares then, while now the busier the thoroughfare the more chance it has to grow.

The electric railroad lines have brought this about, says the New York "Sun." Where they run most frequently they have the tracks and the spaces between the rails and between the tracks almost entirely to themselves. Drivers of vehicles do not care to be constantly turning out for trolley cars, and consequently they keep out of the middle of the streets and off the car tracks. In the horse car days the grass was kept down by the iron-shod hoofs, not only of the car horses, but of those attached to all kinds of vehicles whose drivers found it convenient for themselves and easy for their animals to make use of the smooth rails.

Then the grass did not grow in between the tracks to any extent. Since the advent of the trolley there has been a strong tendency in some towns to encourage the growth of grass upon the part of the road occupied by the tracks, and trolley lines

have been laid out upon many new roads in the outskirts of various cities with the view of having an eye-resting and pleasing strip of greensward the whole length of the line. The roads have electric sprinklers and sweepers, and perhaps the next interesting feature of trolley progress will be a track mower run by a motor to keep the grass down to the condition admired in private lawns and public parks. Then, as a natural consequence, there may be a trolley rake to follow.

TROLLEY FROM NEW YORK TO PHILADELPHIA.

Mr. Frank A. Magowan and J. Henry Darrah, of Trenton, N. J., after nearly a year's hard work, have formed a syndicate of New York and Philadelphia capitalists to construct an electric railway between New York and Philadelphia, the distance being nearly 100 miles as the road runs. The New York and Philadelphia Traction Company has been formed, and associated with it is the Central Jersey Traction Company.

At the head of the enterprise is Mr. J. Canby, of Philadelphia, who has had much experience in traction railways. The syndicate for the traction road through New Jersey is not only formed, but stock has been transferred and a partial payment made to the promoters, Messrs. Magowan and Darrah, and John Blair McAfee, of Philadelphia.

Work upon the new road is to be commenced in a few days. A contract has just been given out for operations between New Brunswick and Bound Brook and Raritan and Dunellen which will amount to $475,000. A power house to cost $100,000 is to be erected near Bound Brook.

The New York and Philadelphia Traction Company was incorporated on July 13, 1894, with a capital stock of $10,000,000, by Frank A. McGowan, who took in the Central New Jersey Traction Company. There will be one thousand miles of road, connecting nearly all the large towns of New Jersey.

The direct line of the main stem will begin at Paterson, where connection will be made with the present system. Then the road will pass through Upper Montclair, Montclair, Bloomfield, Orange, East, West and South Orange, Maplewood, Wyoming, Springfield, Westfield, Fanwood and Northwood, to a connection with the present system in Plainfield, and thence through Plainfield to Bound Brook.

Crossing the New Jersey Central Railway at Finderne, the road will continue through Hillsboro and Weston, and thence to Millston, Rocky Hill, Princeton, Lawrenceville and Trenton.

Branches will run from Bound Brook to New Brunswick, Somerville and Raritan; from Bloomfield to Irvington, and to Morristown, via Chatham and Madison. At Irvington connections will be made with the existing lines, making a direct route to Newark and Jersey City.

From Westfield the road will run to Rahway, connecting there with the line to Lebanon and Boynton, South Beach, Woodbridge and Perth Amboy. From Rahway the line will go to Elizabeth, and a branch will connect Bound Brook with New Brunswick.

From Trenton, the road will pass through Morrisville, Bristol, Cornwells, Terresdale, Tacony, Holmesburg, and Frankfort, and thence into Philadelphia.

AN INGLORIOUS CHAPTER OF TROLLEY ACCIDENTS.

THE newspapers within the past two weeks have recorded a number of serious trolley accidents, most, if not all, of which appear to be preventible. While the heavy summer pleasure travel, and the strain on the men, due to the intense hot weather, may excuse these things in some degree, they should not happen. We present a few typical and local cases, from which lessons may well be drawn.

A dispatch from Lancaster, Pa., of August 10, says: The disaster on the Columbia and Donegal Electric Railway, north of Columbia, at 10:20 o'clock last night, is the worst that has occurred in this county in many years. Up to the present time six persons are dead and sixty-two injured, some of them seriously, and several are expected to die. The accident occurred at a heavy curve just north of the borough limits of Columbia. The exact cause probably will never be known, the motorman being dead, and the statements of passengers widely differ. A large crowd gathered at Chickies Park last evening to enjoy a sacred concert and escape the heat. The ill-fated car—a closed one—was the first to leave the park after the concert, and was packed in every part, both platforms and aisle being crowded. The trip was without incident until the heavy grade just north of Columbia was reached. The car here attained a great velocity, which the motorman was unable to check. The brake refused to work and the supposition is that the brake rigging broke. Passengers were thrown from their seats, and as the lights went out they were thrown into a panic. Several jumped from the flying car, and others tried to do so, as the last curve was reached. Here the car left the track, shot across the turnpike a distance of nearly 100 yards, crashed into a train, and then tumbled into a ditch twenty feet deep. The car was turned upside down, and, as the night was intensely dark, the situation, with the cries of the dying and injured was a frightful one. The passengers who escaped severe injury aided the less fortunate ones, and assistance was soon procured from Columbia, the injured being removed to the hospital in the town, where they received every attention.

On August 8 a collision between a railroad train and a trolley car, by which three persons were seriously injured, the trolley wrecked, and the locomotive disabled, occurred at Homestead Station, North Bergen, N. J. Trolley car No. 102, crowded with passengers, left the Jersey City, Hoboken and Rutherford station, in Hoboken, at 7:30 o'clock. It reached the New York, Susquehanna and Western Railroad crossing at Homestead at 8:02 o'clock. A westbound train from Jersey City was then due. Just as the trolley car reached the crossing the trolley pole slipped from the line wire, and the car was brought to a full stop directly on the crossing. At the same time the lights went out, leaving the car in darkness. At that moment the New York, Susquehanna and Western train came in sight. Its engineer was slowing down, or the consequences might have been more disastrous. The car conductor and the motorman, seeing that a collision was inevitable, shouted to the passengers on the trolley to jump off. All obeyed the order but two persons. They were a man, seventy-two years old, and his wife, sixty years old. They were unable to get out of the car, both being infirm. The engine struck the trolley car, knocking it from the track and leaving it a hopeless wreck. When the old people were extricated from the débris they were found to be seriously injured. When the engine struck the car its engineer was thrown out of the cab and badly injured. He was put on a train going east and taken to Jersey City, where he was sent to the City Hospital.

The cowcatcher and pilot of the engine were smashed and the train was delayed until another engine could be sent from Jersey City to take it to its destination.

On August 8, car No. 106 of the Staten Island Electric Railroad at 2 o'clock p. m. ran into the platform of the waiting room at Port Richmond. The motorman says the accident was caused by the failure of the brakes to work. He says they were all right when he was about a mile from the ferry landing, but when he tried to put on the brakes a short distance from the waiting room they would not work, and the accident could not be avoided. The speed of the car drove it partly through the waiting room, and caused much excitement. Several women and children who were in the waiting room at the time had a narrow escape. Two women, who refused to give their names, were cut about the face by flying glass.

On August 9 trolley car No. 131 of the Nassau line jumped the track at Fifth avenue and Thirty-ninth street, Brooklyn, early in the morning and ran into the gutter. A passenger was thrown out of the car. His left leg was fractured and he was taken to the Norwegian Hospital. Several other passengers were injured, but they refused to give their names to the police, and were taken home for medical treatment.

AMERICAN APPARATUS FOR EUROPE.

Besides selling a fine mechanical and electrical equipment to the Krupp Works, in Germany, the Brown Hoisting and Conveying Machine Company, of Cleveland, have now received an order for three of their largest overhead bridge tramways for the handling of coal and ore, for the Krainische Industrie Gesellschaft, a large Austrian manufacturing concern. These orders have both come entirely through correspondence. The Brown Works have had many inquiries in the past from abroad, but have only of late begun to pay systematic attention to them, with a view to securing the business.

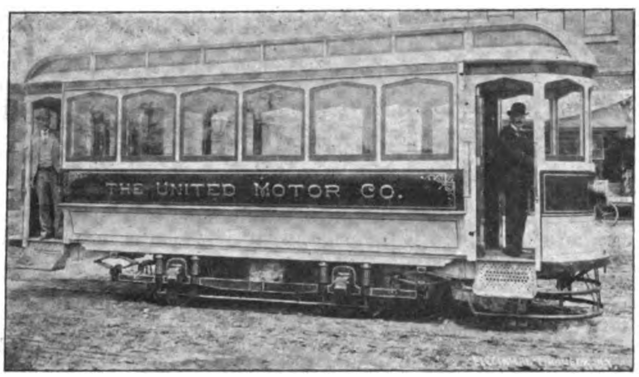
NEW HAVEN, CONN.—It is proposed to handle freight in the Elm City by trolley, and for that purpose the Manufacturers' Street Railway Company, of New Haven, Conn., has purchased the electric locomotive exhibited by the General Electric Company at the Chicago Exposition in 1893. This locomotive has a rated drawbar pull of 7,000 lbs., the weight is 30 tons. It will be used to haul freight cars nearly two miles of the road along the water front. The maximum grade is 2½ per cent., and the guaranteed speed of the locomotive on this grade with a heavy load behind it is seven miles per hour.

TROLLEY VALUES AT LEOMINSTER, MASS.—It is said that Leominster has increased $1,000,000 in valuation in the past year through the electric lines within its limits. And they talked of revoking one of the franchises!

THE WASHBURN SELF-CONTAINED MOTOR CAR.

BY J. S. C.

IN the recent "Fiftieth Anniversary" number of the "Scientific American," the editorial on "The Effect of Inventions on the People's Life" touches upon the early steam engine and its improvements, modern machine tool developments, the telephone, the telegraph, and the supplanting of the now antiquated horse car service by the modern trolley road, and, in emphasis of the tremendous influences of this system of intercommunication upon existing sociological questions, it says, after referring to other factors along these lines, that "The self-contained motor car which can work independently of any central station is still in embryo. Many are in use, especially in Paris, but they are few in number compared to the central sta-



THE "PIONEER" SELF-CONTAINED STREET CAR.

tion car lines. A car motor needs such an exceptional reserve of power that the problem of devising an adequate motor for it is far from easy. The storage battery, for which boundless fields of utility are open as soon as it shall become lighter and more practical, has been tried on street cars and operates a number to-day. The explosion oil engine may yet solve the problem. Hitherto the weight of the motor mechanism and the difficulty of establishing a sufficient reserve of power are the difficulties to be overcome."

The foregoing prophetically calls attention to the needs and the possibilities of more economical and independent means for urban and interurban transportation. Such a system has been designed and the car for practical demonstration has been constructed; a number of successful trial trips have been made which its projectors claim prove conclusively that the system is all they have hoped for.

All independent unit systems, wherein each car is separate and free to go and come independent of every other car, have so far been obliged to equip the car with power apparatus of sufficient initial capacity to meet the maximum demands at any point of the line. All this in the face of an undeniable fact that but 75 per cent. of this amount of power is all that is required for the greatest part of a run. In other words from 50 to 75 horse-power must be provided, the weight of which must be carried continuously, for a five or ten minute use during a trip when 8 to 12 horse-power is all that is required for the remaining fifty minutes of the trip, thus showing a most inefficient combination of elements.

This new system, devised by Mr. Geo. A. Washburn, of Cleveland, O., consists of a suitable car body and trucks, a prime mover in the shape of an explosive engine, a dynamo motor combined in one machine, and a light storage battery.

The car is provided with electric lamps throughout and it is capable of traversing any of the city tracks, whether trolley wires are provided or not. The car could be placed upon the L. S. & M. S. tracks and a journey to New York City undertaken without making any other preparation than the procuring of a few gallons of liquid fuel.

This car it is thought will introduce a new element into the rapid transit problems in that present steam railroads may enter into active competition with existing local lines, for the reason that a single car can be purchased for about the same cost as a large trolley car and as soon as this purchase is made the company is at once ready to commence operations, without the necessity of building a large power station, stringing overhead wires and erecting the poles to support them, with the attendant cost and loss of time in getting under way for active operations.

This car is a near approach to an automatic equipment. Before starting the car on its first trip out from the factory, the engine is set in operation and, being disconnected from the car axles, it rotates the shunt-wound dynamo motor and charges the storage cells. As soon as these are charged the car can be set in motion for actual service. The engine is of about one-third the maximum capacity required, and as the car is started from a standstill more power is required than it possesses. Here then the most beautiful and flexible part of this system shows itself, because the storage battery, automatically, turns in and helps out the engine, and as soon as the car is under way, the demands for power drop below the capacity of the engine, and the power not required for propelling the car is automatically, as before stored in the cells for future use. When the car slackens up for a stop the engine continues at its highest efficiency, under full load, to the standstill of the car, and upon again starting, the storage cells again automatically "help out." From this it will be seen that the car is an independent unit, not hampered by trolley wires and power stations.

Should unforeseen accidents happen, enough power would be available, either in the battery or engine, to reach the nearest station at reduced speeds, so that a car would not become "dead."

New cross-country lines can be started with this system at a cost of but a fraction of the amount necessary to equip the present trolley roads, hence making it possible to extend electric railways into sections which capital will not now touch.

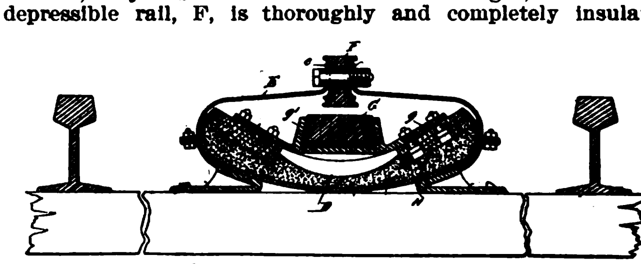
This car is owned by the United Motor Company, of Cleveland, O. The president of the company is Mr. J. J. Shipperd, who is prominently connected in many street railway enterprises.

GRUNOW'S CONDUIT RAILWAY SYSTEM.

A NEW electric conduit railway system invented by Mr. William Grunow, of Bridgeport, Conn., is shown in the following illustration. The conduit, which is shown in cross section, consists of a continuous trough which sets between the tracks and upon the cross-ties, and is filled in throughout its length with asphaltum or any material which is a nonconductor of electricity and which will also not absorb moisture. The asphalt is arranged so as to form a gutter, D, in the central part of the conduit, the sides being inclined.

To the opposite sides or edges of the trough are bolted longitudinal flexible elastic spring-plates, E, which are curved or shaped in cross-section, as shown, and which are upturned at their inner edges, as shown at e. These support between their upturned edges a depressible rail, F, which is thoroughly insulated from the metal plates, and from the bolts passing through them, which hold them rigidly together.

It will thus be seen that there is provided a tubular or hollow conduit, all joints of which are made water-tight, and that the depressible rail, F, is thoroughly and completely insulated



GRUNOW'S ELECTRIC CONDUIT.

throughout its length. Inclosed in this conduit and lying about midway, free and clear of the inner walls of the conduit, is a conductor, which is preferably of a size large enough to carry the full current without the use of feeders. This conductor is supported at intervals by cross bars or supports, g, provided with flanges, g, and from these cross bars or supports the conductor is fully insulated. These cross bars rest upon and are bolted to insulating blocks, H, which may be formed of glass, hard rubber, porcelain, or similar material, and which are embedded in the asphaltum. It will thus be seen that the conductor is free and surrounded by air, one of the best known conductors, and that it is fully insulated from its immediate supports and also from the conduit walls.

The depressible rail, F, is formed in sections whose ends are insulated from each other, but which are mechanically connected so as to form one rigid rail throughout its length. The object of forming the rail, F, in the sections described is to provide means whereby only one or two sections at a time may be charged with the electric current and the section or sections so charged will be those directly under the car.

In operation, the device by which contact is made with the rail, F, is secured to the bottom of a car in such manner as to bear upon the rail, F, with a force sufficient to depress it in contact with the conductor. The amount of this pressure is immaterial, and may be made to suit the requirements of the case or the situation of the line.

TELEPHONY AND TELEGRAPHY.

BELL TELEPHONE FIGURES.

The instrument statement of the Bell Telephone Company for the month ending July 20 shows a sharp falling off in the number put out from previous months, and also from last year. The instrument exhibit follows:

Month July 20.	1896.	1895.	1894.
Shipments	12,584	13,837	6,430
Returned	10,490	7,513	5,754
Net output	2,094	6,324	676
Since Dec. 20.	1895-96.	1894-95	1893-94.
Shipments	126,678	98,896	47,455
Returned	53,667	47,121	40,449
Net output	73,011	51,775	7,006
Total outstanding	749,547	634,281	573,497

THE PACIFIC CABLE.

In the discussion of the Colonial votes in the House of Commons on August 11, Sir Charles Dilke, Advanced Radical, said he hoped Great Britain would not be persuaded to grant a subsidy for a Pacific cable. The first cable, he added, should be from Gibraltar to Cape Town and Australia, which was of the utmost importance.

The Secretary of State for the Colonies, Mr. Chamberlain, said that the Government had not yet pledged itself to grant a subsidy for the laying of a Pacific cable, but the Government was pledged to make an inquiry into the advantages of that route for a cable and regarding the proportionate distribution of the cost. Strategically, he added, the laying of a Pacific cable was of great importance, and, moreover, he continued, it would have great support from Canada and Australia.

THE NEW FRENCH CABLE.

The Paris "Temps" states that the manufacture of the submarine cable which is to be laid between Brest and New York has already been commenced and will be completed by next summer. The new line will be open either in the month of August or September, 1897. Our contemporary says that the new transatlantic cable, which will be nearly 6,000 kilometres long, will henceforth assure the independence and security of French telegraphic relations with the American continent. In consequence, the government has granted a subvention of 800,000 francs per annum for thirty years for the laying down and repair of the cable, which will be constructed and laid by exclusively French means, and will be under the control of the State.

NEWS AND NOTES.

BICYCLE TIRES AND LIGHTNING.

It has been generally asserted and supposed that a bicyclist was pretty safe in a thunderstorm, owing to the insulation from the ground afforded by his rubber tires. The case is now recorded of the death of a Mr. Walter Scott, at Chicago, who was struck by lightning while on his wheel. An inquest was held on the body of Scott. S. Carlson, a teamster, testified that Scott passed him on his wheel going south in Calumet avenue and had proceeded about fifty feet when there came a bright flash of lightning and the bicycle rider fell. When the witness reached him he was dead. The jury returned a verdict of death by shock resulting from a stroke of lightning. It was wet weather and the body as well as the machine of the victim may have been very wet. The ground around the wheel was wet with rain.

PLANTS WANTED IN MEXICO AND HAYTI.

A special dispatch from Washington of August 1 says: The United States Consul at Zurich, Switzerland, informs the State Department that the Mexican Consul there is trying to secure bids from Swiss firms on the new electric light installation for the City of Mexico. The Consul recurs to the fact that, returning to his post from home recently, he crossed the Atlantic with a Haitien who had secured the concession to light Port au Prince by electricity, and was on his way to Europe for the plant. The Consul says he had always been under the impression that the United States could beat the world on electrical appliances, and yet here is business right at our doors slipping away from us because our neighbors have been left in ignorance of our qualifications in the desired line. These neighbors undoubtedly want to purchase for the least money, and there appears to be no valid reason why Americans cannot satisfy the demand in every way.

DR. PROGER ON THE VALUE OF ELECTROZONE.

Electrolyzed salt water, besides its use as a disinfectant for sewage, is now employed as an antiseptic in Paris hospitals. Dr. Proger, chief surgeon of the Deaf and Dumb Children's Asylum at Asmeres, recently told the Académie de Médicine, as the result of long experiments, that "the electrolyzed saline water is neither caustic nor irritating; it may be applied to the mucous membrane as to the skin; it instantly removes all bad odors; stop all putrescent fermentation; kills microbes more effectually and rapidly than any other antiseptic; cleanses and heals fetid wounds and sores, and hastens healing; it is an ideal antiseptic. Consequently, it appears to me of the utmost importance to make it known, and to draw attention to all the applications that it may be put to both from a domestic point of view for deodorizing and cleaning, and from a medical point view as an antiseptic and healer par excellence." Dr. Proger used the preventive and disinfectant with success in cases of angina, coryza, and incipient diphtheria as well, the Hermite process of production being employed.

ELECTRICITY ON THE NEW CURRENCY.

The new $2 and $5 silver certificates have been printed and are ready for issue. Like the $1 certificates, they are a striking departure in money-making. Black ink is used in printing the front of the notes, while the back is of the conventional green.

The $2 note was designed by Edwin H. Blashfield, of New York, and the face contains an allegorical representation of "Science Presenting Steam and Electricity to Commerce and Manufacture," and consists of five partly nude female figures in graceful poses.

Walter Shirlaw, of New York, designed the $5 note. The face has an allegorical picture representing "America enlightening the world," a beautiful female, partly nude, holding in her right hand, uplifted, a lighted incandescent lamp. Reclining at her feet is a female figure of Fame with the traditional trumpet.

The notes are beautiful specimens of the engraver's handicraft, and in that respect will compare favorably with any work in that line.

A THREE-LEAF ELECTROSCOPE.

In a recent communication to the Académie des Sciences, M. L. Benoist described a simple improvement made by him in the gold-leaf electroscope, with a view to an increase of its sensitiveness. M. Benoist merely employs three leaves in lieu of two. When the electroscope is charged the central leaf remains rigidly vertical, whilst the two outer ones diverge equally on either side of it. The sensitiveness of such an instrument is markedly greater than that of an ordinary two-leaf electroscope, each of the outer leaves being repelled four times more powerfully by the central leaf than by the opposed leaf, so that the same divergence is obtained with a smaller charge, and that is so, although the charge is divided between three leaves. A simple calculation shows that for small angles the sensitiveness is something like 50 per cent. greater than that of a two-leaf instrument, and a general formula shows that the relative sensitiveness increases as the angle of divergence becomes greater. In a two-leaf electroscope the sensitiveness becomes zero at about 90 degrees from the vertical. With a three-leaf apparatus the limiting angle is 120 degrees.

AN ECONOMICAL ENGLISH PLANT.

For the past three months an interesting isolated plant has been in operation at Messrs. J. Snook & Co., of Nottingham. This plant includes a 60 horse-power water tube boiler, two 25 horse-power engines, one 500 light dynamo, four 6 horse-power electric motors, five electric fans, six electric irons, etc. The whole of the operations of lighting, ironing, heating and ventilating in this establishment are carried on electrically. The cost of generating power for all these varied operations during the past three months has been very carefully noted, and after allowing 10 per cent. for depreciation and all charges for wages, coal, water, oil, and sundries, the cost of generating amounts to one penny per unit.

A CANADIAN ELECTRIC LOCOMOTIVE.

The Canadian General Electric Company, at Peterboro, Ont., has been building a large electric locomtive rated at 400 horse-power. The hauling capacity is about 15 loaded freight cars at the rate of 30 miles an hour. It is proposed to use this locomotive for hauling pasenger and freight cars for the Hull Electric Company, between Hull and Aylmar.

VOL. XXII. NEW YORK, AUGUST 19, 1896. No. 433.

CONTENTS.

THE EDISON CONVENTION.

THOUGH not a large body numerically, the association of Edison Illuminating Companies is one of great importance when we consider the capital invested in Edison plants, and the influence and experience of the men who manage the various companies included within its membership. There was a time when it looked as though the association would die out just as the Telephone Association did, "unwept, unhonored and unsung," but at the present hour it is perhaps stronger than ever before in its history. The mere fact that Mr. Samuel Insull is willing to assume its presidency, and that Mr. R. R. Bowker consents to stand in line for the succession, is enough to indicate that the association realizes its dignity and value and is determined to live up to its opportunities of usefulness.

It is, of course, to be regretted that the deliberations of such a body are not made public, for there are obviously many points in regard to which the data brought forward by the members is very valuable to all engaged in the industry. Still this information is not altogether buried, for we need only call attention to the elaborate articles that have appeared in The Electrical Engineer on the Edison stations in Chicago, New York, Boston, Brooklyn and Milwaukee to show that while such companies are slow in saying what they propose to do, they are willing to let the public know what they have done.

In extending to Mr. Insull our good wishes for a prosperous term of office, we need hardly dwell with emphasis on his acquaintance with both sides of the central station art,—namely, the manufacturing and the distributing aspects. While he has been known as an intensely loyal Edison man, first, last and all the time, he has been singularly successful in preserving his independence of judgment; and it is safe to say that now as president alike of the association and of the great local lighting company in the West he will preserve that independence of action so essential to the welfare of every local company in the land. In fact it might even be said that Mr. Insull's change of base from the manufacturing of apparatus to the production of current is indicative of the change that has taken place in the industry. The period when the parent companies as creators of local enterprise were all important has passed away, and the local companies are emphatically the masters of the situation instead.

TROLLEY CAR ACCIDENTS.

ANYONE who has witnessed the sufferings of horses during the recent hot weather must have thanked God that there are now 12,133 miles of electric railway in the United States, and only 1,219 of road operated by horses. Some of us can remember the times when every street car track in New York in such a hot spell was strewn with dead and disabled horses; and it is little short of marvelous that the metropolis is still willing to present a spectacle of inhumanity in this respect, and be one of the few cities where horses are tortured in this way.

But while as a general thing the horse has benefited by the change to electricity, it is sadly true that human beings have not yet derived a proper amount of safety to life from the adoption of mechanical power. Accidents are still far too numerous, and in almost every case the casualty would seem to be preventible. We give particulars of one or two recent accidents on another page, and would ask whether it is not possible by the adoption of air brakes and other means to prevent such occurrences. We will go further, and say that the non-adoption of the best appliances now readily obtainable amounts to little less than manslaughter, and that the sooner exemplary punishment is made of the lines subjecting their passengers to wholly unnecessary risks the better.

PHYSIOLOGICAL EFFECTS OF X-RAYS.

FROM the evidence of various experimenters, it is apparent that considerable more investigation will be required to determine what the physiological effects of X-rays are, or even whether any such effects are produced by them at all. The testimony on this subject is very conflicting, even taking only that of the highest authorities. Prof. J. J. Thomson, in the Rede lecture, at the University of Cambridge, states that X-rays do not exert any of those deleterious effects on bacteria which are fortunately associated with ultra-violet light. In contradiction to this statement we print elsewhere a note concerning some experiments made by Dr. William Shrader, of the Missouri State University, on the effect of Röntgen rays on disease germs. In nearly every instance the germs were found to be destroyed by the action of the rays. The experiments with diphtheria bacilli appear to be conclusive, and from other sources we have heard of a number of equally successful experiments in treating consumptive patients with X-rays, but in the face of such contradictory evidence it is necessary to suspend judgment for a time until more data on the subject is brought to light.

In respect to one effect of these rays the evidence is pretty well united. Nearly all those people who have worked extensively in this field state that wherever the rays pass through the flesh the latter becomes apparently sunburned and the hair falls off the exposed surface. This whole subject opens up a field of the utmost interest and one from which highly important results from a medical standpoint may occur.

We deeply regret to note here the death of Dr. Shrader, whose investigations are referred to above, and who died from the exhaustion caused by his unremitting study of the subject.

FAN MOTORS AS LIFE SAVERS.

FROM Wednesday, August 5, to Wednesday, August 12, there were 1,255 prostrations by heat in New York City, and 625 deaths, the temperature on the street, in the shade, seven days out of the eight reaching over 100° Fahr. This is a terrible record, and one that would have been far more ghastly, but for the passing away of the "hot wave" and the arrival of cooler weather. The record would also, we are convinced, have been more serious and the death roll longer, in New York and all over the country, but for the general use of electric ventilators and fan motors. The currents of air set in motion are the breath of life to workers of every kind, and when one has become accustomed to their mitigating influence, it seems almost impossible that other people should not eagerly seek the same boon, now so freely within reach. There are offices, restaurants, barber shops, stores, factories and houses that would simply be unendurable in such terrific heats were it not for the fan motors, large and small; and to their credit must be put an infinite amount of comfort and respite during the past two weeks.

At the same time it is obvious that much may be done yet to enhance the effects obtainable with the fan motor. The majority of them are still too large. In other words, where a fan is used for one person, the speed is very generally cut down by a resistance, simply because it is not easy to endure the tremendous breeze created when the motor is fully let out. It would seem possible to place at command fans of lower speed and less cyclonic tendencies, and it would also seem possible to improve on some of the present forms of fans, so that by different shapes of blade a greater variety of effect, at varying distances and for offices or rooms of different sizes, the required effect of coolness could be secured.

Aside from giving another great lesson in the use of electric fans, the recent hot weather, unequalled, it is said, since 1872, has offered a splendid argument for electric power in general, whether from central stations or in the distribution of energy from large isolated plants. It has been pitiable to see the condition of many men running small steam plants in confined spaces, and to reflect that in most cases a small, cool electric motor would have done the same work, with less worry and suffering on the part of the attendant and general economy for the owner of the plant.

POLICE AND FIRE ALARMS.

TWO English gentlemen from whose premises "police alarms" were recently rung in over the district messenger system, write to the newspapers complaining that no policemen came, but that after the usual long "wait between the acts" a small boy appeared to inquire what was wanted. In one case the need of help was urgent, but the boy explained that the office did not keep "bobbies" on hand and that the calls were not answered because the boxes were often "messed about." The reason for non-service thus vouchsafed was probably not without warrant, and people will certainly increase the efficiency of the district system by ringing only for what they want and only when they want it. It is worthy of mention here, in this connection, that several thermostatic fire alarm systems lately turned in a warning and turned on the water under the influence of hot weather—an evidence of alertness and fidelity in things inanimate one would hardly look for in such trying times.

A LARGE GAS ENGINE PLANT.

WE print elsewhere the first part of an abstract of a paper read before the Institution of Mechanical Engineers, at Belfast, by Victor A. H. McCowen, describing a gas engine central electric plant in that city which is rather remarkable in point of size as well as in regard to its details of equipment.

In this country the price of gas engines, and, in most places, the price of gas is far too high to permit of their being used to any considerable extent except for light, intermittent work, and almost any American engineer would hear of a similar plant of this size with a feeling of surprise. Besides the unusual fuel, the type of engine is one which we are not familiar with on this side of the water, but from the description given we should be inclined to think that the closeness of regulation necessary for the proper running of electric generators would be more certainly attained by means of the finely graduated impulses in the cylinder than would be possible with the ordinary method of missing explosions. Tests of these engines will be given in a following issue. The accounts of the plant show that the gas fuel has cost 2.9 cents per B. T. unit sold, during its first year of working, and this figure will compare very favorably, we believe, with a good many coal burning plants of the same size for the first year's operation.

SOCIETY AND CLUB NOTES.

N. Y. STATE STREET RAILWAY ASSOCIATION.

The next annual convention of this body is to be held at the Hotel Bennett, Binghamton, on Tueday, Sept. 8, at 10 a. m. This is the fourteenth meeting and promises to equal any of its predecessors in interest and importance. A long list of topics for discussion has been prepared by Mr. G. Tracy Rogers, the president, and several have already been allotted. The meeting will be followed on the same day by a general entertainment, including excursions and a banquet in the evening. It is hoped that the street railway companies of the State will be well represented; they can all count upon a very cordial reception from the Binghamton Railroad Company. Arrangements have also been made for the hospitable inclusion of supply men.

SEVENTEENTH EDISON CONVENTION.—CONEY ISLAND, AUGUST 11, 12 AND 13.

THE seventeenth convention of the Association of Edison Illuminating Companies was held at the Oriental Hotel, Manhattan Beach, Coney Island, August 11, 12 and 13, 1896.

The first session was called to order by the president, Mr. C. L. Edgar, at 11 a. m., August 11, and was devoted to the reports of committees on Welsbach light, storage battery, etc. The meeting adjourned at 1 p. m.

The second session was called to order at 2:30 p. m., when a paper was read by Mr. C. E. Pattison, of Boston, on "The Storage Battery in Actual Operation in the Boston Edison Stations." This paper gave the experience of the Boston Edison Company since the installation of its first battery several years ago, and the data as to the depreciation, maintenance, etc., was clearly stated. This paper was fully discussed by several members of companies using storage batteries.

The next paper was by W. I. Donshea and H. A. Campbell, entitled, "A Storage Battery in the New York Edison Stations." This paper gave the history of the battery in the stations of the Edison Electric Illuminating Company, of New York, from the trial of the Crompton-Howell type in the Fifty-third street station down to the present time. This paper, like its predecessor, was fully discussed and the favorable results were commented upon.

The third session was called to order August 12, at 10 a. m., by President Edgar, and was opened by a paper by Alexander Dow on "The Selection of Alternating Current Apparatus for a Central Lighting Station." This paper was immediately followed by one in the same line, entitled, "The Alternating Current System as a Pioneer," by W. S. Barstow, of Brooklyn. Both papers were then discussed and many representatives of Edison companies present gave their experience with alternating systems used in conjunction with the Edison system. The Chicago and Cincinnati companies briefly outlined the work they were doing in this direction.

The fourth session was called to order at 2:30 p. m. Mr. R. S. Hale, of Boston, read a paper on the "Wright-Demand System of Charging for Current." This was followed by interesting discussion as to the results met with in a system of discounts as outlined in a paper presented before the last convention. The Chicago, New York, Cincinnati, Brooklyn and several other companies gave their experience in the new system of charging for incandescent light.

A paper was then read by Mr. John Wolff, of Brooklyn, on "A Self-Cooling Condenser in the Second District, Brooklyn, Edison Station." This paper described the construction and operation, and gave a year's result with the apparatus in question. This paper was discussed by the Detroit and New York Edison companies.

The last paper of the convention was read by W. S. Andrews, of Schenectady, on "Some Recent Developments and Modifications of the Edison Underground System and the Use of Cables as Auxiliaries Thereto." This paper provoked an animated discussion as to the merits of the several underground systems and the use of different makes of cables.

The treasurer's report was then read and accepted, pleasure being manifested at the splendid financial condition of the association and the good work of the treasurer.

The committee on nominations then made a report of the officers for the ensuing year, which report was accepted. These officers are—President, Samuel Insull; vice-president, R. R. Bowker; secretary, W. S. Barstow; treasurer, J. W. Lieb, Jr.. Executive Committee—C. L. Edgar, Chairman; Alex. Dow, G. R. Stetson, A. W. Field, J. H. Vail. Ex-officio Members—S. Insull, R. R. Bowker, W. S. Barstow, J. W. Lieb, Jr.

During the meetings of the convention the ladies were entertained by the Brooklyn Edison Company by a visit to Sousa's concert during the second session, and a trolley party and luncheon during the third and fourth sessions (under the escort of Mr. Ethan Allen Doty), president, of the Brooklyn Edison Company). Tuesday evening, August 11, the members of the association with ladies visited Pain's Fire Works and "Cuba," and on Wednesday evening Rice's "Evangeline," both entertainments being given through the courtesy of the Brooklyn Edison Company.

Thursday, August 13, was taken up by a visit to the Schenectady works of the General Electric Company. The members of the association with ladies left Manhattan Beach on the 8 a. m. train, taking a special train from the Grand Central depot at 9:35. After the train had started the party was served with breakfast and luncheon, through the courtesy of the escorting company, and a quick trip was made, without stop, to the Schenectady works. Here the ladies of the party were given a reception by the ladies of the General Electric Company's representatives, and a drive through the country around Schenectady. During this time the members of the association were escorted through the works, where all details were fully explained and exhibited.

Mr. Steinmetz exhibited several phenomena with high tension current (as high as 150,000 volts) and a long line of newly designed alternating apparatus for transmission and distribution, meeting the admiration of all.

The special train left Schenectady on return at 5:30 in the evening, arriving at Grand Central depot at 9:45, an elaborate dinner having been provided en route.

Throughout this most delightful trip every courtesy possible was shown to the members and ladies, and it served as a fitting finale for this most successful convention.

Delegates Present—Thomas A. Edison, Llewellyn Park, Orange, N. J.; W. E. Gilmore, Edison Laboratory, Orange, N. J.

General Electric Company.—S. D. Greene, general manager lighting department; E. W. Rice, Jr., third vice-president; W. S. Andrews, manager, central station sales; A. D. Paige, manager lamp sales (incandescent lamp department); J. R. Lovejoy, manager supply department; J. W. Howell, engineer lamp works; W. S. Clark, wire and cable department; John Kruesi, mechanical engineer; Caryl D. Haskins, meter department.

Edison Electric Illuminating Company, of Atlanta.—H. T. Edgar, general manager; Jas G. Rossman, electrician.

Edison Electric Illuminating Company, of Boston.—C. L. Edgar, vice-president and general manager; C. E. Pattison, R. S. Hale.

Edison Electric Illuminating Company, of Brooklyn.—W. S. Barstow, general superintendent, W. F. Wells, electrician; John Wolff, superintendent steam plant; Theo. Guillaudeu, chief engineer; C. V. Driggs, superintendent underground department.

Chicago Edison Company.—Samuel Insull, president; Joseph Insull, Luther Stieringer.

Appleton (Wis.) Electric Light and Power Company.—A. L. Smith, president.

Electric Light Company, of Atlantic City, Camden, N. J.—E. A. Armstrong, J. E. Burleigh.

Cincinnati Edison Electric Company.—John I. Beggs, vice-president and general manager.

Cleveland (O.) Electric Illuminating Company.—Samuel Scovil, vice-president; Robert Lindsay, general superintendent.

Columbus (O.) Edison Electric Light Company.—A. W. Field, secretary and manager.

Edison Electric Illuminating Company, of Cumberland, Md.—J. S. Crider.

Des Moines (Ia.) Edison Light Company.—J. A. Colby, treasurer and general manager.

The Edison Illuminating Company, Detroit, Mich.—Alexander Dow, general manager; Hoyt Post, director; Henry Ford, chief engineer.

Elgin City (Ill.) Railway Company.—Chas. Musterfeld, manager.

New Bedford (Mass.) Gas and Edison Light Company.—G. R. Stetson, president; C. R. Price, treasurer.

The Edison Electric Illuminating Company, of New York.—R. R. Bowker, first vice-president; J. W. Lieb, Jr., general manager; W. I. Donshea, district superintendent; W. H. Lawrence, C. N. Moore, J. Van Vleck, Arthur Williams, E. A. Leslie.

The Edison Electric Light Company, of Philadelphia.—W. H. Johnson, secretary and manager; J. H. Vail, engineer in chief.

Rochester (N. Y. Gas and Electric Company.—G. A. Redman, general superintendent electric department.

Wilmington City (Del.) Electric Company.—Reginald Van Trump; A. E. Kennelly, Philadelphia.

During the convention, the electrical industries not within the ranks of the association were represented by several well-known attendants at such proceedings. The list included Messrs. E. B. Kittle, J. W. Godfrey, J. F. Outwater and Hugo

Reisinger, R. B. Corey, J. P. McQuaide, C. W. Price, S. L. Coles, T. C. Martin, T. R. Taltavall, H. L. Lufkin, S. A. Douglas, W. A. Stadelman, A. P. Eckert, W. S. Eckert, and others.

THE EDISON ASSOCIATION TRIP TO SCHENECTADY.

The Association of Edison Electric Illuminating Companies concluded its convention proceedings, held at the Oriental Hotel, Manhattan Beach, by a trip on a special train to the works of the General Electric Company, at Schenectady, N. Y. The train left the Grand Central station at 9:35 a. m., ran on the schedule of the Empire State Express, and reached Schenectady at 1:40 p. m., when it was switched into the yards of the company. A large number of the delegates accepted the invitation and the few who excused themselves on account of the heat, had reason to regret their decision, the weather being much cooler and more bearable on the train than at the beach.

On the arrival of the delegates at Schenectady, they were received by Mr. E. W. Rice, Jr., third vice president; G. L. Emmons, superintendent of the works; A. L. Rohrer, and a corps of engineers. The delegates first visited that part of the factory devoted to the manufacture of the smaller classes of supplies, such as sockets, cut-outs, switches, lightning arresters, commutators, etc., etc. The switchboard department next occupied their attention, and considerable admiration was expressed at its magnitude and the intricate and beautiful work in process of completion. Adjoining this, search lights are manufactured, and some idea was gathered of the extent of the business in this direction by the number of projectors under construction and test. A climb to the projector testing platform gave the delegates a splendid bird's-eye view of the entire works lying on the banks of the Mohawk River, covering 43.21 acres, 76 buildings in all with a floor space of 681,553 square feet, in which all the machinery is driven by electricity.

A glance was given into the brass punching shop, the store house and the porcelain works, where all the porcelain bases for sockets, switches, cut-outs, small cleats, etc., as well as the heavy insulators for long distance transmission work are made. These are tested to 50,000 volts alternating before shipment.

The visitors were then conducted to the main factory and passing by the big foundry, entered the shop devoted to the manufacture of heavy dynamos. Here they saw generators of all sizes from the small ¾ kilowatt to the great 1,500 kilowatt in all steps of manufacture. Already under way were the three-phase dynamos to be used in the transmission of power to Salt Lake City from a point 36 miles distant, similar in character to those now generating current at the Big Cottonwood Stairs for transmission to the same city: Rotary converters for the conversion of power, for Buffalo, transmitted from Niagara Falls, monocyclic generators, railway generators, direct current lighting generators, induction motors of all sizes, small direct connected sets for marine work, etc., etc.

Considerable attention was given to the new testing shop, just completed, in which apparatus of the character mentioned above was undergoing careful test under the eyes of a body of bright active young men. The next shop visited was the wire and cable shop, containing on the ground floor the rubber manipulating stranding, insulating and vulcanizing machinery, and on the upper floor the braiding machinery and the printing office. A sniff was given to the compound shop where the insulating compound is put on the wires, but the delegates refrained from entering.

Passing the power house, in which all the boilers, steam engines and working generators are confined the visitors reached the building in which the Siemens cables are manufactured, and were shown the operation of the great lead presses. Here too, they saw the manufacture of the armature coils and commutator leads, on forms, ready for placing in complete shape on the cores in the adjoining room.

At the far end of the ground is building No. 20, in which the armature laminations are punched and toothed. Here the striking features of the monocyclic system are demonstrated in an experimental plant. The current at 1,000 volts is taken from a monocyclic generator and raised to 21,000 volts in two 35 kilowatt oil insulated transformers. At this pressure it passes to a line about 3,100 feet long, which terminates at the punch house in two similar step-down transformers which reduce the pressure to 110 volts. At this pressure it is turned into the induction motors which drive all the punch presses, and into arc and incandescent lamps.

The visitors were then treated by Mr. Steinmetz to an experiment with very high voltage currents. This consisted in producing an arc at 150,000 volts between terminals about 15 inches apart. Four large oil insulators were used to bring the current up to the required pressure. The arc which was formed appeared as a beautiful undulating pink flash which hung waving in the air for about ten seconds, and was then drawn upwards to vanish as soon as its length had reached four feet or more. Various pressures were used from 70,000 volts up, between varying distances, the effect being always the production of the beautiful evanescent arc.

The next building visited contained the 30-ton electric locomotive now being overhauled and put into condition for use on a branch of the New York, New Haven and Hartford Railway. In view of the fact that the Pennsylvania Company have practically abandoned for the time their experiments with other systems of electric traction, the fact that the N. Y., N. H. & H. R. R. people, who are doing so much to introduce electric traction on their lines, continue to adopt the methods and apparatus of the General Electric Company is interesting.

A visit to the show room of the supply department, containing samples of the new long-burning arc lamps, and improved double carbon lamps, concluded the tour through the works.

The visitors re-embarked on the special train at 5:40 p. m., and reached New York at 9:40 p. m.

The trip was made under the care of Mr. S. Dana Greene, assistant general manager and manager of the lighting department, to whose genial courtesy and urbanity is entirely due the pleasure which each visitor experienced and acknowledged.

It may be mentioned as an evidence of the pains taken to render the trip through the Schenectady works complete, as well as interesting, that each of the guides was furnished with an elaborate miniature blue print marking the itinerary from shop to shop, the arrow heads indicating the routes in and out. This systematic method enabled the visitors to cover a large extent of territory and yet to pause as long as they chose at any point where special features demanded study.

LETTERS TO THE EDITOR.

ANOTHER FLATTENED LAMP.

Referring to the article entitled, "A Peculiar Lamp Accident," on page 148 of your issue of August 12, I beg to say that I send you to-day under separate cover an incandescent lamp similarly distorted. This lamp was found by one of the Inspectors of this association in the kitchen of a dwelling which had been damaged by a fire caused by the explosion of a gasoline stove. The fire was undoubtedly hot enough to soften the glass bulb of the lamp, and the pressure of the outer air on the softened bulb containing vacuum, was sufficient to bend the lamp into its present shape.

Philadelphia Fire Underwriters' Association, Philadelphia, August 13, 1896.

CHAS. A. HEXAMER, Secretary.

(The lamp sent us has the glass globe intact, but is badly flattened and is folded up upon itself, very much in the style of a dried pear. Eds. E. E.).

LITERATURE.

A BRIEF HISTORY OF OLD FORT NIAGARA.—This pamphlet by Mr. Hugh Porter, of Niagara Falls, illustrated by half tone cuts made from photographs by Mr. Orrin E. Dunlap, is interesting and timely at this period when the region and spot it refers to are attracting so much attention. Mr. Porter tells his story in a simple, direct manner and brings out a number of curious and pathetic details in regard to the struggle for ownership of the Niagara valley. The pamphlet is well printed, and the cuts are excellent.

PERSONAL.

MR. ELMER P. MORRIS has been appointed agent in the East for the Electric Railway Equipment Company, of Cincinnati, O., and has taken an office at 36 Dey street, New York. This company are large manufacturers of iron and steel poles for electric railway work, and also of all kinds of line material and motor parts. They have recently largely increased their facilities, and will carry a handsome line of samples in New York. Mr. Morris is also agent for the Simplex Interior Telephone Company, and the Bradford Belting Company, both of Cincinnati.

MR. C. S. BIDWELL, who has been electrician and mechanical superintendent for the Ashtabula Rapid Transit Company since the line was put in operation four years ago last April, has severed his connection with the company. The Trumbull Electric Company, of Warren, O., has elected Mr. Bidwell to the position of general superintendent for the company. The line of which he will have change is eight miles in length, extending from Warren to Niles and connecting with the line from Niles to Youngstown.

A MODERN VILLAGE LIGHTING PLANT.—NORWOOD, OHIO.

BY THOS. G. SMITH JR., M. E.

WHILE all are familiar with the use of direct, constant potential current for operating incandescent lamps and motors, the application of this character of current to the operation of arc lamps for street service is in a measure new, and a description of one of the latest installations for this purpose may be of interest.

The plant about to be described is used primarily for the illumination of the streets of the village of Norwood, Ohio, and it is intended ultimately to furnish current for commercial purposes as well. At the present time the service is almost wholly devoted to the street lighting, with the exception of some 20 incandescent lamps in the station building and some few others now being connected on the commercial circuits. The street lights consist of about 150 arc lamps operated two in series on 220 volts. This is the largest number of lights of this type, so far in use in any village lighting plant in this section of the country; and this station is probably the only one operating street lights exclusively, or in which the incandescent service is a small fraction of the entire load.

The station is a one-story brick structure, with slate roof, built as an addition to the waterworks station; it is designed for the accommodation of three units of the present size, without encroaching on the space devoted to office purposes. The station has three exposures, south, west and north, with a gallery along the west end, forming a convenient storage and testing room.

The present generating unit consists of one 135 kilowatt multipolar, slow speed dynamo mounted on the shaft of a 200 horse-power cross-compound, fixed cut-off engine; dynamo and fly-wheel located between the engine bearings. The dynamo is of the Siemens & Halske make, with outside commutator, and is fitted with their latest form of independent brush holder ring which is mounted on an adjustable pedestal, with roller bearings at three points; this ring is controlled by a hand wheel at the rear of the dynamo. The machine is compound wound and automatic in regulation.

The engine is of the cross-compound, fixed cut-off type built by Houston, Stanwood & Gamble, with a capacity of 200 horse-power, at 150 revolutions per minute, and 100 lbs. steam pressure, non-condensing. The engine frames are mounted on a sub-base which also furnishes support for two of the roller bearings for the brush holder ring. The combination of a heavy fly-wheel with a high speed form of throttling governor, gives excellent practical regulation.

The switchboard is of white marble fixed in a neatly finished oak frame, located at the center of the east side of the building, three feet from the wall. On this board are mounted the instruments and switches for the control and operation of the plant, as follows: Ampere and volt meters, of the Weston circular pattern; main and circuit switches of the Electric Engineering and Supply Company, tubular frame type; Westinghouse circuit-breaker; voltmeter switch; ground detectors; rheostat hand wheel and switchboard lights. The circuits from the board are carried overhead and out from a wire tower located centrally on the roof.

The system of distribution is virtually a double two-wire system, having three wires so arranged that one is the common negative and the other two are separate positives; one of the latter being for the arc circuit and one for the commercial circuit. This enables a separation of the arc and commercial services controllable at the station.

There are two centers of distribution to which feeders are run and from which sub-feeders lead to distributing mains. There are two of these mains which form closed rings about the territory to be covered, and are connected by tie mains. The lamp loops are connected across the mains, and in some cases between the mains and the sub-feeders. The line poles are 30 feet long and the lamp poles 35 feet, all set one-fifth of their length in the ground, and guys are avoided where possible. The lamps are suspended from ⅜-inch galvanized, stranded steel cable secured to the heads of the poles by means of adjustable eye-bolts. Sleet-proof pulleys are used, one in the center of the cables and the other swiveled to the poles. The hoisting ropes are ¼-inch galvanized stranded steel cables, with hemp core, and are secured at lower end by oblong rings slipped over hooked pins, with "Yale" padlocks fastened through the eye in the hook. The arc lamps are of the "Manhattan" enclosed type, designed to operate two in series on 220 volts, consuming four amperes per pair of lamps, and burning 150 hours with one pair of carbons without readjustment.

The results of operation have been gratifying on account of mellow, steady light, with such perfect diffusion as to cause entire absence of shadow under the lamps; also uniformity of current consumption, with very low flushing current on starting. Both ampere and volt-meter needles stand perfectly steady during the operation of the plant, giving an excellent illustration of the uniformity of the load.

The incandescent lamps are 220 volt 16 candle-power lamps, with single filaments, and so far as we have been able to judge are a success; they appear to withstand a greater range of voltage than the 110 and 50 volt lamps. In fact we have run some of our lamps on over 265 volts for considerable periods of time without noticeable injury.

The operation of this plant, though extending over only a short time, has been of such satisfactory a nature as to impress all who have examined it, beside proving a complete refutation of many vehement statements made by the representatives of some of our leading manufacturers of series lamps.

Persons interested in the installation of lighting plants for this purpose or in the improvement of existing plants, will find the examination of this plant valuable to them, and the writer will be pleased to furnish any further information that may be desired.

ELECTRICAL INSPECTION IN PITTSBURG.

About a year ago a scheme was conceived by Morris Mead, the city electrician, which has proven to be of much good to the city of Pittsburg. The idea was to have the erection, construction and inspection of all appliances used for electrical purposes placed under the supervision of the department of public safety in order that safety, comfort, convenience and welfare of the people, and also protection from careless or negligent use of dangerous substances might be insured. Experience has shown, says the local "Leader," that in the construction and increase of wires and appliances used for electrical purposes upon the public streets and in private buildings there is great danger to life and property. Many fires have been caused by bad wires and severe shocks have been sustained by coming in contact with a wire that has become uninsulated by rubbing against something. Until that time no adequate means had been provided by the city for placing the control of such wires and appliances in the hands of the department of public safety, and an ordinance granting this privilege was passed.

The ordinance provided that the department of public safety be given the supervision over all electrical conductors now in use in the city, which includes telegraph, telephone, trolley and other lines and appliances in which electricity is used, and the construction thereof. It also vested the department with the power to supervise the construction of wires and appliances used in private houses, and gave them the right to prohibit the use of either wire or appliance that would be defective or dangerous, either in material or workmanship.

A number of inspectors were appointed, whose duty it is to visit buildings and thoroughly examine the electric wires or appliances therein. If a defect is found the owner of the building is notified to attend to it at once, and the refusal to take cognizance of this notice subjects the offender to severe punishment. Since the adoption of this new idea—eleven months ago—1,339 buildings have been inspected, which is on an average of 122 per month, to say nothing of the outdoor work that has been done. Many defects have been found, and on many occasions these would have been the cause of much damage had they not been attended to. The city, in this respect, is in a very good condition at present, which is due to the passing of the said ordinance. No fires of any account have been reported as caused by defective electric wires, and many accidents among machinists who have to tinker with electrical apparatus have been avoided. The scheme was a good one, and as time goes by the benefits derived therefrom will be more noticeable.

THE PACHUCA, MEX., POWER TRANSMISSION.

The Regio Electric Power Transmission Company of Pachuca will begin the last of this month to send power into that important mining city from Water Falls, 25 miles distant, and it is estimated it will be able to furnish 1,200 horse-power. Several great reduction works will take this power at an annual charge of $250 per horse-power per 24 continuous hours. The Pelton water wheels are employed, and all machinery and supplies are from the United States.

PATERSON, N. J.—A big burst in the Main street water main is attributed to electrolytic action due to escaping railway current. There is no proof, however, that the alleged cause of the trouble is the real one.

Synopsis of Current Electrical Literature.

EDITED BY MAX OSTERBERG, E. E.

Biographical:

SIR WILLIAM R. GROVE.—Obituary.—"Elec. World," Aug. 8, '96.

Central Stations:

READING ELECTRICITY WORKS.—An interesting and well illustrated description of an alternating current plant.—Lond. "Lightning," July 30, '96.

Dynamos and Motors:

LOAD LOSSES IN DYNAMOS.—By W. M. Mordey. A note bearing on Mr. Blathy's load loss. (See Synopsis, Aug. 5, '96.)—Lond. "Elec.," July 30, '96.

Electro-Chemistry:

IMPROVEMENTS IN THERMO-ELECTRIC BATTERIES.—By James Asher. Several methods of securing good economy in the Clamont type of thermo-electric batteries.—"Elec. Rev.," Aug. 12, '96.

THE THERMO-TROPIC BATTERY AND A NEW METHOD OF DEVELOPING ELECTRICAL ENERGY.—By C. J. Reed. Writer thinks to have discovered a new phenomenon which he briefly describes in "Elec. World," Aug. 8, '96.

Isolated Plant:

ELECTRICITY ON THE ST. PAUL.—By Joseph W. Gavan. Five generating sets are installed, each of which consists of a dynamo of 360 amperes at 115 volts and is direct coupled to a marine engine of 475 revolutions per minute. The rudder is operated by electricity.—"Elec. Doings," August, '96.

LIGHTING IN ELECTRIC SQUARE, BUFFALO.—Description of a large isolated plant. Current is generated in four direct connected units. Three of the engines of 160 horse-power each drive 100 kilowatt generators, one 115 horse-power engine drives a 75 kilowatt dynamo. 145,000 feet of conduit and 290,000 feet of single wire are in the building. Further details in "West. Elec.," Aug. 8, '96.

Lighting:

A NEW SYSTEM FOR ELECTRIC ILLUMINATION OF STAIRCASES.—Description of a device said to be patented by the Allgem. Elektr. Ges., by means of which all the lights may be turned on or off from any floor. (This hardly seems to be a patentable invention, since every good wireman can and has done the same thing for years past in this country.—Ed.)—"Leitschr. für Beleuchtungswesen," July 30, '96.

THE EVOLUTION OF ARTIFICIAL LIGHT AND LOCATING AND RELOCATING THE LIGHTING FIXTURES.—By Henry Hopkins. Paper read at the recent session of the Street Lighting Convention at New Haven, Conn. The author traces in a short but interesting manner the first stages of lighting.—"Elec. Doings," August, '96.

ELECTRICITY IN PRIVATE HOUSES.—By Theodore Waters. See Transmission and Power.

Measurements:

AN ELECTRIC FREQUENCY TELLER.—By Albert Campbell, B. A. A portable instrument which depends on resonance for its working.—Lond. "Elec.," July 31, '96.

Miscellaneous:

INSURANCE OF ELECTRICAL PLANTS.—By R. H. Pierce. Paper read before the Northwestern Electrical Association. After a general introduction, author gives the requirements for standard electric light and power stations.—"Elec. Rev.," Aug. 12, '96.

ELECTRICALLY HARDENED STEEL.—A Swiss engineer by the name of Vaux is credited with this invention, a short notice of which appeared in the "Am. Man. and Iron World," Aug. 7, '96.

RIGHTS OF ELECTRICAL COMPANIES.—By W. Clyde Jones. Paper read before the semi-annual meeting of the Northwestern Electrical Assoc. Author discussed the following points: (1) Relation of the electrical industry to the governing power upon whom it depends for the exercise of the essential franchise for the use of the streets and highways; (2) the relation to private persons and abutting property owners; (3) the relations between various companies, electrical and otherwise, which conflict in the exercise of their franchises.—"Am. Gas Light Journ.," Aug. 10, '96.

Power Transmission:

ELECTRICITY IN PRIVATE HOUSES.—By Theodore Waters. Author describes a modern dwelling, paying special attention to elevators, which are easily controlled, and which require no attendants.—"Elec. World," Aug. 8, '96.

MEASUREMENT OF INSULATION RESISTANCE OF STREET RAILWAY CABLES.—By E. J. Houston, Ph. D., and A. E. Kennelly, Sc. D. A method by means of loss of charge measured with a condenser is explained and demonstrated with a numerical example.—"Elec. World," Aug. 8, '96.

Roentgen Rays:

ROENTGEN RAYS OR STREAMS.—By Nikola Tesla. A highly interesting communication, in which the author gives additional information in support of his theory of material particles.—"Elec. Rev.," Aug. 12, '96.

DELETERIOUS EFFECTS OF X-RAYS ON THE HUMAN BODY.—Mr. H. D. Hawks, who has been exhibiting the Röntgen ray apparatus is suffering from peculiar burns of the skin, which he thinks are directly attributable to the Röntgen ray effects.—"Elec. Rev.," Aug. 12, '96.

THE SURVIVING HYPOTHESIS CONCERNING THE X-RAY.—See Synopsis Aug. 5; also "Electricity," Aug. 5, '96.

Railways:

THE SYSTEM OF THE CONSOLIDATED TRACTION COMPANY, of New Jersey. An extended description of the entire system, with many illustrations and a map showing the location of all the lines.—"Street R'way Journ.," August, '96.

RECENT ELECTRICAL OVERHEAD WORK IN SAN FRANCISCO.—By S. L. Foster. Two salient features are especially mentioned; first, the poles are designed, built and set for a given strain and no more than the expected strain is put upon them; second, the height of the trolley wire is twenty-one feet above the rail. A number of views illustrate the mode of construction.—"Street R'way Journ.," August, '96.

STATISTICS OF MILEAGE, CARS AND CAPITALIZATION OF AMERICAN STREET RAILWAY COMPANIES.—We herewith give the total for the United States:

No. of roads, 916:
Horse.—Miles, 1,219; cars, 5,383.
Electric.—Miles, 12,133; cars (motor) 26,242; cars (trailers) 8,729.
Cable.—Miles, 599; grip cars, 3,329; trail cars, 1,542.
Miscell.—Miles, 519; dummy engines, 760; coaches, 2,197.
Total.—Miles, 14,470; cars, 48,182.
Capital Stock.—Total, $784,813,781; per mile track, $54,200.
Funded Debt.—Total, $590,596,391; per mile track, $40,800.
Capital Liabilities.—Total, $8,375,410,172; per mile track, $95,000.—"Street R'way Journ.," August, '96.

Telephony, Telegraphy, etc:

MECHANICAL FEATURES OF TELEPHONE LINES.—By Dr. V. Wietlisbach, of Berne, Switzerland. Theoretical discussion of the subject.—"Elec. Eng'ing," August, '96.

WHALES TO BE KILLED BY ELECTRICITY.

An apparatus for electrocuting whales is described by the Boston "Journal of Commerce." A dynamo, with power-producing apparatus, is to be placed on a whaler, and not used until the whaling grounds are reached. On board there is to be placed a big reel of insulated wire, which is to be placed in a boat when a whale is sighted. One end of the wire is connected with the dynamo, and at the other end, which will be in the boat, will be a hard rubber stick, about four feet long. The wire is carried through the rubber stick, and is attached to a piece of metal twenty-four inches long and one inch in diameter. This metal rod is sharp at the end, so as to penetrate the flesh of the whale easily. The combined rubber and metal rods will be used just as a harpoon is now used, and when near the big fish the harpooner will throw the electric barb. At the time of striking there will be a current of 10,000 volts running through the wire. When the point of the needle strikes the whale, a current connection will be formed with the dynamo, the whale will get the full shock of the high voltage, and will be dead in the fraction of a second. At least this is the calculation of the enterprising captain of the whaler.

UNION CITY, IND.—Mr. J. B. Bailey, Jr., manager of the Toledo, O., Cedar Company, advises us that a telephone plant is to be installed at Union City and Winchester, Ind., and that the two towns will be connected by a toll line.

BATH, ME.—N. G. Shaw & Sons are planning to equip their big sawmill with electricity as a motive power next season.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED AUGUST 11, 1896.

Alarms and Signals:—

RAILWAY-CROSSING SIGNAL. J. Sheecraft, Harveyville, Kas., 565,518. Filed September 17, 1895.
Operated by train approaching in either direction.

ELECTRIC TIME-ALARM. Herbert E. Lipscomb, Richmond, Va., 565,761. Filed June 18, 1896.
Details of construction.

AUTOMATIC SIGNAL. John Pressley Coleman, Edgewood Park Penna., 565,839. Filed June 1, 1896.
Comprises a pivotally-mounted blade and floating lever pivotally mounted to the signal-blade, and two independent motors connected one to each end of the floating lever.

Secondary Batteries:—

CHARGING AND DISCHARGING SECONDARY BATTERIES. Edw. N. Dickerson, New York, N. Y. 565,727. Filed May 26, 1892.
Consists in combining a thermopile with electrical control from the secondary battery, whereby the said thermal source of electricity shall be put in operation whenever required by the battery for the purpose of charging.

STORAGE-BATTERY SYSTEM. Fred. D'A. Goold, Brooklyn, N. Y., 565,741. Filed February 27, 1896.
Means whereby a low-tension continuous current can be employed to charge several groups of storage-cells, group by group, at a transformer-station.

Distribution:—

SYSTEM OF ELECTRICAL DISTRIBUTION. Fred. D'A. Goold, New York, N. Y., 565,740. Filed November 2, 1895.
The combination of several sections of storage-cells connected in series in a permanent order for charging, a consumption-circuit requiring a current of lower tension than the charging-current, and means independent of the series circuit for successively connecting the sections of cells to the consumption-circuit.

Dynamos and Motors:—

DYNAMO-ELECTRIC MACHINE. E. Caemmerer and F. G. Mayer, Chicago, Ill., 565,529. Filed December 4, 1895.
Consists of a field-magnet comprising a core requiring only one magnet-coil, a sleeve adapted to contain said core, and pole-shoes on said sleeve and said core arranged alternately and forming two equal magnetic fields at the ends of said sleeve and said core in which the armatures are adapted to revolve.

DYNAMO-ELECTRIC MACHINE. E. Caemmerer and F. G. Mayer, Chicago, Ill., 565,530. Filed December 4, 1895.
A field-magnet comprising an outer casing, and a core situated within said casing and supported upon non-magnetic supports.

ARMATURE FOR DYNAMO-ELECTRIC MACHINES. D. P. Thomson and A. H. Armstrong, Schenectady, N. Y., 565,647. Filed May 13, 1896.
Comprises a core having slots, the sides of which are parallel, the radii passing through their centers, L-shaped teeth having undercut portions, coils, each occupying an aliquot portion of the slot, and wedges engaging with the undercut portion of the teeth for retaining the coils in place.

CUT-OUT FOR ELECTRIC MOTORS. Ernest P. Warner, Chicago, Ill., 565,867. Filed March 5, 1895.
Details of construction.

Lamps and Appurtenances:—

SOCKET FOR INCANDESCENT LAMPS. Harvey Hubbell, Bridgeport, Conn., 565,541. Filed June 6, 1896.
A pull-socket.

METHOD OF MANUFACTURING INCANDESCENT LAMPS. Frank S. Smith, Pittsburg, Pa., and James A. Vandergrift, Allegheny, Pa., 565,576. Filed January 31, 1895.
Means for supporting and protecting incandescent lamps during the process of fusing and annealing the same.

ADVERTISING ELECTRICAL PHOSPHORESCENT LETTERS OR SIGNS. Daniel McFarlan Moore, New York, N. Y., 565,775: Filed January 7, 1895.
Consists of an electrical conductor shaped into a letter, an evacuated inclosure containing the conductor, and means for interrupting and closing the electric conductor within the inclosure.

PHOSPHORESCENT ELECTRICAL ILLUMINATION BY METALLIC COATING UPON GLASS. Daniel McFarlan Moore, New York, N. Y., 565,776. Filed January 24, 1895.
Consists of an evacuated inclosure, a metallic coating formed upon the surface thereof, relatively yielding electric terminals within the evacuated inclosure, an electric conductor connecting one of the terminals with the coating, and means for rapidly alternately opening and closing the terminals.

PHOSPHORESCENT ELECTRICAL ILLUMINATION BY SECONDARY CURRENTS. Daniel McFarlan Moore, New York, N. Y., 565,777. Filed January 24, 1895.
Similar to above.

ELECTRIC ARC LAMP. John A. Mosher and Wm. Batholomew, Chicago, Ill., 565,861. Filed Sept. 23, 1895.
Comprises a frame having vertical guide-rods, a carbon holder adapted to slide upon the guide-rods and having a knife-edge bearing thereupon.

FILLING FOR INCANDESCENT LAMPS. Jas. McFarlane, Glasgow, and Wm. Burges Edgar, Partick, Scotland, 565,862. Filed June 27, 1894.
A moveable contact having a tread arranged for engagement on opposite sides, and an oppositely-acting wedge engaging alternately with opposite sides of the tread and mounted upon an axially-moving key arranged transversely to the movement of the contact.

Miscellaneous:—

ELECTRICALLY-OPERATED SHEDDING MECHANISM FOR LOOMS. Elmer Gates, Philadelphia, Pa., 565,446. Filed August 5, 1895.
In a loom, in combination a pair of solenoids, an electric circuit, means for throwing said solenoids alternately into and out of circuit, a core or magnetizable device, a warp thread eye, and devices connective of said eye and said core.

ELECTRICALLY-OPERATED JACQUARD MECHANISM FOR LOOMS. Elmer Gates, Philadelphia, Pa., 565,447. Filed August 5, 1895.
In a loom, in combination, a pattern sheet embodying conducting spaces, a roll in contact with said sheet, electrically actuated mechanism to occasion the rotation of said roll, a conducting wire leading to said mechanism and equipped with a switch adapted to be thrown by a moving part of the loom.

ELECTRICALLY-OPERATED REED FOR LOOMS. Elmer Gates, Philadelphia, Pa., 565,448. Filed August 5, 1895.
Similar to above.

MAGNETIC SHUTTLE-MOTION FOR LOOMS. Elmer Gates, Philadelphia, Pa., 565,449. Filed August 5, 1895.
Details of construction.

APPARATUS FOR TREATING SEWAGE. Oluf E. Meyer, Milwaukee, Wis., 565,491. Filed March 4, 1890.
Embodies an electric screen through which the liquid is caused to pass, and by which the organic matter contained therein is oxidized.

ELECTRIC CIGAR LIGHTER. Friedrich Wilhelm Schindler-Jenny, Kennelbach, Austria-Hungary, 565,571. Filed October 2, 1895.
A glow wire and a resistance wire are both placed in the same casing.

ELECTROLYTIC SEPARATION OF VEGETABLE FIBERS. Bertrand S. Summers and Chas. O. Boring, Chicago, Ill., 565,706. Filed November 4, 1895.
The fibers are subjected to electrolytic action in the presence of a solution which is adapted to destroy the gum while not affecting the fibers themselves.

ELECTRIC HEATER. R. Van R. Sill, Cleveland O., 565,574. Filed March 20, 1896.
A hermetically-sealed radiator having vertical chambers communicating with each other at their upper ends, a comminuted resistance filling said radiator and an electrode extending into the lower end of each chamber, and having contact with the resistance material.

ELECTRICALLY-OPERATED STRINGED MUSICAL INSTRUMENT. Willard H. Gilman, Boston, Mass., 565,739. Filed July 21, 1894.
A banjo to which metallic fingers are attached which fret and pick the strings, the fingers being actuated by electromagnets.

Railway Appliances:—

ELECTRIC RAILWAY. William Grunow, Jr., Bridgeport, Conn., 565,453. Filed August 27, 1895.
For description see page 180.

ELECTRIC CONDUIT RAILWAY. John B. Linn, Cleveland, O., 565,624. Filed January 11, 1895.

ELECTRICAL VEGETATION EXTERMINATOR. Marshal S. Cummings, Thomasville, Ga., 565,671. Filed April 30, 1896.
A current distributor adjustably suspended from a vehicle so as to contact with adjacent vegetation.

RAIL BOND. F. H. Daniels, Worcester, Mass., 565,672. Filed June 20, 1896.
The terminal is provided with an opening for a drift-pin.

TROLLEY WHEEL. John B. Dailey, Philadelphia, Pa., 565,725. Filed October 22, 1896.
Comprises a trolley wheel and two grooved pulleys, one upon either side of said wheel, journaled upon the shaft, and contact springs adapted to bear against the ends of said pulleys.

Switches, Cut-Outs etc.:—

ELECTRIC SWITCH. C. Bach, Jr., Milwaukee, Wis., 565,662. Filed November 11, 1895.
A knife switch blade having a handle in pivotal connection therewith, a slotted handle engaging bracket provided with a forwardly extending foot, and a spiral spring connecting the handle with the bracket foot.

ELECTRIC SWITCH. William L. Denio, Rochester, N. Y., 565,673. Filed January 25, 1894.
Especially adapted for use on signal lines.

SWITCHBOARD FOR ELECTRICAL DISTRIBUTION SYSTEMS, Lewis B. Stillwell, Pittsburg, Pa., 565,811. Filed August 6, 1895.
Two sets of cylindrical bus bars, each of which comprises a plurality of sections differing in size and joined end to end; a series of feeder switches and a series of dynamo switches connected alternately to said bus bars and means for actuating said switches.

Telegraphs:—

PHOTOGRAPHIC TELEGRAPH RECORDER. Clement Ader, Paris, France, 565,657. Filed October 24, 1895.
Details of construction.

Telephones:—

TELEPHONE-EXCHANGE SYSTEM. Albert F. W. Meyer, Blue Island, Ill., 565,627. Filed August 8, 1895.
A switchboard having contact plugs, subscribers' lines leading immediately to said plugs without passing intermediately through any form of resistance, said plugs forming the terminals of said subscribers' lines and line annunciators in the ground branches from the grounding plates on which said plugs rest.

MULTIPLE SWITCHBOARD. Robert McGuire Andrews, Richmond, Va., 565,823. Filed April 17, 1896.
Details of construction.

REPORTS OF COMPANIES.

NEW YORK EDISON EARNINGS.

Treasurer Williams, of the Edison Electric Illuminating Company of New York, gives the following July earnings, inclusive of high tension systems:

	1896.	1895.	Increase.
Gross	$ 156,891.32	$ 135,693.59	$ 21,197.73
Net	67,270.56	58,533.59	8,736.97
Gross, 7 months ...	$1,262,795.96	$1,151,641.78	$111,154.18
Net, 7 months	611,803.55	549,535.91	62,267.64

"SILVER SCARE."

With regard to several proposed new enterprises, the information that has reached us takes a stereotyped form, as follows: "Nothing definite yet; silver scare is in the way."

LEGAL NOTES.

INJUNCTION AGAINST THE WALKER COMPANY.

The General Electric Company has secured a temporary injunction against the Walker Company and Charles N. King, of Jersey City and Cleveland, restraining them from making and using a certain form of trolley described in patent 495,443 as a "traveling contact for electric railways." This suit is one of a large number which have been brought by the General Electric Company on its two fundamental railway patents, the underrunning trolley and the overhead switch. Nineteen suits have been brought against railways and manufacturers on the former and thirteen on the latter patent, and in no case has a temporary injunction been denied. The trolley patent was established by Judge Townsend in the suit against the Winchester avenue railway, and the overhead switch patent was sustained by Judge Coxe, in the suit against the Elmira and Horseheads railway, his decision being affirmed afterwards by the Court of Appeals.

It will be remembered that the United States Circuit Court of Appeals, sitting in New York, on July 29, greatly modified the Townsend decision as to trolley bases, and left the street railway companies freer to buy where and of whom they chose. This decision was given in our issue of August 5.

MONEY CLAIMED FOR A FENDER.

Ulysses B. Stuart, through his attorney, A. S. L. Shields, has begun suit in the Philadelphia Common Pleas Court against the Philadelphia Traction Company and George D. Widener, to recover $100,000 damages for alleged breach of contract. The plaintiff states that during the month of November, 1894, Mr. Widener, who was vice-president of the Philadelphia Traction Company, on his own behalf and on behalf of the company, verbally agreed with the plaintiff that if he would invent and produce a new and useful car fender that would prevent persons from being injured he would receive $100,000.

The plaintiff states that he carried out his part of the verbal contract and invented the fender, but in April, 1895, when he requested payment of $100,000 it was refused.

OBITUARY.

DR. J. A. MONELL.

Dr. Joseph Augustus Monell, who had been a practicing physician in this city for about forty-five years, died last week. He was born in Middletown, N. Y., in 1826. He was graduated from a medical college in Philadelphia, and afterwards from the College of Physicians and Surgeons of this city. He was a member of the New York County Medical Society, the New York Academy of Medicine, the New York Pathological Society, the Physicians' Mutual Aid Society and the New York Electrical Society, electricity being a subject that interested him greatly. His widow and a son survive him.

W. G. CAMERON.

William G. Cameron, forty years old, an electrician and contractor, of Woodside, L. I., was killed on Wednesday night last in the power house of the Steinway Electric Railroad, Astoria, Long Island. Mr. Cameron built part of the Steinway Road, and was known to all the engineers and workers about the power house.

After returning from New York City Wednesday night, Mr. Cameron went into the power house to converse with the engineers for a few minutes. He went into the motor room for a short time, and then disappeared. The engineers thought he had gone into another room. He, however, had been caught in the shafting. His body was whirled around by the belt, and the first the engineers knew of his being in the machinery was when he uttered a cry.

On looking into the machinery, the engineers saw his body dashed against a side wall of the building, and fall to the ground, a distance of forty feet. When reached Mr. Cameron was dead. His body had been crushed in a terrible manner.

EDWARD MAY.

Mr. Edward May, president of the Mount Morris Electric Light Company, died suddenly in his office at Van Dam and Greenwich streets at 6 o'clock p. m., on August 10, during the extremely hot weather. Mr. May was overcome by a sudden illness and an ambulance was summoned. When the surgeon arrived, however, Mr. May was dead. Mr. May was born in Minden, Westphalia, Germany, fifty-two years ago, and came to the United States in 1867. He afterwards became interested in electrical concerns, and together with his brother Julius and other capitalists he organized the Mount Morris Electric Light Company. This company was one of the pioneers in the electric lighting business in this city, and when the majority of the other electric lighting companies opposed the placing of the wires underground the Mount Morris company advocated the measure. In addition to being the president of the Mount Morris company, Mr. May was also president of the Yonkers Electric Light and Power Company, vice-president of the Globe Electrical Construction Company and vice-president of the Eagle Gold Mining Company.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

PIONEER ENCLOSED ARCS.

We hear that the business of the Electric Arc Light Company has increased so rapidly of late on account of the wonderful success of the "Pioneer" enclosed arc 150 hour lamp that additional forces are required in the active management. Mr. J. H. Astruck, well known downtown as a bright and courteous business man, has joined the already strong staff of the "Pioneer." Prof. L. B. Marks, the chief electrician, has charge of the scientific end. Mr. Joseph Bijur has the factory in charge and Messrs. Hubbard & Armstrong have the city sales department in charge. Arrangements have thus been made to handle a very large business most readily.

THE YAUX ELECTRICALLY TEMPERED STEEL TOOLS.

From European sources comes a report of the experiments carried out by M. Yaux, of Strasburg, in the presence of a committee of engineers. It appears that a drill tempered by electricity penetrated through a piece of steel quite as quickly as a drill of the best quality of steel tempered in the ordinary manner would have done, and a circular saw tempered by electricity severed bars of iron with a remarkable degree of ease. With shears of electric steel a bar of steel one and three-eighths inches wide and three-fourths of an inch thick was cut in two in a cold state, the same operation being repeated five times on the same bar, with no alteration whatever observable on the edge of the shears; and a simple table knife, tempered by this new process, cut eleven times in succession a piece of iron wire one and a half millimetres thick as easily as if it had been a piece of string. All the explanation of this process consists in the statement that the tools are dipped, after being heated, into a conducting bath traversed by electricity.

OUTAGES OF CITY ELECTRIC LAMPS.

IN the last annual report of the City Electrician of Cincinnati, considerable attention was given to the question of the outages of city electric lights. The difficulty in the case of outages seems to lie in the difference between those reported by the police department and those acknowledged by the illuminating company having the contract for the city lighting. His report states that "it is not customary to deduct lamps that are out less than an hour, although entire circuits have been out for from fifteen to forty minutes for which no deductions were made."

"I do not think (although it is a legal point) that it was ever intended or contemplated in the contract that the 'hour clause' should refer to whole circuits or districts, and would recommend that a system be devised so that when whole circuits are out for less than one hour the time of outage could be reported and deducted, and suggest that a man be placed at the electric light station to keep tab on circuits only, noting and reporting the time said circuits were out."

The total number of outages reported to the electrical department from all sources was 35,238 hours and 44 minutes, representing a money value of $775.40, out of which the Cincinnati Edison Electric Company acknowledged only 10,924 hours and 33 minutes, or $240.35. The money lost to the city, therefore, by the difference in these reports amounted to $535.05.

THRESHING BY ELECTRICITY.

A special dispatch from Avondale, Pa., of August 12, says: Henry Palmer and some other farmers in this section are using the electric current to furnish power to run their threshing machines. Many barns have been destroyed by sparks from the steam engines, and it is thought by means of electricity this danger will be avoided.

ELECTRICAL MARINE EFFECTS AT HALIFAX, N. S.

At the Halifax, N. S., Carnival just closed one of the principal attractions was the electrical illuminations of the warships and the illuminated procession, in the harbor, of steamers, yachts and boats. The flagship "Crescent" was decorated from the water line to the trucks with incandescent lamps indicating plainly the shape of the hull as well as the masts, yards and funnels, even more minutely than was done on H. M. S. "Blake" when she was in New York. The other English and French war-ships and the cable ship "Mackay Bennett' made wonderful displays with their search lights and blue fire. The illuminated procession had a very pleasing effect, the steamers and yachts being decorated with all sorts of lights. But what was pronounced the handsomest exhibit of all was the steamer "Annie," on which had been placed a special engine and dynamo with strings of incandescent lamps covered with fancy shades and Wheeler reflectors. This installation was the work of John Starr, Son & Co., Ltd., the electrical firm of Halifax, who had a party of friends on board. Among the visitors thus entertained was Mr. S. A. Chase, of the Western Electric Company of New York.

RECENT INSTALLATIONS OF THE BALL ENGINE CO.

We give below a long and encouraging list of recent installations made by the Ball Engine Company of Erie, Pa:

Ohio State Reformatory, Mansfield, O., two 150 horse-power engines direct connected to Card dynamos; Warner Lock Company, Lyons, Iowa, one 60 horse-power engine; Aberdeen Electric Light Company, Aberdeen, Miss., one 100 horse-power engine; Baltimore Sugar Refining Company, Baltimore, Md., one 40 horse-power engine; Lynchburg Cotton Mills, Lynchburg, Va., one 60 horse-power engine; Carpentersville, Elgin and Aurora Railway Company, Elgin, Ill., one 400 horse-power vertical compound condensing engine, direct connected to General Electric Company generator; Electric Light Plant, Ovid, N. Y., one 70 horse-power compound engine and steam plant, complete; one 35 horse-power engine for Mexico; Edison Electric Illuminating Company, Baltimore, Md., one 300 horse-power cross compound engine; McIntosh, Hemphill & Company, Pittsburg, Pa., one 100 horse-power engine, direct connected to Westinghouse generator; Crocker-Wheeler Electric Company for Versailles, Pa., one 150 horse-power engine; Western Electric Company, Janesville, Wis., one 40 horse-power engine; Danville Street Car Company, Danville, Va., one 150 horse-power engine; Mohawk Building, Cleveland, O., three 50 horse-power engines, direct connected to Walker dynamos; Harper Hospital, Detroit, Mich., two 70 horse-power engines, direct connected to General Electric dynamos; Booth Packing Co., Baltimore, Md., one 80 horse-power engine; Mt. Washington Electric Light and Power Company, Mt. Washington, Md., one 100 horse-power engine; Lehigh Valley Coal Company, Wilkesbarre, Pa., one 250 horse-power tandem compound; G. & O. Braniff & Company, City of Mexico, one 80 horse-power and one 30 horse-power engine; Tremont Building, Boston, Mass., one 100 horse-power and one 50 horse-power, direct connected to General Electric dynamos.

GENERAL ELECTRIC X-RAY APPARATUS.

Investigators and others practically interested in X-ray work will without doubt be greatly interested in noting the appearance of a large and responsible concern as manufacturers of all kinds of X-ray apparatus. As will be seen in our advertising columns, the Edison Decorative and Miniature Lamp Department (General Electric Company, Harrison, N. J.), is in the field with an entire line of X-ray apparatus of all kinds.

We hope to be able to present to our readers shortly some further description of the apparatus which is now being made and extensively sold by the above concern.

WATERTOWN ENGINES.

W. H. Baker & Co., the well-known chocolate manufacturers, have just completed the equipment of a new plant at Annadale, Dutchess County, New York. The contract for steam plant, including engines, boilers, pumps, heaters, etc., has been awarded to the Watertown Steam Engine Company. The plant to be turned over erected complete and in full running order.

The Watertown Steam Engine Company present the following list of sales during July: One 13&22 x 14 compound condensing engine, direct connected to Westinghouse generator, for Ohio State University, Columbus; one 9 x 10 high-speed automatic for Maggie Mitchell Apartment House, N, Y.; one 12 x 12 H. S. direct connected to Eddy generator for Cameron Apartment House, New York; one 10 x 12 belted engine for Rome Custodial Asylum, Rome, N. Y.; three 9&16 x 14 vertical compound condensing engines, direct connected to Eddy generator, for Pope Bicycle Manufacturing Company, Hartford, Conn.; one 14 x 14 single-cylinder direct connected to General Electric dynamo, for Hotel Stafford, Baltimore, Md.; one 15 x 14 single-cylinder direct connected to Siemens & Halske generator, for Roosevelt Hospital, New York; two 15 x 14 direct connected to Walker generators, for Windsor Hotel, New York; one 13 x 14 and one 10 x 12 direct connected to Siemens & Halske generators for the Chemical Building, St. Louis. Also remodeling the steam plant of the New York State Insane Asylum, at Utica, N. Y., including battery of six 125 horse-power boilers.

RECENT ENGINEERING WORK.

The above is the title of a handsomely-illustrated pamphlet published by Ford & Bacon, engineers, Mail and Express building, New York, in which two of their street railway systems are described in great detail. This concern take entire charge of the engineering details of street railway and other systems, attending to the details of construction, including all civil, mechanical and electrical engineering connected with the work. They furnish all surveyors, draughtsmen, inspectors and clerical force needed for the work, together with all the engineering supplies used.

The descriptions given of the Orleans Railroad system and the Bergen County Traction Company's system which were built by Ford and Bacon, shows their work to be of the highest character.

SELF-LIGHTING OIL LAMPS.

The Empire Self-Lighting Oil Lamp Company, 766 Broadway, N. Y., held an "opening" recently, at which they had on hand a large and varied assortment of lamps all equipped with their electrical self-lighting attachments.

A small, dry electric battery, hidden in the base of the lamp, does the lighting in the most convenient and perfect manner. The arrangement is simple, reliable and safe. It will light the lamp once or twice a day during six to nine months without renewal, and it then costs but sixty cents to replace the battery.

It is not liable to get out of order; a child can light the lamp without danger, and there are no complications whatever. The oil chamber may be removed and the lamp taken apart for cleaning as easily as in the case of a lamp not provided with the attachment.

ELECTRIC CAR HEATERS.

The American Electric Heating Corporation, of Boston, Mass., have issued a new catalogue for 1896-7, describing their electric heaters. These are arranged so that all the heaters in a car may be used at the same time, with three different degrees of heat. The arrangement of the heating coils is such that the principal radiation is from the front surface, i. e., towards the center of the car when placed along the sides, a more efficient method than when both sides of the case may become equally heated. When three divisions of heat only are required it can be accomplished with a pair of single switches of their latest form, or if preferred their combination switch may be used, although the latter is most desirable where more than three variations of heat supply is required.

This concern is exclusively engaged in producing electric heaters, and with its corps of expert electrical engineers there is every reason why the best results of electric heating should be obtained with their product.

WESTERN NOTES.

THE ELECTRIC APPLIANCE COMPANY have been somewhat delayed in getting in their stock of "Electra" high-grade Nuernberg carbons, but have finally received their first carload, and are now ready to talk imported carbons to the Western trade. They will carry the largest stock of imported carbons in the West, and as exclusive Western representatives of the manufacturers, are prepared to make the right kind of prices.

J. HOLT GATES has been appointed Western sales agent of the Walker Company, manufacturers of street railway apparatus, of Cleveland, O. Mr. Gates is also Western sales agent of the C. & C. Electric Company, New York, and in his salesroom at 311 Dearborn street, Chicago, under Manhattan Building, he carries a full line of dynamos and motors, enabling him to make prompt shipments. Now, that he has the Walker and C. & C. companies' agencies, almost any requirement in lighting, power and railway machinery can be filled immediately.

WHAT TWO ORDINARY MOTORS WILL HAUL.

The limitations of electric railway motors are occasionally hard to discover. They sometimes submit to extraordinary overload and perform their duty without accident or even hesitation. An instance of this occurred recently at Madison, Wis., where, according to Mr. F. W. Oakley, the receiver of the Madison City Railroad Company, one of the General Electric Company's double General Electric 800 motor equipments, was overloaded to the extent shown in the illustration. The load consisted of the motor car and four trailers, containing all told not less than 500 persons. With this load a speed of seven miles an hour was maintained, the motor car and train running up the heaviest grades without difficulty. This, we believe, is about the best record made by an ordinary car equipment and speaks well for the sturdiness of the motor and its ability to stand up against abnormal strain.

A FATAL FIRE AT THE FACTORY OF THE A. K. WARREN ELECTRIC CO.

On Tuesday afternoon, August 11, the large factory and repair shops of the A. K. Warren Electric Company, in the extensive building at 465 Greenwich street, New York City, were visited by fire. The building is six stories, of brick, and the fire appears to have broken out in the basement, though its origin is unknown. The bookkeeping offices of the firm were on the ground floor, and the staff there barely had time to get out, so quick was the rush of the flames. A young man named Teer showed great courage in staying long enough to get the books and papers of the firm into the safe. About 60 or 70 men were employed by the firm on the premises, in addition to their outside staff, and in trying to give warning to the hands, the foreman, William Gray, who could easily have escaped, lost his life. He delayed trying to make his escape until the last, and then sought to ascend by the elevator. By the time he had reached the sixth floor the fire was so close behind him that he had not time to try to reach the roof, where he would have been safe, and ran to the fire escape at the front window. The flames followed him, making escape impossible. William Caulfield and Charles Coones, who had reached the roof, looked over the edge and saw Gray on the fire escape below, penned in by the flames.

An electric wire ran across the roof. This they cut in two, and lowering one end to Gray told him to tie it around his waist and they would try to pull him up to the roof.

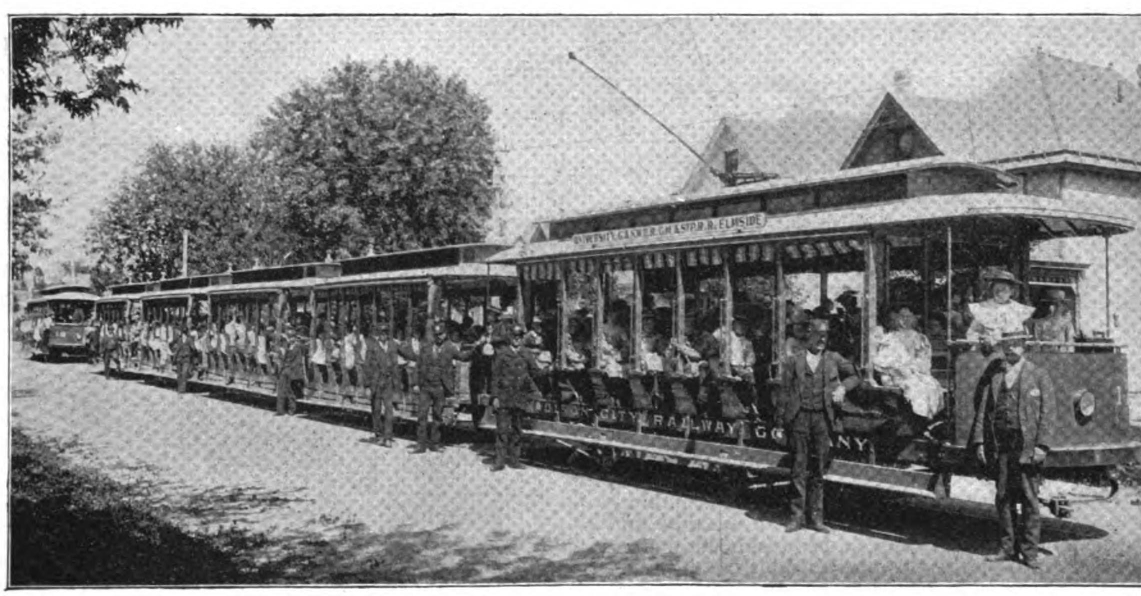
Gray succeeded in passing the wire around his waist, but the flames were so close upon him and the smoke so thick and choking that he could do no more. He sank upon the fire escape, while in only a few moments more he might have been in safety, and there met his frightful death.

He was burned slowly to death and for nearly five hours his charred body, the limbs contorted, showing the frightful agony he had endured, could be seen from the street, the firemen being unable to reach the body until the fire was almost extinguished.

Felix Haas and John Muller, employees of the firm, were also burnt to death; while John Cummings, T. Sharkey, J. W. Teer and N. Stavni were all severely burned. Messrs. Warren and Steers, members of the firm, were lucky enough to have gone out to lunch at the time—about half past two—the pressure of business having detained them at work until that hour. They were insured.

William Gray was once a soldier in the English army and had medals for campaigns in South Africa and Afghanistan. He lost his life through anxiety for his fellow workmen. He leaves a widow and three children.

A. K. Warren & Company inform us that they have taken temporary offices at 20 Desbrosses street, and have already started again with a full force. They are now filling all orders and taking care of their large list of customers. They have the fullest sympathy, in their disaster, of a wide circle of friends.



One Motor Car Hauling 500 Passengers, Madison, Wis.

WESTERN NOTES.

KOHLER BROS, the Monadnock, Chicago, report that they are making good sales of the electrical apparatus manufactured by the Gibbs Electric Company, Milwaukee, for whom they are general agents, and that the factory is working on full time so as to enable them to ship promptly.

ROTH BROS. & CO., 30-34 Market street, Chicago, are still keeping quite busy in getting out their orders, and, although the fan motor business is now nearly at an end, they are looking forward to a good winter trade in dynamos and motors and are in a position to fully equip moderately sized storage battery or steam lighting plants. This young and enterprising concern have not only shipped goods all over the United States, but have also received some very nice orders from foreign countries.

THE ELECTRIC APPLIANCE COMPANY'S complimentary duplicate order book advertising scheme has proven to be a big success and the books are much appreciated by their customers. The Electric Appliance Company still have a number of books left which will be sent free on application.

THE STANDARD HEAT CONTROLLER COMPANY, 211 First National Bank Building, Chicago, feel so much encouraged by the expressions of satisfaction which they have received from those whom they have supplied with their heat regulating apparatus, that they are about to push hard for a large business in the coming fall and winter. As a preliminary step in that direction they have recently published a very handsome illustrated and descriptive catalogue of their regulators which they claim to be up to date in every respect. At the end of the book are shown some of the testimonial letters received by this concern, as well as the names of several people whose dwellings have been equipped.

THE ACME ELECTRIC LAMP COMPANY, 1659 Broadway, New York, are a young concern in the trade, with a new dry battery suitable for bicycle, road wagon and carriage lamps, electric bells, telephones, electric lights for launches and physicians' batteries, etc.

NEW "G. I." ARC LAMPS.

The General Incandescent Arc Light Company are putting out some handsome designs of their long life direct current arc lamps. These lamps are very attractive and ornamental in appearance. The feeding mechanism is simple and reliable. No springs or gear wheels are used. The regulation is close and the adjustment cannot change. Trimming can be done easily and every part can be removed without disturbing the others.

They burn singly on 100 to 125 volt direct current circuits. One pair of carbons lasts 150 hours.

SILEX INSULATION.

The Silex Insulation Company, 39 and 41 Cortland street, New York City, invite the electrical public who are interested in the subject of insulation to a demonstration at their office of the insulating properties of Silex, made under the patented process of this company.

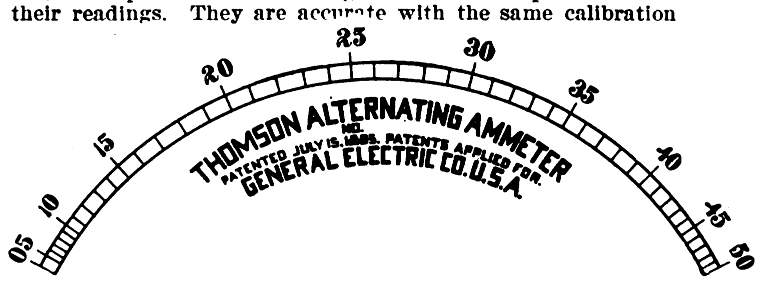
They have also prepared a pamphlet under the title of "A Day with Silex," in which the nature of this substance is described and many of the uses to which it may be put are enumerated. The company state that they are prepared to prove that the problems of perfect insulation and long distance transmission of electrical energy can be solved by their preparation of Silex, and they would be pleased to have their claims investigated.

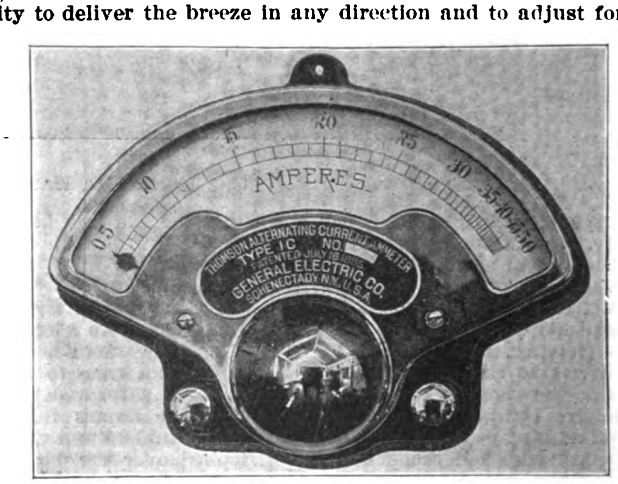
J. D. MILLER & CO.

Mr. John D. Miller and Mr. Edwin H. Ludeman, under the style of J. D. Miller & Co., have issued a notice that they have severed their connection with the Pierce & Miller Engineering Company, and that they will now do business in partnership as above. They will endeavor to meet all requirements in their line of complete power plants, engines, boilers, general machinery and contractors' supplies. They are ready to furnish plans, specifications and estimates. Their offices are in the Taylor Building, Cortlandt street, New York City.

THOMSON ALTERNATING CURRENT AMMETER.

The inclined coil type of measuring instrument developed by Professor Thomson, with the portable forms of which we are familiar, has been adapted for use on switchboards, and a complete series of these instruments is now being manufactured by the General Electric Company. With the accuracy and durability of the portable appliances, they combine, it is stated, the long scale and general mechanical character requisite in modern switchboard practice. The instruments are free from parts liable to change and thus are permanent in their readings. They are accurate with the same calibration





THOMSON ALTERNATING CURRENT AMMETER.

for all commercial frequencies. Each instrument is constructed for either back or front connection, is fitted with a light nickel cover and binding posts and a black enamelled metal base. The ammeters read from 0 to 3½, 10, 25, 35, 50, 75, 100, 150 and 200 amperes; the volt meters from 0 to 75, 150 and 650 volts.

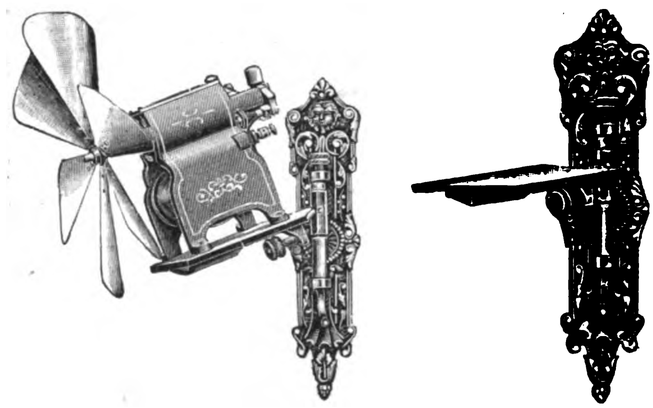
THE DOW PORTABLE ELECTRIC ASSISTANT COMPANY has been organized at Westbrook, Me., to deal in electrical apparatus. It has a capital stock of $100,000. The officers are: G. W. Wheeler, president; W. E. Dow, treasurer, both of Braintree, Mass.

THE AMERICAN ELECTRICAL WORKS CLAMBAKE.

Invitations have been issued by Mr. Eugene F. Phillips for the Eighteenth Rhode Island Clam Dinner given by the American Electrical Works to the electrical fraternity. The date is Saturday, August 22, and the place is the Pomham Club, Providence. A delightful day is confidently expected by everybody.

THE FULLER FAN MOTOR OF THE NORTH AMERICAN ELECTRIC CO.

We illustrate herewith one of the ingenious novelties that the fan motor art has given birth to, and one for which there should be an abundant welcome from the public and the trade. The devices are the patented invention of Mr. John E. Fuller, and are introduced by the North American Electric Company, of 181 William street, New York City. As will be seen, a metal bracket provides for that adjustment of the motor to



FIGS. 1 AND 2.—FULLER ADJUSTABLE FAN MOTOR OUTFIT.

varying conditions that is so essential to securing the greatest comfort, economy and efficiency from the outfit.

There is a substantial and ornamental brass plate which supports a table at right angles to itself on which the motor is placed. A thumb-screw permits tilting the motor so as to carry the current of air in any direction. The plate supporting the motor is hinged to a vertical post which also allows lateral motion. The plate screwed against the wall is elaborately finished. The tables for these brackets are made of different sizes to suit the various fan motors on the market.

The North American Electric Company sell a well finished set of fan motors of different sizes, both incandescent and battery, to suit the consumer's necessities. It is obvious that the ability to deliver the breeze in any direction and to adjust for any new set of conditions is a great advantage and boon; and while many attempts have been made to reach this result, it will be readily admitted that Mr. Fuller has been successful.

THE SOUTHERN ELECTRICAL CONSTRUCTION AND SUPPLY COMPANY, of Norfolk, Va., has made an assignment, Leon Judson, trustee. The liabilities are upwards of $14,000 and include Western Electric Company, $658, and Interior Conduit and Insulation Company, $973.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

MISCELLANEOUS.

ALTERNATING CURRENT MACHINERY AT THE BUDAPEST MILLENNIUM EXHIBITON.—V.

BY ALFRED O. DUBSKY.

A VERY curious experiment shown at the exhibition illustrates the extent to which a careful insulation may be strained. Messrs. Ganz exhibit a three-phase motor of 1 horsepower, working completely submerged in water. There is a large glass vessel full of water, and an ordinary three-phase motor is dipped into it, in such a way that the water circulates freely about it. The air gap is now in reality a "water gap!" It is wound for the regular tension of 300 volts, a tension with which two bare copper conductors connected to the generator terminals melt when under water. The machine works several hours under water every day, without incurring the slightest injury. The rotor has its winding short circuited, and the connections are covered by a mixture of paraffin, tar, etc. The stator is wound in an ordinary way, with a double-covered cotton wire; this is afterwards insulated carefully with a special paste, used for insulating all the Ganz machines.

Another three-phase motor of the same size (1 horse-power) is put upon four spiral springs about 30 cm. above the floor, in order to show the absence of any irregular movement or vibration. While revolving no oscillations of the spring are visible, for the rotor is well balanced. It is, of course, only a common demonstration of a well-known fact, that carefully balanced electric motors never need such solid foundations as are prescribed by steam engine practice.

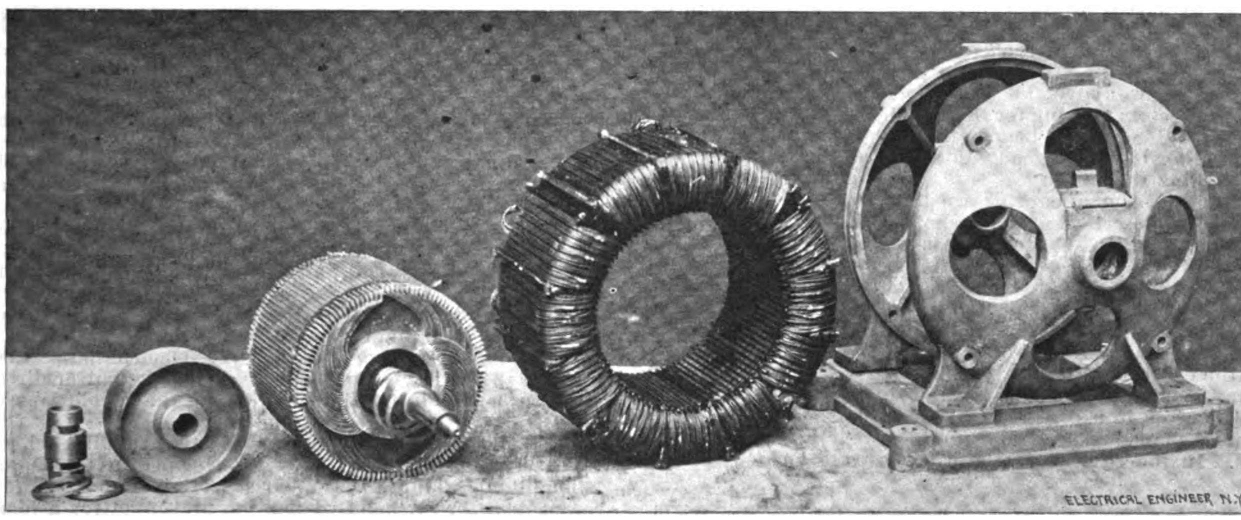

FIG. 22.—PARTS OF THREE-PHASE, 3 H.-P. MOTOR.

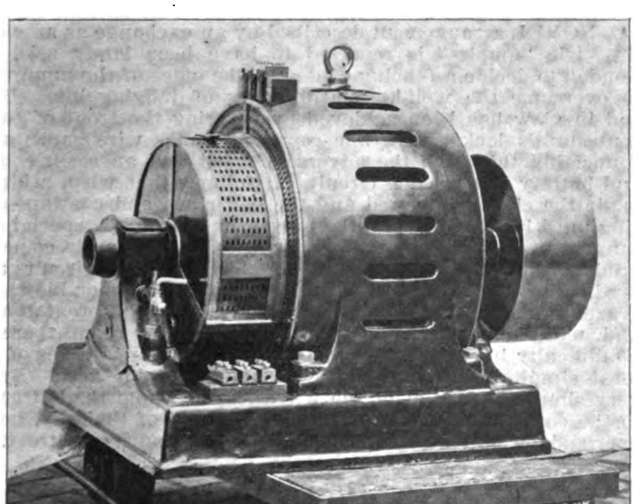

FIG. 23.—NEW TYPE 16 H.-P. THREE-PHASE MOTOR.

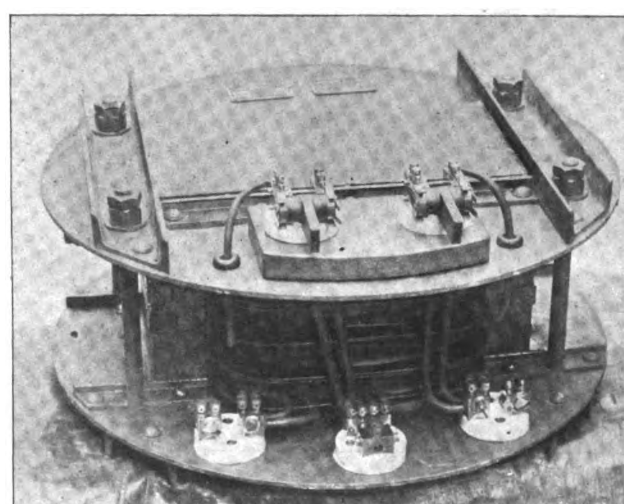

FIG. 24.—NEW GANZ SINGLE-PHASE TRANSFORMER.

Fig. 22 shows clearly the construction and details of a 3 horse-power three-phase motor (4 poles, 1,200 revolutions per minute). The winding of the inducing part is a ring winding, therefore the iron plates are pressed together in a bronze case.

The bearing shields on both sides are made of cast-iron and are held together by long iron bolts traversing the whole width of the motor. The single parts of such a motor are snown here separately. This general type is used for motors up to 8 horse-power in capacity, while a large 16 horse-power motor is illustrated in Fig. 23. The parts of the motor shown in Fig. 23 are made of cast-iron. The motor has a drum winding, which is always advantageous for motors of a large size. Here we have the possibility of using copper bars for the winding, both of the stator and of the rotor, and this a cheaper construction than with wire. Moreover, the magnetic dispersion is also less with such an arrangement.

I may here mention a very little-known method of determinating the curve of the "slip" in testing these motors. This method can be used for alternating current motors in general and is very simple. An arc lamp is put before the pulley of the motor and this lamp is fed by the same current we send into the motor. I should say that this lamp can be of a very primitive construction without any complicated machinery. There is fixed on the pulley a round plate of thick black paper with a line or cross drawn in white upon it. If the motor turns while the lamp is burning, we shall see that the line or cross will revolve with a greater or smaller speed, as the motor is more or less loaded. It is very easy to count the number of these revolutions; this number is directly the slip of the revolving magnetic field in comparison with the field revolutions corresponding to the number of periods of the generator.

The switchboard which controls the single-phase lighting generators and the three-phase central station machines, is situated in the middle of the great machinery hall and located on iron beams about 8 feet above the floor in order to bring it in full view above all the electrical machines. The metallic rheostats serving for the parallel coupling are mounted just below the horizontal beams, they are surrounded by a network, in order to assure good ventilation and prevent anything from touching them.

The high tension apparatus used on this switchboard has been already described in a foregoing chapter. I shall now make some mention of the low tension switches used in the power distribution. Most of these switches have fuses put directly upon them. The switches make a very quick break, as it is attained by the intermediate use of a spring, the handle serving only to give the first impulse.

There is still a great deal of alternating current apparatus in use at the exhibition which remains to be described. The newest Ganz single-phase transformer (5 kilowatts), as shown in Fig. 24, has its iron core made of two parts. Each part consists of E-shaped iron sheets, pressed together by the end-shields. In the cavities of the iron core are located the primary and secondary windings; they are thoroughly insulated, wherefore a short circuit to earth or between the two windings has never happened in regular work. The above-mentioned end-shields are made from thick iron plates stiffened by the use of iron ribs. The shields are round and have a diameter so large that the transformer can be rolled on the floor, which circumstance greatly facilitates their transportation. One of the shields carries the primary terminals, the other one carries three secondary terminals (the middle terminal being for 50 volts), each being supplied with its separate fuse. The primary fuses can be exchanged even during the regular work, as they are provided with long ebonite handles. These same high-tension fuses are used in the cable junction boxes (Fig. 25) which are employed in the primary network of the exhibition.

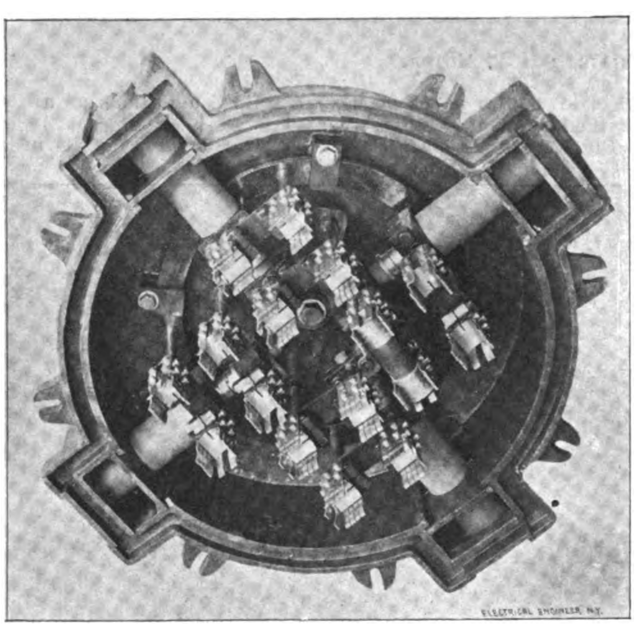

Fig. 25.—Cable Junction Box.

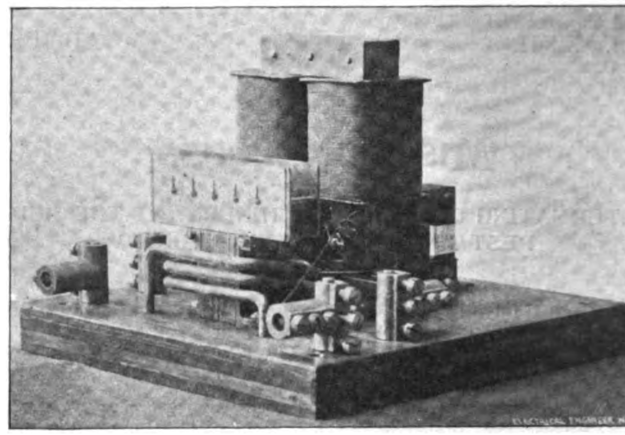

Fig. 26.—Blathy Recording Wattmeter.

In this way the network can be switched without disturbing the regular work of the central station.

The recording wattmeter serving to control the use of electric power by the several consumers, is shown in Fig. 26, and is the apparatus patented by Mr. O. T. Bláthy. It consists of an aluminum disc which is put into rotation by the torque produced by the action of two coils. The main current flows through one of these coils, and the other coil is a shunt, having large self-induction. As the magnetic fields induced by these windings in the respective iron cores, have a lag of about 90 degrees, the aluminum disc will revolve and the number of its revolutions are proportional to the electric power flowing through the mains. A clockwork, giving the power directly in kilowatt hours, is put into motion by the revolutions of the disc.

These descriptions show that the electrical exhibit (chiefly the alternating current part), is well developed at the Hungarian Millennium Exhibition. Industrial work in Hungary is of very recent growth, for political reasons prevented for a long time any activity in this direction. Therefore it is a sign of great vitality of the nation, if, notwithstanding all difficulties, it has produced already such various, new and interesting manufactures during its relatively short experience.

AN ELECTRIC UMPIRE.

A NOVEL arrangement described by an exchange as an electric "umpire" is reported to have been lately used in London to decide a fencing contest. The office of the umpire is to overcome the well-known difficulty of judging hits. The end in view has been achieved by covering the front of each contestant's jacket with fine copper or brass wire gauze and connecting this with the adversary's foil and an electric bell and battery in the same circuit. It follows that when a hit is made the circuit is closed and the bell rings and continues to ring until it is stopped by the person in charge. A special arrangement in each foil-handle provides that only a direct point produces a ring. Two entirely electrically distinct circuits are used, each including a bell, foil and jacket; flicks or blows or grazes produce no result. The bells being of different tones, and, moreover, placed on opposite sides of the room, there is no difficulty in deciding who has scored a hit, or in cases of almost simultaneous hits who delivered the point first. By a very simple arrangement the wires passing from the batteries to the combatants' collars are kept well out of the way, however sudden may be their movements of advance or retreat.

WORLD'S FAIR MEDALS.

The Electrical Engineer is glad to announce that it has at last received its World's Fair Medal, but it does not quite understand why the date of the discovery of the New World appears on the medal, on one side, in Roman characters as MDCCCXCII. The engraver responsible for this funny blunder (?) appears to be C. E. Barber, whose name is very conspicuously cut into the medal.

ALTERNATE CURRENT TRANSFORMERS.—II.

BY J. A. FLEMING, F. R. S.

GENERALLY speaking, in a machine like the Mordey alternator with a very small armature reaction, there is considerable change in the form of the electromotive force curve with the nature and amount of the load on the alternator, but in the case of a machine like the Thomson-Houston or Westinghouse alternator with a large armature reaction there is a very considerable change in the form of the electromotive force which changes in the amount and nature of the load. In the above cases the form of the electromotive force curves have been set out graphically in what are called wave diagrams, in which the

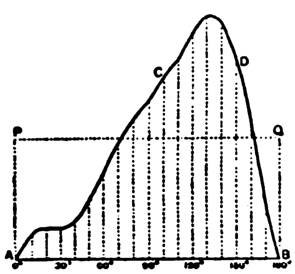

FIG. 16.

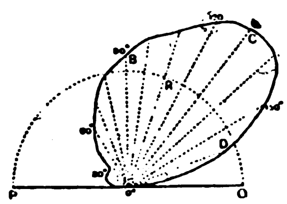

FIG. 17.

horizontal ordinates represent time, and the vertical ordinates represent the magnitude of the quantity which is varying, whether electromotive force or current. For some purposes, this method is not so convenient as that of setting out the curves in the form of polar diagrams.

The differences between these two methods—graphically delineated a periodic quantity—are shown in Figs. 16 and 17. In Fig. 16, part of the curve of the electromotive force of a Thomson-Houston alternator on an inductive load is shown. In Fig. 17 the same quantity is delineated in a polar curve. Instead of drawing vertical ordinates at equal distances to represent the instantaneous values of electromotive force, radii are drawn from a point, O, at equal angular intervals, the magnitudes of which are respectively proportional to the instantaneous values of the periodic quantity. A curve, B, C, D, is thus obtained, which is called a polar curve. It has this interesting property, that if we find the area of the polar curve, and describe a semi-circle on a line, P, Q, passing through the pole, O, the area of which is equal to the area included by the polar curve, B, C, D, it can easily be shown that the radius of this semi-circle represents the square root of the mean of the squares of all the radii of the polar curve. This quantity is now generally called the R.M.S. value, or the root-mean-square value of the periodic quantity. By some writers it has been called the effective or virtual value. Ordinary alternating current ammeters and voltmeters give, as is well known, the R.M.S. value of the periodic quantity they are measuring.

Returning to Fig. 16, if we construct a rectangle, A, P, Q, B, equal in area to the area included by the wave curve, A, C, D, B, then it is easily seen that the height of this rectangle, namely, A, P, represents the true mean value of the periodic quantity represented by the ordinates of the wave curve. In the case of any periodic quantity, such as a periodic electromotive force or current graphically delineated it is found convenient to have a term to denote the ratio between the true mean value of the curve ordinate and the root-mean-square value, and this is called the form factor of the curve.[1] Having thus seen the manner in which we can experimentally determine the form of an electromotive force or current curve, which represents the different instantaneous values of a periodic electromotive force or current, we can now proceed to discuss the manner in which these methods have been applied in the study of the alternate current transformer. Let us first suppose that the transformer to be studied is a constant potential transformer, having two windings, a primary and a secondary coil, both wound round an iron core forming a completely closed iron magnetic circuit. Let the primary coil be joined up through a non-inductive resistance, R^1, as shown in Fig. 2, with a circuit of constant potentials, and let the contact breaker above described, denoted by C, and the electrostatic voltmeter, V, be applied to determine the form of the current curve flowing into the primary coil, P, of the transformer. In order to delineate the form of the curve of primary potential difference, it is necessary to put across the primary terminals of the transformer a non-inductive resistance, R^2, which is divided in a definite ratio, so that by measuring a fraction, say, 1-20th of the whole difference of potentials between the terminals of the primary circuit of the transformer, we can determine the total potential difference. After much experimenting, I succeeded in devising a form of resistance which is now before you, and which is very convenient for this purpose. It is called a resistance cage. It consists, as you see, of a series of brass rods held in a wooden frame, each rod carrying a pair of porcelain heads, with porcelain pins on them (see Fig. 18), and these porcelain heads are kept pressed apart by a spring. Over the pins on these porcelain heads is wound, in zig-zag fashion, a platinoid wire, so as to form a perfectly ventilated non-inductive resistance. Each of these resistances is adapted for withstanding 100 volts pressure, and carrying ½ or 1 ampere, and a series of 20 of these resistances can be put across the primary terminals of a transformer, and will withstand the pressure of 100 volts for as long as necessary. By measuring the fall of potential and delineating the periodic value of the difference of potential between the terminals of one cage, which forms one of a series of 20, we can delineate the whole difference of potential between the terminals of a transformer. In this way we can take curves of primary current and primary electromotive force on the high tension side of a transformer. In the next place we can perform the same operation on the secondary side of the transformer, and obtain the secondary terminal potential curve, and also, if the transformer is sending a secondary current, the secondary current curve for that transformer. When these experiments are carried out for any good closed circuit transformer, and delineated in the form of a series of curves set in their proper relative position, which it is convenient to call a transformer diagram, we find the following results: In the first place, the curve of secondary potential difference is always an exact copy to a reduced scale of the curve of primary potential difference, and it is very nearly exactly in opposition to it in phase. This is shown in Fig. 19 and Fig. 20. Fig. 19 gives us the curves of primary and secondary electromotive force of a Thomson-Houston transformer taken off a Mordey alternator.

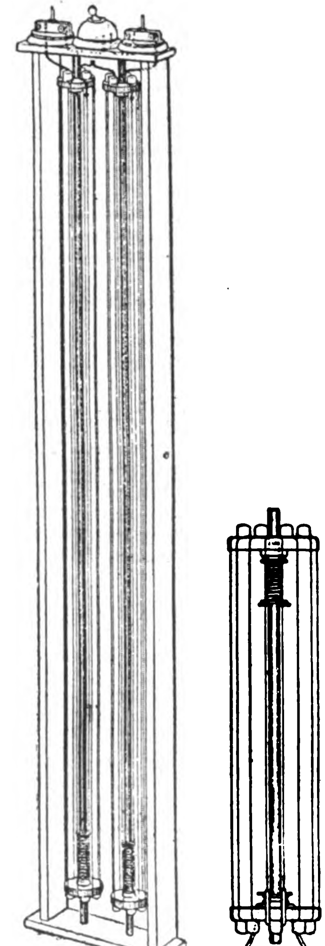

FIG. 18.—NON-INDUCTIVE RESISTANCES.

If the transformer is taken at no load, and if the curves of primary and secondary electromotive force are drawn to such scale as to their maximum ordinates equal to one another, and if they are drawn on the same side of the axis, then it is found

[1] For further information on this point see "The Alternate Current Transformer," Fleming, Vol. I. (new edition), p. 583.

that at no load the transformer curves exactly overlap one another. If the transformer is partly or wholly loaded up on its secondary side, so as to cause it to send a secondary current, then the secondary electromotive force is a little advanced in phase over the curve of primary electromotive force, as shown in the curves. Fig. 20 shows the same thing for the same transformer taken off a Thomson-Houston alternator. Hence we see that the closed circuit transformer acts like an electrical pantograph: it copies electrical potential difference, and the curve of secondary potential difference is always a nearly exact copy of the curve of primary potential difference;

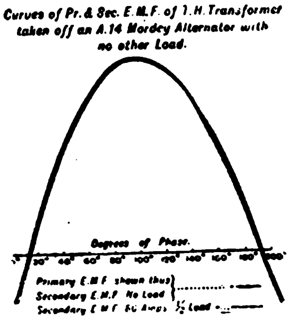

FIG. 19.

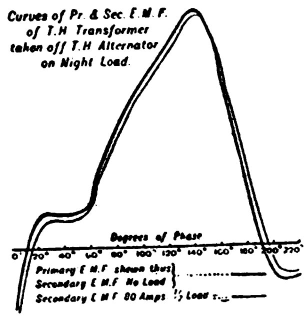

FIG. 20.

but to a reduced scale depending on what is called the transformation ratio of the transformer. On delineating the curve of primary current of the transformer when the transformer is taken at no load, as shown in Fig. 21, we see that the curve of primary current, when the secondary circuit is open, differs in phase from the curve of primary potential difference. It lags behind it, and the same thing is shown by reference to Fig. 14, where the curve of primary electromotive force for another transformer taken off the same alternator is given. It will be seen that even if the same alternator is employed for the test, the curve of primary current at no load is not the same in form in the case of all transformers. The form of this primary current curve is governed by the nature of the iron employed in the core. We then notice that even in cases where the primary electromotive force curve is more or less approximately a sine curve or simple periodic curve, the curve of primary current is always more irregular. Having in this manner delineated the curves of primary current, primary electromotive force and secondary current, we have then to determine the manner in which the induction in the core is varying with relation to these other varying quantities. We can draw out a curve of induction from the curve of a secondary electromotive force in the following manner.

Since the secondary electromotive force of the transformer at any instant is measured by the rate at which the magnetic induction linked with the secondary circuit is varying, we can construct the induction curve in the following way, as shown in Fig. 22. The curve marked E.M.F. represents a transformer secondary electromotive force curve. The whole area of the curve is divided into two equal parts by a vertical line. Starting from this vertical line, half of the curve, say, the right-hand half, is divided up into narrow strips of equal area, which are represented by the cross-hatched slips. The areas of these very narrow slips are then taken with the planimeter,

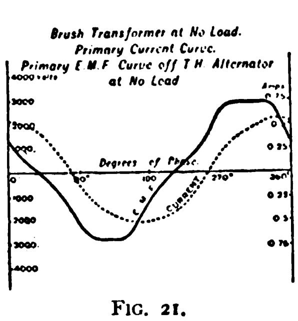

FIG. 21.

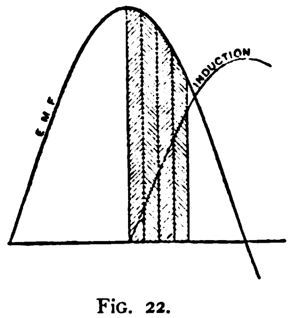

FIG. 22.

and we set off, starting from the middle point of the time axis, the curve of induction by the following method: Starting from the middle point of the time line, we set off on the right-hand side of the first slip an ordinate, which represents to some suitable scale the area of slip No. 1. On the right hand bounding line of slip No. 2 we then set off an ordinate equal to the same scale of the total areas of slips Nos. 1 and 2 together. On the right hand bounding line of the third slip we then in the same way set off an ordinate representing the total area of the first three slips, and so on. In that way we obtain points on a curve which represents what is called the time integral of the electromotive force curve, and this is, therefore, the proper representation for the induction curve. In order to determine the scale to which this induction curve is drawn, we must know what is the value of the maximum ordinate of the induction curve. This can be done in the following manner: If B represents the induction in the core, S the cross-section of the core, N_2 the number of turns of the secondary circuit, n the frequency of the alternating current, and f the form factor of the secondary circuit curve, then it can be shown that the root-mean-square value of the secondary electromotive force is equal to $4\ f.n.N_2\ S\ B$; and hence, since the root-mean-square value of the secondary electromotive force is immediately known from the delineated curve, and also its form factor, we can easily calculate the value of B, that is, of the induction.* That is to say, in this manner not only can we thus delineate the curves of current electromotive force, but also the induction, and represent them graphically on the same diagram. In Fig. 23 are shown the curves of primary electromotive force, primary current, and induction for a Ganz transformer taken at no load. The curve of induction can be determined in the above-described manner, not only from the curve of secondary electromotive force, but also from the curve of primary electromotive force. If this is done, it is found that two curves of induction so obtained do not exactly coincide. The reason for this is the magnetic leakage of the transformer. This last term is best defined by saying that when the transformer is at work, and sending a secondary current, the whole of the magnetic induction which is linked with the primary circuit is not linked with the secondary circuit. There is, as it were, an escape of induction from the secondary circuit, which is called the magnetic leakage. In discussing in a later lecture the testing of a transformer, we shall consider how this quantity can be measured. Having delineated the whole of these curves for a transformer, we are then in a position to draw a hysteresis diagram for the transformer. To do this, we have to set off in the form of a cycle curve the variation of induction with mag-

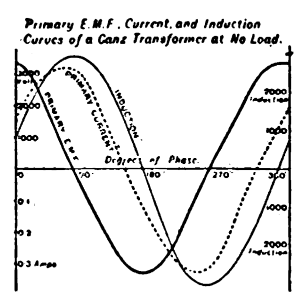

FIG. 23.

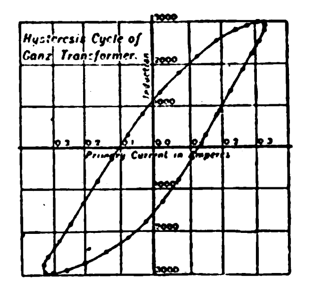

FIG. 24.

netizing force. It can easily be shown that if we construct a closed curve, by setting off on a horizontal axis the different instantaneous values of the primary ampere-turns of a transformer on open secondary circuit taken at equal time intervals during the phase, and if corresponding with these we set off the vertical ordinates representing the total induction in webers in the core of the transformer corresponding to these different values of the ampere-turns, then the total area of that curve integrated in turns of a unit of area—one side of which represents a weber, and the other side of which represents an ampere-turn to the selected scale will give us the value in joules of the energy wasted in the core of the transformer in one complete magnetic cycle, and in this manner we can determine from the transformer diagram the power wasted in watts in the core when the transformer is on open secondary circuit. This power is spoken of as the iron core loss in the transformer, and it can be determined directly from the transformer diagrams. In a later lecture we shall see how it can be more conveniently determined by one single direct measurement with the wattmeter. The diagram in Fig. 24 shows the hysteresis diagram thus determined for a Ganz transformer.

We have now briefly reviewed the chief actions going on in the transformer. Let us sum them up. If we apply to the terminals of a transformer a periodic electromotive force varying according to any law, we find that we have a periodic current set up in the primary circuit, which lags behind the primary electromotive force when the transformer is on open secondary circuit, but which gradually comes into step with it, in proportion as the transformer is loaded up. In good closed circuit transformers a very small amount of loading up—even as much as one-fiftieth of full load—will suffice to bring the primary current curve into step with the primary electromotive

*See "The Alternate Current Transformers," Vol. I. (New Edition, Page 358).

force curve. Secondly, we have a periodic magnetic induction in the core, which differs in phase, both from the primary current and the primary electromotive force, and it is found that this magnetic induction curve is always a more regular curve than the curve of primary electromotive force. When the curve of primary electromotive force is approximately a simple periodic curve, then the curve of induction is more nearly a simple sine curve. Thirdly, we have a curve of secondary electromotive force which is similar in form to, and exactly opposite in phase to, the curve of primary electromotive force when the transformer is on open secondary circuit, or when it is sending a small secondary current into a non-inductive resistance. If the secondary circuit of the transformer is practically non-inductive, as it is when the transformer is practically a load of incandescent lamps, then the curve of secondary current is always in step with the curve of secondary electromotive force, and can be deduced from it. Lastly, we have a curve deduced from the curve of induction and primary current of no load, which give us the hysteresis curve of the transformer. The curve of primary current of no load is generally spoken of as the magnetizing current, and the total power taken up in the iron core in watts is spoken of as the iron loss of the transformer.

II.—THE CONSTRUCTION OF THE TRANSFORMER.

In the previous lecture we have examined the general facts connected with the action of the transformer, and we have next to consider questions of transformer construction. The three organs of a transformer being the primary and secondary circuits and the iron core, the constructive problem is reduced to winding these circuits on the core, and properly constructing that core to receive them. We will consider, in the first place, the manufacture of the core. This has to be built up of iron wire or sheet-iron, so divided or laminated that eddy currents cannot be set up in it. If it were not for this lamination, the periodic change of induction taking place in the core would set up in the mass of the metal local electric

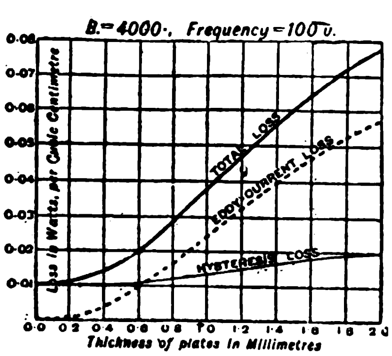

FIG. 25.—HYSTERESIS AND EDDY CURRENT LOSSES IN WROUGHT IRON PLATES.

currents which would dissipate energy. Mathematical investigation has shown that, for frequency of 100, or thereabouts, it is useless to make the iron—whether in the form of wire or sheet—less than 1-100th of an inch in thickness, that is, about ¼ mm., and useless to laminate it all, unless the laminations are less than 1 mm. in thickness. You will find in the "Electrician," Vol. 28, pp. 599 and 631, investigations by Prof. J. J. Thomson and Prof. Ewing, which deal elaborately with this matter. I have found that their rather complicated formulæ are not fitted for use in the workshop, but that they can, for all practical purposes, be replaced by a much more simple formula, which furnishes all the necessary information for transformer core construction. In the case of good sheet-iron, and for the range of induction usually employed in transformer work, which is not more than 3,000 or 4,000 C.G.S. units, that is to say, 30 to 40 microwebers per square centimetre, if we represent the eddy current loss in watts per cubic centimetre of the plates by a symbol, E; and if we call t the thickness of the plate in mils., that is, in thousandths of an inch, and if B is the maximum value of the induction per square centimetres in C.G.S. units, and n the frequency, then it can be shown that very approximately $E = \left(\frac{t\,n\,B}{10^8}\right)^2$. Although this is a hybrid formula, containing units of different kinds, and may be horrible to purists, it will nevertheless be useful in the drawing office, and we can simplify it still more if we reckon the maximum induction in webers, and call I this induction per square centimetre, then $E = (t\,I\,n)^2$. In some works it is the custom to reckon the induction per square inch, instead of per square centimetre, and the thickness of the plate in fractions of an inch. If $t_{,}$ is the thickness of the plate in inches and $B_{,}$ the induction per square inch, and $E_{,}$ the eddy current loss in watts per lb. of plates, then $E_{,} = \frac{1.4}{10^{10}} t_{,}^2 n^2 (B_{,})^2$. The general custom is to use plates for transformer construction of about .014 inch in thickness, and the standard induction which is generally selected is 2,500 lines of induction per square centimetre, or 2,500 C.G.S. units. This is equivalent to 16,125 per square inch. Under these circumstances, by the above formula, it is shown that the loss in watts per pound of

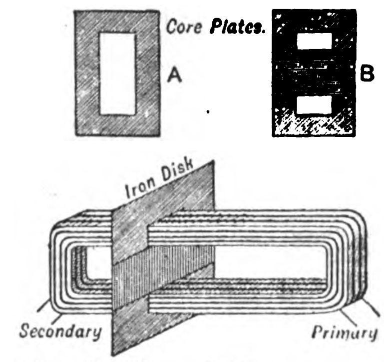

FIG. 26.—MORDEY'S TRANSFORMER.

plates due to eddy currents would be .07 watt; the frequency being 100. It may be noted that any increase of temperature as the transformer is worked, by increasing the resistance of the iron tends to diminish the eddy current loss. It will, therefore, be seen that by employing plates of a thickness not greater than 14 mils. eddy current loss is reduced to a very small amount. One point, however, to which your attention ought to be called is, that unless the iron plates are properly arranged, eddy current loss may exist in them, however thin they may be. If, either by reason of magnetic leakage, or any other disposition of the magnetic induction, lines of magnetic induction move through the iron in such a manner that their direction is not always parallel to the direction of the lamination of the iron, then, under those circumstances, eddy currents may be set up in the core, which are not hindered by lamination. This source of waste was present in many of the earlier forms of transformer. In addition to the loss of energy caused by eddy currents in the core, there is, of course, that other source of loss called the hysteresis loss, which is due to the magnetization and demagnetization of the core, and to the fact that the induction is not in step during the whole period with the magnetizing force, but lags behind it. The investigations of Steinmetz have shown that the hysteresis loss in iron sheets can be represented by a simple empirical formula which fits the facts fairly well. It is found that the hysteresis loss per cubic centimetre per cycle in the iron is related to the maximum value of the induction during the

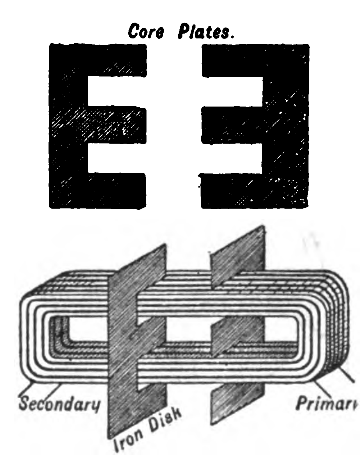

FIG. 27.—WESTINGHOUSE TRANSFORMER.

cycle by a simple exponential law, and may be, for all practical purposes, closely expressed by the following formulæ:—

Let H = hysteresis loss in watts per cubic centimetre,
and H^1 = hysteresis loss in watts per lb.,
then $H = \eta\, n\, B^{1.55}\, 10^{-7}$
$= {\cdot}0032\, n\, B^{1.55}\, 10^{-7}$.

Where n in the above formula is the frequency, and η is a coefficient called the hysteretic constant, which depends upon the

nature of the iron. The value of η may vary from .002 to .005. If we reckon the hysteresis in watts per lb., then we have

$$H_{,} = 0{\cdot}88_{n}\,(B^{1})^{1\cdot55}\,10^{-9},$$

where $B_{,}$ = induction per square inch.

The exponential constant may vary from 1.55 to 1.6. Thus, for example, if n = 100, and if $B_{,}$ the induction per square inch = 16,125, corresponding to induction per square centimetre of 2,500, the $H_{,}$ = .29 watt per lb., and H = .005 watt per cubic centimetre. These formulæ have been deduced from experiments made with various kinds of transformer iron; and although they are empirical formulæ, in the sense that they are not deduced from first principles, yet, nevertheless, they are exceedingly useful, and agree so well with experience, that they enable us to calculate the hysteresis loss at any one induction, when we know it at another. We may, therefore, put together the two expressions obtained for the eddy current loss of the hysteresis loss in iron, and state that, for all practical purposes, and within the limits of the induction usually em-

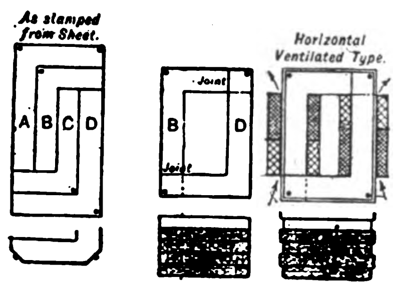

FIG. 28.—SCOTT TRANSFORMER.

ployed in transformers, the total energy loss in the iron, made up partly of eddy current loss, and partly of hysteresis loss, may be expressed as follows:

T = the loss per watts in cubic centimetres ;
$T_{,}$ = the loss in watts per lb.; then

$$T = {\cdot}0032\,_{n}B^{1\cdot55}\,10^{-7} + \left(\frac{t\,_{n}B}{10^{8}}\right)^{2}.$$

$$T = {\cdot}088\,n\,(B_{,})^{1\cdot55}\,10^{-9} + \frac{1{\cdot}4}{10{\cdot}10}\,(t_{,}\,n\,B_{,})^{2}.$$

Where B is the maximum induction in C.G.S. units per square centimetre, and $B_{,}$ per square inch.

The curves in Fig. 25 show the variation of hysteresis and eddy current loss in plates of various thickness for a maximum value of the induction of 4,000 C.G.S. units calculated from the formulæ of Prof. J. J. Thomson.

My own experience is, that these formulæ agree very well with experience and with the results of measurement. I made some years ago a careful study of the old form of Ferranti transformers, and found a very fairly close agreement between the results of measurement of the core loss in these transformers and the results obtained by calculation from the above formulæ. In specifying for iron for use in transformers, it is now the custom to adopt a standard induction of 2,500 C.G.S.

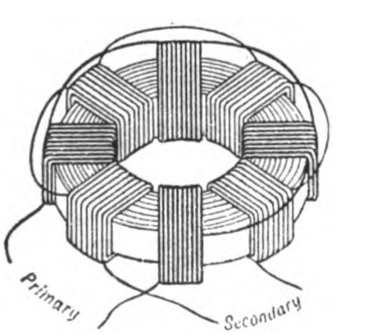

FIG. 29.—TYPICAL CLOSED CIRCUIT TRANSFORMER.

units, or lines of induction per square centimetre; that is to say, the standard induction is 25 microwebers per square centimetre—and the standard frequency is 100. Under these conditions a good transformer iron ought to have a hysteresis loss, varying from .25 to .5 watt per lb. It is possible, under some conditions, to get iron with less hysteresis loss than this, but as we shall see presently, there are some difficulties in keeping it in this condition. Having selected the iron, the next thing is to stamp out the core plates, and afterwards to carefully anneal them. It is now well understood that the slightest tooling or handling of iron after it has been annealed hardens it, and raises its hysteresis loss—hence the greatest care has to be taken that the plates are not damaged after annealing. The plates have then to be insulated to keep them from electric contact with one another. The old practice was to insulate the plates with thin paper, but paper takes up too much space, and it is now usual to paint the plates with an insulating paint or varnish, which, however, must be able to withstand, without deterioration, the highest temperature which the transformer may reach in work. Even using varnish, the varnish takes about 10 per cent. of the space of the iron. In selecting the iron for the core plates, it is more important to choose an iron with small hysteresis loss than large permeability. These two things are not necessarily connected together. The number of devices which have been adopted for cutting the iron into the core plates, as to avoid unnecessary waste of metal, is very large. In Fig. 26 is shown the manner of building up the core of a Mordey transformer. In Fig. 27 the mode of building up a Westinghouse transformer is also shown. In this case, as in that of the Mordey transformer, where a cross piece is used, or where there are overlapping iron plates, it is customary now to use packing pieces of sheet iron to fill in the levels, and to get as much iron as possible into the space. In Fig. 28 is shown the method of stamping the core plates from the sheet and constructing the Scott and Addenbrooke transformer. The iron core having been constructed in such a manner as to afford a completely closed iron circuit for the lines of induction due to the magnetizing force of the primary coil, the core is then covered with shellaced calico and mica, in order to insulate it from the primary coil; and the greatest care ought to be taken in this respect, because it is not sufficient to insulate the coils of the transformer from one another: they must both be insulated from the core. Thin ebonite is often used as a material for insulating the core, and an India-rubber compound called woodite is a very good material to use. The primary and secondary coils are generally wound on formers; they must be insulated from each other by ebonite or mica, and the primary and secondary coils should be so overlayed or intermingled (as shown in Fig. 29, which represents a typical closed iron current transformer) to avoid producing magnetic leakage. In large transformers it is customary to leave a space between the high and low tension coils for the purpose of ventilation, and in the same way air spaces or ventilation spaces have to be left in the iron core. The primary and secondary coils are sometimes separated from one another by a metal shielding plate, which is connected to earth. This is, however, not so good a plan as an effectual separation of the primary and secondary coils by an insulating shield. In the design of the core it is important to reduce the reluctance of the magnetic circuit as much as possible, in order to produce a large power factor. The term "power factor" is defined as a number representing the ratio between the true power taken up in the core to the product of the primary potential difference and the primary current (root-mean square values being understood). This product is called the apparent power taken up in the core.

CONTEMPORARY ELECTRICAL SCIENCE.

The Aurora Borealis was the subject of much discussion at the Lübeck conference of German physicists and physicians. Herr Ebert described some experiments, summarized in Wiedemann's "Beiblätter," which attained a considerable measure of success towards imitating the celestial phenomena in question. Spheres, plates, and cylinders of brass and of iron were exposed in a vacuum to electromagnetic waves. Halos and auroras were observed to encircle them, and these were powerfully influenced by magnetic forces. Up to a certain point their luminosity increased with the strength of the magnetic field, but where the lines of force impinged vertically on the surface the aurora was thrust aside. All this points to the explanation that the sun sends out electromagnetic waves which produce the aurora at the more intense points of the earth's magnetic field. Another speaker, Herr Paulsen, of Copenhagen, inclined rather to the view that the aurora, especially the steady glowing kind, is due to a fluorescence of the air under the influence of cathode rays emitted by the sun, the distribution of the fluorescence being governed by the earth's magnetic field. Since these rays facilitate the production of ozone, and the latter is a strong cloud-former, we have also an explanation of the cloud formations which almost invariably attend the displays. In the "Physical Review" we have another lady student of the electric arc. Miss Caroline Baldwin studied the spectrum of the arc photographically and found that carbon spectrum is chiefly formed at the negative carbon, and its brilliancy is increased by zinc, cadmium, or copper cores. The carbon bands are only few at the positive carbon; and cores of the light posi-

tive metals, potassium, sodium, lithium, and others, so effectually screen them that it is not surprising they escaped Prof. Snow's bolometer altogether.—London "Electrician."

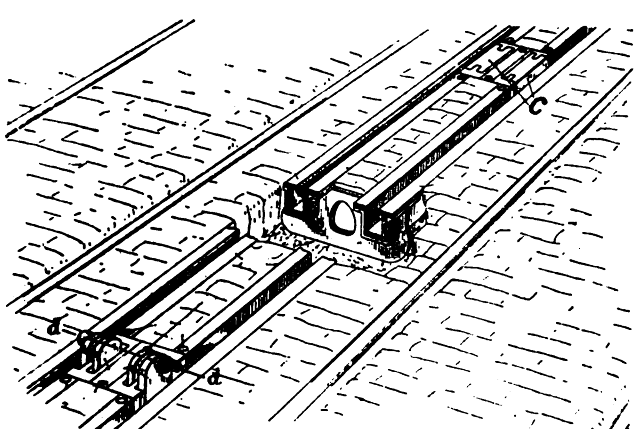
ELECTRIC TRANSPORTATION.

LINN'S ELECTRIC CONDUIT RAILWAY.

BEFORE even the time when the overhead trolley had achieved any considerable success, the idea of a sectional conduit system, in which the current should be always confined to the section of the roadbed directly beneath the car, was being prosecuted by a number of inventors.

This field still remains an open one and will undoubtedly prove a profitable one to the inventor of a thoroughly practicable sectional conduit system whose cost of installation is not prohibitive.

We illustrate in the following diagram a system of the sectional conduit system invented by Mr. John B. Linn, of Cleveland, O. In this system the conduit is designed to be placed on the roadbed outside of the tracks, or, as in the illustration,



LINN'S ELECTRIC CONDUIT RAILWAY.

if the track is a double one, both conduits are placed close together in the space between the two pairs of tracks. A runner is carried along the side of the car, whose ends bend downward and travel in the conduit slot. At intervals of less than the length of a car the switches c, d are placed at the surface of the conduit. When in the position c the main conductor which is below in the conduit is cut off from the switch which consequently carries no current. But as the car passes, the forward end of the runner on the side of the car raises the switch into the position shown at d, in which position it is brought into contact with the main conductor and conducts the current to the car motor by means of a suitable collector. The switches are spaced so that before one leaves the runner at the rear end of the car, the next switch will be raised by the front end of the runner, making the contacts not only successive but continuous.

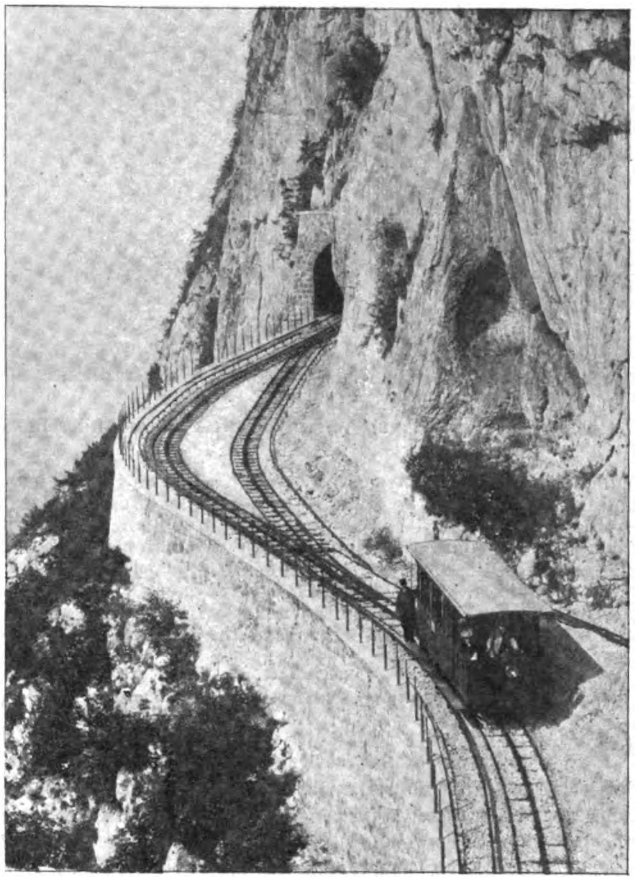
THE ELECTRIC RAILWAY UP MONT SALEVE, GENEVA.

ONE of the most striking features in the present electrical development of Switzerland is the manner in which the loftiest peaks are being attacked by electric railway engineers, with the object of building roads to their summits or else up to the best points from which tourists can view the surrounding ranges and valleys. The recent National Exposition at Geneva, and the holding of an electrical congress there, has given special prominence to the road that has been carried up and around Mont Saleve, a huge mass towering above Geneva to a height of over 4,000 feet and giving from its plateau at the top a magnificent view of the whole pile of Valaisian Alps, beginning with Mont Blanc itself on the right, to the south and west, and ending with the Dent du Midi, the Dent d'Oche and Lake Leman to the left, on the north and east. There are other Alpine panoramas to be obtained by means of electric railway ascents, in other parts of Switzerland, but this view cannot be surpassed.

While in every sense a Swiss road, the Chemin de Fer Electrique du Salève runs chiefly over French territory, just as Mont Blanc, the glory of Switzerland, is essentially a French or Italian mountain. The visitor leaves Geneva by the ordinary trolley line to the outskirts of the city, then exchanges to a clumsy steam tramway, and then embarks on the mountain electric road. The lower portions of the line are in constant operation, but the travel over the upper section to Treize Arbres (Thirteen Trees), on top of Mont Saleve, is limited between June 1 and September 15, and even then some of the dispatches are not made unless the weather is fine, for there is nothing more dismal and melancholy and dangerous than a Swiss mountain in bad weather.

The electric part of the road is about 4 miles in length, single track and turn-outs, and of twin lines built so as to form a loop, giving the passenger alternative routes. It was built and equipped by the well-known Compagnie de l'Industrie Electrique of Geneva. The system used is that of the third rail, the contact apparatus being placed outside the track, and the current-carrying rail being placed a few inches above the ground for insulation, on short posts. The gauge is one metre. Between the rails, which are solidly laid on a well ballasted

track, runs a rack rail. Where the grade is extreme, the rack is double, the teeth being set so as to give the car a two-fold grip. Additional security is furnished by air-brakes, but even then the experience is found quite exciting by the passengers, especially where the grade reaches 25 per cent. and where curves at not much less are taken on a 35 metres radius. Current is supplied to the line at a potential of 600 volts for a water power plant, and is brought to the road across the mountain sides by aerial cables connected about midway in the system. Each car has two Thury 4-pole motors of 25 horse-power each, and there are 12 motor cars and 4 trailers. The generating plant at Arthas, away down in the recesses of the deep cut Arve Valley, has two Thury dynamos of 165 horse-



Steep Grade, Turn-Out and Tunnel, Mont Saleve Electric Road. Section Overlooking Geneva and Lake Leman.

power each, and a small exciter of 15 horse-power, and the two turbines are of the Richter make, with vertical axis, each being of 185 horse-power. The generators are 12-pole machines, and each weighs 19 tons. Everything about the plant, line and rolling stock is solid, and the road is carefully operated.

After climbing the precipitous face of the mountain, overlooking Geneva and the lake, and giving beautiful glimpses northward of the rushing blue Rhone and of the Jura Alps, the road passes through a tunnel and comes out on the inner side of the Little Salève. It then proceeds, rising rapidly, up the valley of the Arve until it reaches by various turns and detours, the summit of the Great Salève. The views are extremely fine all the way up, the winding Arve being almost always in sight with its brown waters rushing from the glaciers of Mont Blanc to join the blue pellucid Rhone streaming out of Lake Leman at Geneva. On top of Salève is a large restaurant from whose balcony and windows on any clear day Mont Blanc is in full evidence, while if the day is not clear, one may be lucky enough to see tremendous effects of light and shade and of storm and cloud rolling over the eternal snowy peaks. It is needless to say that the road is well patronized, and as good rates of fare are charged, there is no reason why the owners should not be well satisfied with their investment.

TROLLEY FARES RAISED IN DETROIT.

The Citizens' Street Railway Company, controlling about ninety miles of track, has returned to the old plan of selling six tickets for a quarter. For seven months and a half patrons have been getting eight tickets for 25 cents. The managers claim they have spent $4,000,000 in putting in the best system of electric railways in the country, and they cannot get a fair return on the investment at the low rates. It will be interesting to see what Mayor Pingree says now.

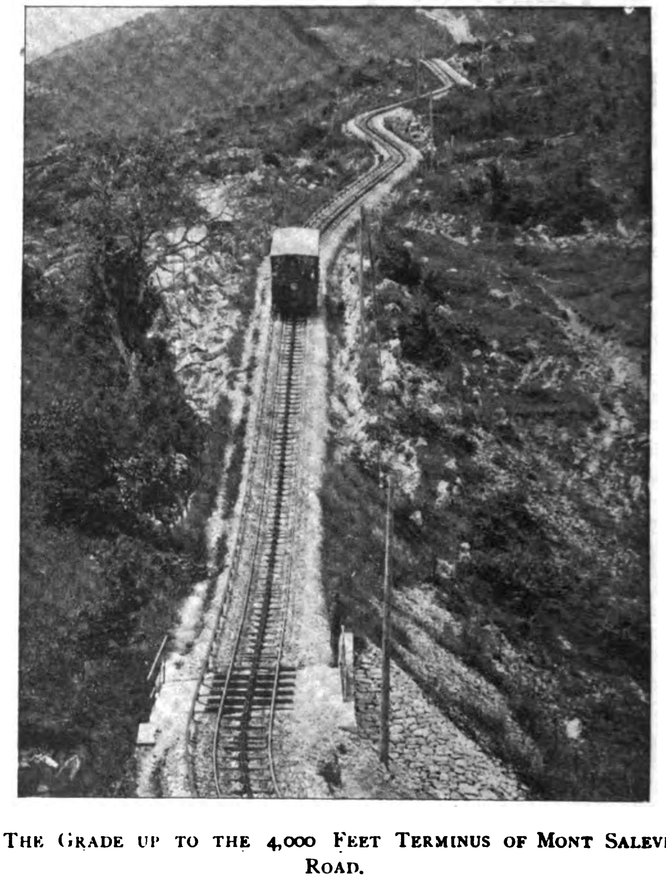
A "PAPER" ROAD SCHEME IN MILWAUKEE.

A special dispatch from Milwaukee, Wis., of August 17, to the Chicago "Journal," says: The movement to secure competition in the street railway business in Milwaukee has proved a grand fizzle. The "Milwaukee and Waukesha Electric Railway Company," an alleged corporation possessing no corporate existence, was granted a franchise by the common council a short time ago to build and operate a street railway system. The franchise provided for paralleling the tracks of Henry C. Payne's local railway monopoly, the Milwaukee Electric Railway and Light Company. It was provided in the franchise that the company to which it was granted should never pool issues with, sell out to, or enter into a combination with any other street railway company. The promoters of the so-called Milwaukee and Waukesha Electric Railway Company claimed to have purchased the railway of the Milwaukee and Wauwatosa Motor Railway Company, a bankrupt concern.

During the past few days negotiations have been pending for the sale of the motor railway to the local street railway monopoly, with the proviso that in the event of the purchase being effected the new street railway scheme should be abandoned. Henry C. Payne and the other officers of the local monopoly considered the proposition, as well as the granting of the franchise by the common council as the culmination of a sand-bagging scheme, and have given the facts to the press for publication.

When the franchise was before the common council for consideration its passage was opposed by nearly every paper in the city, on the ground principally that the promoters of the Milwaukee and Waukesha company were not men of wealth and were unable to make any showing of possessing or being able to obtain the necessary capital to build the proposed road.

It was also shown at the time that the company had not been

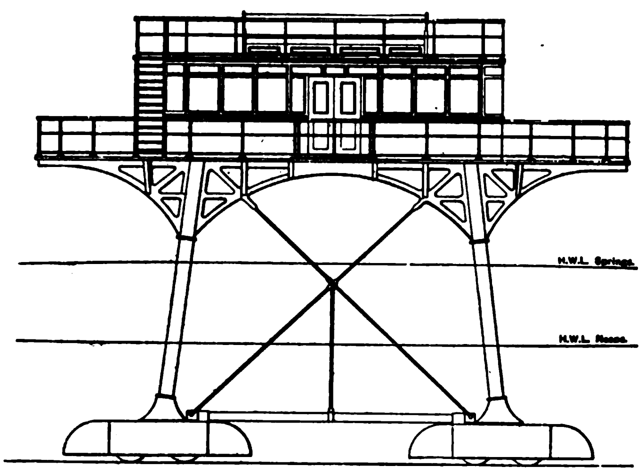


The Grade up to the 4,000 Feet Terminus of Mont Saleve Road.

incorporated, and even at the present time it has no corporate existence. It does not now seem probable that any use will be made of the franchise granted it, and it will probably be forfeited through a default in complying with its provisions.

THE BRIGHTON—ROTTINGDEAN SEA TROLLEY ROAD.

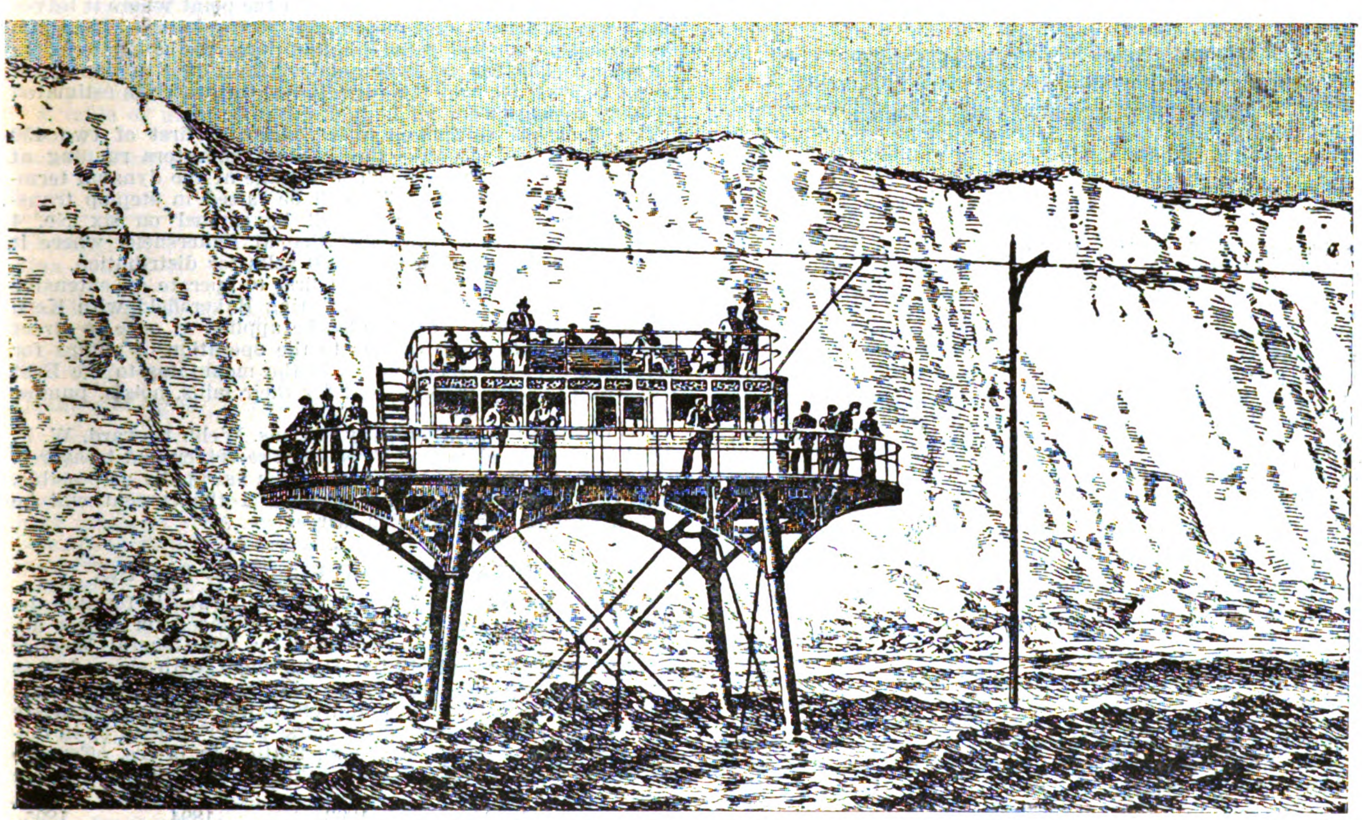
SOME months ago we called attention to the novel transmarine trolley railway proposed by the indefatigable worker, Mr. Magnus Volk, for the stretch of seashore between Brighton and Rottingdean, on the south coast of England. This curious and interesting road has now been finished and is



MOTOR CAR, BRIGHTON-ROTTINGDEAN TRANSMARINE ROAD.

certainly well worthy of notice, while it is to be hoped that the company will be handsomely rewarded for its courage and enterprise.

The rails run along the foreshore at a distance of about 150 to 250 yards from the base of the cliff, slightly above low-water mark; at high tide they are covered by 14 feet of water. Instead of two rails connected by tie-rods, there are two pairs of 54 lb. rails, a distance of 18 feet intervening between the two outers. Each pair of rails (2 feet 8½ inch gauge) is laid separately, on concrete blocks mortised to the chalk below. In 1893, when the act was obtained, the chalk was covered in some places by a layer of sand 3 feet thick. During the storms of last winter the sand was all swept away, to be subsequently slowly silted up again. The steepest gradient is 0.3 per cent.; the sharpest curve has a radius of half a mile.



VOLK'S TRANSMARINE TROLLEY ROAD, BRIGHTON TO ROTTINGDEAN, ENGLAND.

The car, which was designed by Mr. St. George Moore, joint engineer to the company, with Mr. Volk, was constructed by the Gloucester Wagon Company. It is supported by four splayed-out legs, each leg consisting of a 12-inch steel tube, running on a four-wheel bogey. The wheel base is 28 feet. Each of the two leading bogies is driven off vertical shafting inside the tube by a 30 horse-power vertical motor, to which current is conveyed on the overhead trolley system at a pressure of 500 volts. The deck of the car is 24 feet above the rails, and measures 50 feet by 22 feet; it carries a saloon 25 feet by 12 feet. The structure by itself weighs 40 tons, and with motors, gearing, and 150 passengers, the total weight is 60 tons. The speed is six miles an hour.

The deck appurtenances, says "Invention," to which we are indebted for one of our illustrations, are carried out as if for a steam yacht. The railings surrounding the deck are made of iron with a wooden top and safely barricaded with wire netting. An ample supply of seats are to be seen with reversible backs, so that the passengers can face in any direction in which the car is traveling. A saloon is placed in the center of the deck, measuring 12 by 25 feet, and is provided with plate glass windows, and a large ottoman, with palms and flowers growing in a center box. A stained glass dome rises over the center, and outside is a second gallery, railed round, forming a promenade with deck seats.

THE LIVERPOOL ELEVATED ELECTRIC ROAD.

The Liverpool (England) elevated electric road again makes a good showing. During the first half of this year some 313,010 train miles were run over the six miles of line now working, and 3,739,575 passengers have been carried. The revenue accruing from passengers, together with the carriage of parcels, etc., has amounted to 23.9d. per train mile; while the total expenditure out of revenue has not exceeded 15.1d. per train mile, or approximately 63.2 per cent. Out of this last-named sum, the total generating expenses at the power station have absorbed 3.39d. per train mile, of which only about one-half penny per train mile has been paid for fuel. The rolling stock, consisting of 38 coaches of 56-passenger capacity, or 19 trains of 112-passenger capacity, has not been increased; but work has been pushed forward on the extension of the line, and the additional mile or so which is now being constructed will, it is expected, be completed by next autumn. The sum of £11,166. 7s. 5d. is available for the 5 per cent. dividend on the Preference shares, and the 2¾ per cent. dividend on the Ordinary shares.

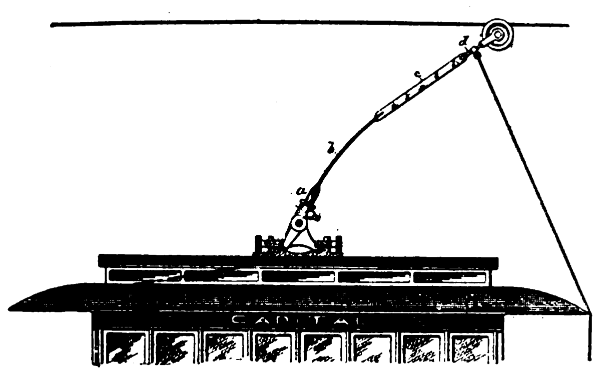
PROF. SHORT'S SPRING TROLLEY POLE.

A SIMPLE trolley pole has been invented by Mr. Sidney H. Short, of Cleveland, Ohio, which is designed to keep the trolley wheel against the wire, with the proper degree of pressure, without the use of springs or weights, and a general view of the same, mounted on a car, is shown in the accompanying engraving.

On the roof of the car a base is fastened having two lugs which project upwards and through which screw-stops are threaded.

The base is provided between its ends with arms between which a socket-piece is supported by means of a pin. The socket-piece holds the lower end of the trolley pole. The trolley pole is made of spring or elastic material, so that the trolley wheel at its free end will be maintained in contact with the under face of the trolley wire with the necessary degree of pressure, entirely independent of any auxiliary springs such as are generally used for this purpose.

The spring trolley pole should be constructed so as to give sufficient lateral motion to permit the trolley wheel to keep its contact with the wire on curves and switches. It should be made of spring steel, and its lower end, a, is made cylindrical in form and is inserted into the socket piece in which it is held by means of a set-screw. Immediately above the lower round portion a the pole is made with a flat or ribbon-like section b. In other words, the section b of the pole is so formed as to permit the pole to bend toward or away from the car, and so that the resilience of the portion b will act to press



SHORT'S SPRING TROLLEY POLE.

the trolley wheel against the wire. The section c is also made flat, but its longest diameter is fixed at right angles to the longest diameter of the section b, and the free end d of the pole, to which the trolley wheel is attached, is made round in cross section and quite small as compared with the lower end or section a of the pole.

From this construction of the trolley pole it will be observed that its most elastic portion with respect to the trolley wire and the roof of the car is in the section b, which is nearer the roof of the car than the trolley wire, and as the section c cannot bend in the same direction as section b there will be no liability of the upper portion of the pole striking the trolley wire. By making the section c of the pole flat in a direction at right angles to the section b the necessary lateral movements of the trolley wheel will be readily permitted.

When the pole is in operation the lower end of the socket will be in engagement with one of the stops and it will have no movement whatever. All movement of the trolley wheel as it runs against the wire is permitted by the spring of the trolley pole itself. When the direction of the car is to be changed, the pole will be then turned, so that the lower end of the socket will bear against the opposite stop.

By means of the adjustable stops the tension of the spring pole can be regulated and the pressure of the trolley wheel against the wire adjusted.

THIEVES CARRY OFF TROLLEY WIRE.

At an early hour on August 18 thieves stole about a thousand feet of feed wire from the Camden, Gloucester and Woodbury trolley road in the region of the bridge, near Mantua, N. J. Men with some knowledge of electricity must have committed the theft, as no depreciation in the current was felt at the power house, nor along the line, as would have been the case had the current been grounded or the circuit opened. The scene of the robbery is rather lonely at such an hour.

POWER TRANSMISSION.

THREE-PHASE POWER PLANT ON THE KERN RIVER, CALIFORNIA.

THE power of the Kern River, the third largest stream in California, is now about to be utilized, the work undertaken by the Power Development Company being nearly completed. The contract for the electrical equipment has been awarded to the General Electric Company, whose three-phase apparatus will be used to transmit the power of the river to Bakersfield, a distance of fourteen miles as the bird flies.

The point selected for the power house is at the mouth of the canyon on the north side of the Kern River, almost sixteen miles northeast of Bakersfield by wagon road. Here the stream, after a boisterous course of 100 miles from the slopes of Mt. Whitney through a series of rugged precipitous canyons forms a number of cataracts and rapids previous to taking a placid course through the cultivated valley lands. The point of diversion of the necessary flow for the power is some 9,000 feet up the canyon. To secure a bed for the flume a roadway had to be cut from the solid rock along the sides of the canyon. All the timber was hauled by a team a distance of sixteen miles to the south side of the river. A bridge was thrown across and a tramway 325 feet long with a grade of 30 per cent. laid up the steep hill to the point where the flume was to end. A steam sawmill was then set up at the foot of this tramway, the timber cut to proper dimensions, loaded on the cars and hauled up the grade.

The flume was begun at the power house end. This flume is 8 ft. wide and 6 ft. deep and is covered. A railroad track is laid upon the cover for the full length of the flume, 8,000 feet. There are no sharp angles, the changes in the course being made by curves and tangents. The grade is 5.8 to the mile, and 475,000 feet of red wood is used in the construction of the flume which at one point is carried on an arch with 60 ft. span over a bad place on the cliff. The flow is calculated at 280 cubic feet per second. At its terminus at the mouth of the canyon 8574.9 feet from the point where it leaves the river, it is 202 feet above the power house. Here the water enters a steel pipe 540 feet long and 5 ft. 6 in. in diameter. The fall from the end of the flume to the power house is 201.9 ft., and the capacity of the water is estimated at 7,500 horse-power.

The electrical equipment will consist at first of two 450 kilowatt General Electric three-phase generators running at 257 revolutions per minute. The voltage at the dynamo terminals will be 550 volts. This will be raised in step-up transformers to 11,000 volts and will be carried on six No. 4 bare copper wires to the substation at Bakersfield, where it will be transformed down to 2,000 volts for distribution.

The current will be utilized at first to operate an extensive system of electric railroads connecting Bakersfield with Kern and other districts. It will also be applied at once to street and house lighting, as well as to the operation of pumps for irrigation purposes. The mines in the mountains to the East will also probably take current for their mills, hoists, pumps, etc.

The president of the company is Chas. Webb Howard, W. F. Goad is vice-president and C. N. Beal secretary and treasurer. The work is being pushed to completion as rapidly as possible, and it is expected that by November 1 the current will be turned into the transmission wires.

SOME STATISTICS OF ELECTRIC POWER.

The economy and efficiency of electric power is forcibly demonstrated by the extent of the orders placed for power apparatus. We have been furnished by the General Electric Company's Power and Mining Department with some figures which illustrate not only the growth in the use of electric power, but also its economy and efficiency. These figures are represented in the unfluctuating horse-power instead of in dollars which, on account of the fluctuation in prices, offers no standard gauge. The figures taking cognizance of electric power apparatus only:

	1892.	1893.	1894.	1895.
Horse-power	13,719	18,762	42,379	46,727

In 1896 the missionary work of the past four years began to come to rapid fruition. From January 1 to July 31, the total horse-power of the apparatus amounted to over 48,000 horse-power. During the same period in 1895 the aggregate orders amounted to 25,737 horse-power. From Jan. 1 to Aug. 18, the total amount of power apparatus ordered during 1896 was increased to the respectable figure of 62,164 horse-power.

Such a showing in face of the universal dullnes in business everywhere is remarkable, and perhaps emphasizes the fact that during hard times the truest economy is the use of apparatus which costs least to operate. It is said that in every manufacturing establishment using electricity as its motive power, the output has not only been increased, but its quality improved.

INTERNATIONAL CONGRESS OF ELECTRICAL ENGINEERS AT GENEVA.

THE Congress, which has just come to a close, was opened on Aug. 4 by Mr. Th. Turrettini. Among the 230 members present, we may mention Messrs. Ferraris and Mengarini, from Italy; G. Knapp and Von Hefner-Alteneck, of Berlin; Mascart, Hillairet, and J. Blondin, of Paris; and C. S. Bradley, of New York. A few English electricians also attended the meetings, but the Institution of Electrical Engineers, of London, was not officially represented.

The first report was by Dr. Wietlisbach, of Bern, on "Telephonic Disturbances Caused by Electric Traction." The following precautions were advocated:

1. Where telephone wires cross a trolley line used for pressure not exceeding 750 volts, it is sufficient to protect the wires by fuses.
2. Where the pressure used is above 750 volts, the trolley line must be efficiently connected to earth.
3. The telephone companies are strongly recommended to use double wire.

On the question of magnetic units, a paper was read by Prof. Ed Hospitalier, of Paris, recommending the conclusions of the American Institute of Electrical Engineers. The Congress, after a long discussion, adopted the C. G. S. system as practical units, and gave the opinion that it was not necessary to use any special nomenclature. According to this decision such names of units as Gauss, Weber, Gilbert, etc., would be abandoned.

The report of Mr. André Blondel on "Photometric Units" was the next to be read. The decimal candle = $^1/_{20}$ violle, adopted by previous Congresses, is maintained. It can, however, be provisionally represented for practical purposes, and within a few per cent., by the Hefner lamp.

A table of units of light adopted by the Congress is given below:

	Name of Unit.	Definition.	Dimen ions.
Intensity........	Candle.	I	I
Flux..............	Lumen.	$\phi = I\delta$	I
Illumination......	Lux. (= lumen square metre)	$E = \frac{\phi}{S}$	I L^{-2}
Brilliancy........	Candle. (per square centimetre)	$i = \frac{I}{S}$	I L^{-2}
Quantity of light..	Lumen-hour.	$Q = \phi T$	I T

The opinion of the Congress was also solicited on the subject of the protection of overhead lines from atmospherical discharges. Various well-known magnetic and mechanic lightning arresters were advocated. The method of putting both poles to earth through a water resistance was said to give very good results. In the case of continuous currents, it was recommended to place in series with the lightning arrester a self-induction, and again between this and the dynamos, a capacity, the bed-plate, as well as both poles of the machine, being carefully insulated.

One day was devoted to the question of "Transmission of Power at Long Distances," Mr. Thury, of Geneva, defending, with much ability, his high tension continuous system against all opponents.

Much care was taken to provide accommodation and entertainment for the members of the Congress, and all foreign delegates were welcomed with the utmost cordiality and kindness. During the week several brilliant receptions were held, and various electrical works in the neighborhood were visited. The Congress is being followed by an excursion, which will include visits to the most interesting technical installations in Switzerland.—London Electrical Review.

"LITTELL'S LIVING AGE" is to add next November a monthly supplement, free of charge to subscribers, which will give excerpts from the magazines and new books, and a list of new publications of the month. Occasional translations will also be given from the reviews and magazines in foreign languages.

LETTERS TO THE EDITOR.

A MAYOR IN SEARCH OF LIGHT.

I am authorized by the City Council to correspond with various companies manufacturing electric light machinery to ascertain the probable cost of equipping a plant in Des Moines for the purpose of lighting the streets, etc., and possibly furnish private consumers. Our last appropriation for lighting our streets and public buildings amounted to $50,000, and we find that the expenditures for the year will amount to about $52,500. For this amount we operate 167 arc lights, moonlight schedule, 121 arc lights on all-night schedule, 938 gasoline lamps, seventeen incandescent lamps, 318 gas lamps, also gas for City Hall, etc.

We also ask your opinion as to whether the city can maintain and operate an independent plant, the capacity of which would be sufficient to furnish the lights above stated, at a cost that would reduce the amount expended at present for such service. Any information in detail that you can give us will be appreciated. JOHN MACVICAR, Mayor.

City of Des Moines, Ia., Aug. 20, 1896.

ON THE USE OF FUSES AND MAGNETIC CIRCUIT BREAKERS.

In your issue of August 12 there appeared an interesting article by Mr. Wm. Baxter, Jr., in which he called attention to the fact that if the size of the generator be sufficiently increased in proportion to that of the engine, then, in case of an overload, the engine will be overpowered and stop; and thus do away with the need of any fuse or circuit breaker. Even granting the premise, it seems to me that this is an exceedingly expensive substitute for a fuse. If, on the other hand, we should cut down the size of the engine, instead of enlarging the generator, we would simply defeat the object that we have set out to accomplish. I fail to see how the arrangement proposed would avail anything that a fuse would not accomplish. In case of short circuit or overload it would protect the dynamos by putting the lights out. The practical station man cares little whether his circuit is complete in a metallic sense or not if his engine is not running. His aim is to give uninterrupted service, or, if accident should leave his customers in the dark, to re-establish the circuit just as quickly as possible; and I promise him that he can throw the lever of his circuit breaker quicker than he can start up his engine.

Though Mr. Baxter has thrown out one good suggestion, the problem for most of us is probably just as vexing as ever. Perhaps the best protection to the customer, aside from installing an ample capacity of both engines and dynamos is the expensive method of keeping a storage battery in parallel with the generators, or so connected that it will be cut in automatically in case it is needed. There are many stations where the presence of the battery would be justified by other reasons. Yet the battery should in general be protected by a circuit breaker of some sort.

This discussion is rather one of station design than of protective devices, the use of which latter, I fear, must be decided for each individual case in the future as it has been in the past.

GEO. R. ALBERS.

University of Kansas, August 15, 1896.

LITERATURE.

MOLECULES AND THE MOLECULAR THEORY OF MATTER. By A. D. Risteen. Boston: Ginn & Co. Cloth. Illus. 8vo. 223 pages. Price, $2.

This is a book that has been out some little time, but which we venture now to recommend to our readers, not a few of whom will find it of help in the study of the subject, and especially useful at a time when the discussion of the X-ray has set all the molecular theories and electrical phenomena in a new and puzzling aspect. Prof. Risteen first takes up the molecular hypothesis and then deals necessarily with the kinetic theory of gases, the molecular theory of liquids; the molecular theory of solids; molecular magnitudes; and the constitution of molecules. The book is based on a series of lectures, but is none the worse for that, as it gives a freedom and play to the expression and thought that is welcome, and, for many students, a positive help.

CONTENTS.

OTHER CARS THAN ELECTRIC.

THE latest statistics published as to the overwhelming adoption of electricity on street railroads would go to show that for a little while at least the method of operating surface rapid transit systems in America would remain fairly well settled. It is not conceivable that the whole plant can be again changed at an early date, even if we escape the evils of a silver basis, and enjoy the prosperity due to a single definite gold standard. The investment that has been made during the last ten years must pay for itself, and aside from financial considerations we are of opinion that something better than the trolley for the bulk of the work has still to be brought forward. It is true there has lately been a little stir over the compressed air cars now on trial in New York City, but the claims made for them remain to be proven and the verdict of previous experience is dead against them, as it is against steam applied directly for similar work.

In the August issue of "Cassier's Magazine" we find an article by Mr. George S. Strong, who is well known as an inventive engineer, and who on this occasion comes forward as the advocate of gas cars. He presents a series of figures which enable him to dismiss from consideration electricity and compressed air, on the score of expense and inefficiency, and he goes so far as to say that if electrical locomotives were furnished free coal a railroad company could not afford to own them. As a reply to such statistics we would refer only to the recent articles in our columns by Mr. W. Baxter, Jr., who came to a very different conclusion. But the main point in Mr. Strong's article is his contention that gas, and compressed gas at that, will solve the problem alike for regular railroads and for street car lines. There can be no question as to the greater use of gas engines in the near future, probably in far larger units than the public is now familiar with, but their utility is far more likely, it appears to us, to be found in helping to generate electric current than in superseding electric motors.

Mr. Strong asserts: "For street car work, compressed gas with the gas engine makes it possible to run a car 750 miles with one charge and at a cost of less than one-third what it now costs to run the same car by electric motor, or one-third what it is likely to cost for the compressed air motor." This is a splendid showing—on paper—but we confess our scepticism as to the existence now or later of a gas car able to run 5 miles an hour for a solid, uninterrupted week, or three-quarters of the way to Chicago, on one charge of gas.

With Mr. Strong as a pessimist on the subject of electric traction must be classed Mr. J. Sturgeon, who, in a paper read before the Tramways Institute of Great Britain and Ireland, a week or two ago, came forward to advocate the cable as against electricity. It is interesting to learn from this gentleman that the history of electric traction for tramways has been one continuous record of financial failure! According to him, overhead electric traction had already seen its best days, and was doomed to follow in the wake of the accumulator; so now there were signs and tokens of another new departure in the form of conduit systems of electric traction. Still, according to this authority, all was useless, for there is nothing in

the nature of such systems to lessen the cost. "It was a hopeless task that electric tractionists had taken upon themselves, and the new departure was bound to depart, too, on the same road as the others." The effect of these gloomy vaticinations was greatly spoiled by their author's attempt to crack up a new form of cable gripper, but it is simply amazing that such talk can be indulged in freely when the real facts are readily ascertainable as to the enormous and enlarging success of electric traction in every part of the civilized globe. Even England will have her fair quota of electric roads, of one type or another, in due season, and Mr. Sturgeon will have to seek other markets for his gripper.

A CITY IN THE CLOUDS.

IT is natural that in a region where there is an absence of hills, the people should show a liking for tall buildings that will enable them to get up in the air and survey the surrounding country. The development of the modern high office building in Chicago is certainly attributable in some degree to the flatness of Cook County; and now that the tendency has become more pronounced, the taste growing by what it feeds upon, there is a likelihood that even in cities where the topography does not invite to the construction of lofty edifices, their number will rapidly increase, for purposes of business and pleasure alike. Electricity with its special advantages in elevators, lighting and power distribution has done much to help forward this new departure in building, and, as in the case of the proposed tall tower to which attention is directed in an article elsewhere in this issue, it is evident that electricity is depended upon also for its assistance in spectacular effect.

A few years ago there was a decided prejudice against office or residential apartments under the roof in what were the tall buildings of those days, but now no discrimination exists against the top floors. On the contrary, their superior light and airiness, their ready accessibility by swift elevators, and their remoteness from the noise and dust of the street, make them desirable in winter as well as in summer. In such a city as New York, to-day, a large proportion of the people live and work and go to the theater at a height of 100 feet in the air, and their number is decidedly on the increase. Now that the church steeples are having their diminished heads hidden by the overtopping office structures and apartment houses, we may see the churches also resume their conspicuous place by becoming a part of the city in the clouds. The future for electric elevators under these changing conditions is obviously a bright one.

MUNICIPAL TAXES AND WASTE.

AT a time when one hears so much about the saving to be effected by municipal plants and the municipal management of various enterprises, it is well to remember that the evidence is almost wholly the other way. As we have before pointed out, it is a question of fact; and if the municipalities can work cheaply the thing is settled, so far as any individual case is concerned. So long as the record of municipal work is one of high taxation and terrible extravagance in the majority of places, it certainly is absurd for some economists to infer as they do that the alleged success of one or two city plants is enough to offset the teachings of a grim experience.

San Francisco, for example, has had advocates of a municipal plant, but at the present moment the burden of taxation is frightful. In San Francisco the tax rate reached, last year, $2.35 on the $100, and many owners of business property actually saw four months' rent absorbed by taxes. This excessive tax was due to criminal waste in the various municipal offices, which experts have estimated at $2,000,000 a year. And yet it is the opinion of some persons that rates should be raised even higher so that there should be more money to waste. The outcry in San Francisco has been so strong that the tax rate during the current year will probably be $1.60 on the $100, which in itself is high enough, on any consideration. It will be a long time, we should think, before any San Franciscan will want to entrust any more business to municipal management that he can carry out under the economies of private enterprise.

THE NEW FRENCH ATLANTIC CABLE.

IT might have been thought that there were enough Atlantic cables to take care of the traffic now offering, and it has often been assumed that there would be no early addition to the number. But the French Government has now given powerful support to the latest plan for another cable from Brest to Cape Cod, as already noted in these columns, and as a spirit of patriotic independence appears to be at the bottom of the enterprise, we see cause for expecting that presently Emperor William will also be wanting an exclusive German cable starting from some point on the coast of the Fatherland and running directly to these shores. The sentiment at the back of the French scheme in not concealed. The cable is to be manufactured entirely on the soil of France; it is to be laid by Frenchmen and at least one of the laying ships is to be French; it is to be managed by Frenchmen, and the French Government has guaranteed a substantial subsidy of $160,000 a year for no less than thirty years.

It is, of course, to be understood that this cable will be owned and operated by the Compagnie Francaise des Cables Telegraphiques, to which belongs the existing "P-Q" (Pouyer-Quertier) cable, and that it will link into the West Indian and South American cables under French and Dutch control. The gross estimated revenue of the system is $500,000, and as there is no appreciable new source of income of that amount, it is likely that other lines may suffer and that a new cutting of cable rates may ensue. The cable is to be working by next year, by which time perhaps an improvement in business may come to relieve the competitive tension.

DETROIT CHEAP FARES.

THE fact that the Detroit Citizens' Road had lost $80,000 in receipts during the present year, as a result of its 3-cent fares, is sufficient explanation for the adoption of a higher rate, as announced in our columns this week. Detroit has been the scene of a cheap fare experiment that has deeply interested the street railway community and the result appears to be sheer failure. One manager in a large city said at the time that the 3-cent rate would wipe out the capital of his company in about ten years, and that is certainly the fate that began to stare the Detroit managers in the face. It is to be hoped that the incident will have its lesson in other places where the agitation has been taken up. As a matter of fact, the only reasonable alternative offering to the flat 5-cent fare is the European plan of charging a cumulative fare by a punched ticket system. That has its disadvantages, and it is undeniable that the American can ride further and better for a nickel than can other people elsewhere.

One point worth noticing is that lower fares do not seem to have greatly stimulated travel, and the inference is that the travel to be won by cutting the fare one cent or even two is often a negligible quantity. More travel is to be secured by keeping up the fare and by providing special features of comfort and convenience, as well as maintaining the road in good physical condition.

AN ALLEGED TELEPHONIC-TELEGRAPHIC COMBINATION.

NOTE is made in our pages this week of another "consummation" of the deal that has been so long coming off between the Western Union Telegraph and the American Bell Telephone Companies. It is alleged that the Western Union has absorbed the telephone entirely, which even if true, is a little surprising. Meantime, those most concerned have little to say on the subject. Denial is piled on denial, but only in an end-of-the-summer, languid kind of way. Vice-President Van Horne, of the Western Union, knows of no such arrangement, while Treasurer Driver, of the American Bell, is ready neither to affirm nor contradict. The old contract runs out in November, so that a new arrangement would certainly be timely if it has not already been made these many months.

TELEPHONY AND TELEGRAPHY.

RUMORED CONSOLIDATION OF WESTERN UNION AND AMERICAN BELL.

With regard to the reports and rumors in circulation of late as to the news terms between the Western Union and American Bell Companies, the following appears in the Boston "Commercial-Bulletin:"

"We understand upon the best authority that the Western Union Telegraph Company controls at the present moment the American Bell Telephone Company. The importance of such control will at once appear to every one who appreciates how the two have come in competition during recent years. The Western Union dividends had become threatened through the competition of the Bell company and of the Postal Telegraph Company, but it has long been a fully arranged plan for the Western Union to secure control of the telephone company. The two together can probably make it very warm for the Postal Telegraph Company, or the final outcome may be a combination of all three.

"Mr. J. Pierpont Morgan has been the largest purchaser of Bell Telephone stock at auction here, but the manner of purchase has been very cleverly concealed. Western Union stock has ruled weak on the New York Stock Exchange during the past few days, but this weakness is thought to be part of the programme of those conducting this gigantic deal. The combination of these two concerns will mean an almost impregnable monoply of both the telegraph and telephone business in the same hands."

The Western Union Company is capitalized at $100,000,000 and the American Bell Telephone Company at about one-half that amount. In 1893 the capital was $17,500,000, and was then increased to $20,000,000. In the following year it was increased to $50,000,000, and the issue of $1,000,000 additional stock was authorized in June, 1895. The stock is quoted at about 200. Western Union, at its closing price on Aug. 21 of 73⅝, was worth $73,625,000, while American Bell at 200 was worth $100,000,000.

A SUIT TO KEEP UP TELEGRAPHERS' SALARIES.

The telegraph operators on the line of the Union Pacific have filed a suit in the Federal Court at Omaha. The case is brought in the name of the Order of Railway Telegraphers. The plaintiffs allege that the receivers have reduced wages in violation of Judge Caldwell's order of 1894, wherein the court ruled that no cut in wages could be enforced without an order of the court. They specify where wages have been cut, and ask to have them restored. It is further alleged that the officials of the company are hostile to organized labor, and particularly to the Order of Railway Telegraphers, and that a systematic effort has been made to weed out leaders of the order by summary dismissal without excuse.

TELEPHONE WORKMEN KILLED BY DYNAMITE.

For some time past workmen have been employed in rebuilding the Pennsylvania Telephone Company's line between Lancaster and New Holland. The new poles are being set 5 feet deep and the holes for them were being blasted out with dynamite, of which about 250 pounds had been received some days before the accident. At the time of the explosion there was from 50 to 100 pounds on hand which had been stored in a summer kitchen of the Eagle Hotel at New Holland. The explosion occurred in the morning just after the foreman had given orders to have the dynamite placed on the construction wagon where it was generally carried under the back seat. Just how the accident occurred will never be known, for Cannon, the one man who could have told everything, was blown to pieces. When the explosion occurred the driver of the team, F. Hammond, had just taken his seat on the 'bus and was about driving out into the yard from under the shed.

Out of the nineteen workmen employed on this job three were killed outright and thirteen were injured.

So tremendous was the force of the explosion that the stable, wagon shed and summer kitchen were blown to pieces. The hotel was badly damaged, looking inside as though a tornado had passed through it, and every building within two blocks of the hotel, which is in the heart of the town, had its windows knocked to pieces. In many instances, the sashes themselves and doors were blown out. Every sash and door in the hotel was blown out, and the furniture itself is badly damaged, entailing a total loss of $5,000. A singular fact is that an unexploded box of dynamite was afterward found in the ruins of the shed where it had been placed beside the box that exploded.

WESTERN UNION WIRES IN SYRACUSE, N. Y.

Work is now being actively carried on in putting the Western Union wires underground in the city of Syracuse, N. Y. The cables have been supplied by the Standard Underground Cable Company, of Pittsburg, and the work is in charge of Mr. Edward Sullivan, of their staff. Wooden duct subways had already been laid. The city retains the right to use the Western Union subway for police and fire alarm service, and these wires are also soon to be removed from the poles.

ROENTGEN RAYS.

ROENTGEN RAYS IN MEDICAL RESEARCH.

There was recently at the new Animals Institute, London, a private view of some exhibits for a competition in improvements in the Röntgen rays to aid in the diagnosis of lameness and disease in the human subject or the lower animals. The Institute is at present offering gold medals for the best photographs of the internal frame that assist in the diagnosis of disease, and the competitors include medical men, scientific institutions, and also photographers. A good number of photographs of diseased parts has been collected, but the competition will remain open for some time longer. The fifth quinquennial gathering of the International Homœopathic Medical Congress was held last week in London. On the opening night, Dr. Gerard Smith gave a display of Röntgen photography and other novelties.

REPORTS OF COMPANIES.

AFFAIRS OF ARCHER & PANCOAST CO.

The Archer & Pancoast Company, manufacturers of gas and electric light fixtures, whose salesrooms are at Nos. 18 and 20 West Twenty-fifth street, this city, and which has a factory at Flushing and Carlton avenues, Brooklyn, went into the hands of receivers, on August 19. Justice Smyth, of the Supreme Court appointed Albert C. Hetherington, William S. Fearing and Peter F. Meyer receivers, with a bond of $100,000, on the application of President Pancoast and other directors of the company. Mr. Fearing is vice-president and general manager, Paul Thompson, treasurer, and Mr. Hetherington a director. Thomas B. Odell was appointed referee, and the order to show cause for the dissolution was set down for February 5, 1897.

It was said by the officers that the company was insolvent, that it had recently found it impossible to obtain money in any considerable quantity, owing to the financial stringency all over the United States, and that within the last week the bank with which the company had always done business had refused further to extend its line of discount. To save the assets from slaughter and make the best possible disposition of the property, the officers deemed it best to apply for receivers. The total liabilities are $806,780, and the nominal assets $821,063. Of the liabilities, $705,017 are mortgage liens on all the property of the company, except accounts receivable. These mortgages are for purchase money of factory, $55,000; to secure notes, $267,482, and to secure income bonds, $378,465. There is due for merchandise $51,025 and for loans by stockholders $37,074.

The assets consist of real estate and factory in Brooklyn, $200,000; machinery, etc., $201,552; models, patterns, etc., $100,000; merchandise, $139,037; improvements at factory, $17,844; store fixtures, $12,000; goods in New York store, $37,067; stock of other companies, $11,000; accounts receivable, $102,563. Of the accounts, $18,000 are probably uncollectable, and $14,414 have been pledged to secure advances. The officers believe that there will be no equity in the assets which are covered by the mortgage liens leaving only the accounts to pay the unsecured debts. The company did not have any rating at Bradstreet's. It is a reorganization of the old Archer & Pancoast Manufacturing Company, which went into the hands of receivers on May, 1893, with liabilities of $1,100,000. The property was sold to the Reorganization Committee for $600,000, and the present company was formed by the creditors in November, 1894, to carry on the business. About 400 persons were employed by the company.

THE OHIOPYLE FALLS of the Youghiogheny River are the latest to receive the attention of the power transmission promoter. Mr. D. S. Stewart, of Ohiopyle, Pa., owner of large property in the neighborhood, is interested.

ELECTRIC HEATING.—It is stated that the stock of the American Electric Heating Corporation is about to be listed on the Boston Stock Exchange.

Electric Lighting.

ELECTRIC LIGHTING IN BELFAST.—II.

BY VICTOR A. H. MC COWEN.

Concluded.

In the high-speed four-cylinder engines the compressed air connection is made to the bottom right-hand cylinder, which for starting purposes is specially provided, firstly, with a valve to close the mixture admission port, secondly, with an exhaust passage and a valve to close it, and thirdly with an inlet for the compressed air. The valve of this inlet is worked by a double-throw cam, thus giving an impulse for every revolution in this cylinder. The speed increases quickly, and as soon as the explosions take place in the other cylinders, the compressed air is shut off, the starting cam thrown out of action, and the gas turned on to this cylinder.

Mains, Feeders, and Distributors.—These are mostly bare copper strip in concrete culverts. The strip is simply supported on earthenware insulators placed 6 feet apart, which are held in place by a pitch setting. The strip is laid in before the cover flags are put down; and extra copper can be drawn in at any time without raising the flags. Everywhere the culvert is placed beneath the footway. The lengths average 25 yards, and are built with a fall towards the junction boxes in order to allow any water that may get in to drain off. The average depth of the copper below the surface is 20 inches. The space required for a three-way culvert for a distributing main is 27 inches wide, with a minimum depth of 18 inches below the surface. For a five-way culvert, which takes the distributing mains and a pair of feeders, the space required is 34 inches wide, with a depth of 18 inches.

TABLE 1.—Test of No. 6 Tandem Engine and Dynamo. Taken April 24, 1896.

Culverts.—Three-way and five-way culverts are built of cement concrete in the proportion of five of gravel and broken stones to one of Portland cement. The side walls are 6 inches thick, and the bottom 4 inches, all faced inside with cement. The covering slabs are 2-inch Kilrush and Caithness flags. The culvert when dry is itself a fair insulator, which is a great advantage where there is a possibility of sometimes getting a sag of the strip between the insulators, as may occur through the carelessness of workmen. At street crossings, and under narrow footways where there is no room for a culvert, insulated cables in cast-iron pipes are used. Connections between the lengths of strip, or between cable and strip, are made in the street boxes by means of gun-metal grip-boxes, which clamp the ends together.

The copper strip is 1 inch wide and 0.2 inch thick, giving 0.2 square inch section. This is the section used in all the distributing mains, both for middle and outer wires. When the lamp density—that is, the number of lamps per yard—increases, the section of the outer wires can be increased by putting in another strip on the top of the present. The section of the feeders varies from 0.4 to 0.8 square inch, according to the length; the longest feeder at present is 520 yards.

The distributing mains are all in parallel, and are connected at as many points as possible in order to equalize the pressure. They are brought back to the station to supply current for the lighting, etc. The middle wire is brought back from four different points of the network. The pilot wires are in the form of three separately insulated conductors, twisted together and cased in lead; some have paper insulation and others impregnated jute. The joints are protected, either by a lead sleeve soldered to the lead covering and filled with insulating oil, or by being placed in a special joint-box, which is filled with insulating material run in hot. The pilot wires are drawn into cast-iron pipes laid along one side of the culvert.

On account of the wet nature of the ground and the comparatively low level of the city, special precautions had to be taken against water getting into the culverts or accumulating in them; and the aim has been to make the whole watertight. The street boxes are built of brick, faced inside with cement, and the bottoms are concreted. They are provided with a cast-iron frame and cover, the latter being filled with concrete. A water-tight joint is made between cover and frame by the use of House's slow-setting cement. Junction-boxes placed in the roadway are provided with specially heavy frames and covers, the latter being filled in with wood blocks. The covers are provided with inspection plugs, which allow of a rapid examination of the system being made without lifting the covers. Any accumulation of water can be removed through the inspection-plug hole by means of a small hand-pump. A record is kept of the condition of the boxes, and of the dates of their having been pumped out. The covers are also lifted periodically for the ventilation of the culverts. No trouble has been experienced from gas accumulating in the culverts. At the laying of the mains all defective gas services were renewed, and those that ran close to the culvert were coated with a mixture of pitch and tar.

TABLE 2.—Tests of No. 2 Single Cylinder Double-Acting Engine. Taken June 5 and 6, 1896.

No. of test	I.	II.	III.	IV.	V.	VI.	VII.
Duration of test, min.	30.0	30.0	30.0	30.0	30.0	30.0	15.0

Per I. H. P. hr., lbs.	....	....	84.0	117.0	....	130.0	....

Note.—In tests I. to V. both ends of the cylinder were working, no explosions being missed. In tests VI. and VII. one end only of the cylinder was working.

The service mains are rubber-covered cables drawn into wrought-iron pipes, which are laid from the nearest street-box. They are connected to the corporation-main fuses immediately inside the building. The connections to the distributing mains are clamped in the case of bare copper strip, and insulated T-joints are employed for connecting to cable.

Throughout the system the positive and negative mains have certain relative positions under the foot-way, namely, the negative main or feeder is everywhere next the curb and the positive next the houses. In the street-boxes the positives are colored blue, the negatives red, and the middle wire black; the service cables are colored in the same way.

General Remarks.—From the experience here gained the author is of opinion that a gas-engine station necessitates more attention than a steam-driven station; and more drivers of a better class are required for a given power than in the latter station. A couple of men are always required for the electrical

starting of an engine. Without their help the strain on the armature would be too great, if the current were switched on when the machine was standing.

The following statement shows the cost of current sold from January 23 to December 31, 1895:

Number of units sold	82,771
Number of lamps connected (equivalent in 8c. p. s.)	10,500
Revenue from sale of current	£2,186
Average price obtained per unit	6.34d

	Cost of Production. £	s.	d.	Per unit Sold. d.
Fuel (Gas)	501	3	0	1.450
Oil, waste, water, and stores, including ignition tubes	80	4	3	0.233
Salaries and wages at generating station	444	17	4	1.290
Repairs and maintenance of buildings, engines, dynamos, and accumulators	93	16	8	0.272
Repairs and maintenance of mains	76	4	6	0.221
Rents, rates and taxes	236	0	0	0.684
Management expenses, etc.	413	9	11	1.200
Insurance	23	2	0	0.07
Total	£1,868	17	8	5.42

A machine can be started up and got on circuit in about two minutes, the stand-by units being kept plugged up on the switchboard and the ignition tubes kept hot. For the sake of efficiency the machines are run as near to full load as possible, but, as far as governing is concerned, they can be run at any part of their load. The cost of fuel (gas) per Board of Trade unit sold for the year ending December 31, 1895, worked out at 1.45d. This, with gas at 2s. 3d. per 1,000 cubic feet, is equivalent to 53.6 cubic feet per unit sold, or 59 feet per unit generated. The total efficiency of units sold to generated is 91 per cent. This is equal to an average consumption during the year of 44 cubic feet of gas per E.H.P. hour. A plotted curve showing the cost of gas per unit of electricity, generated and sold, throughout the year proves that it varies very little, whatever the output may be. The cost of engine-room stores, including oil, waste, water and ignition tubes, amounts to 0.23d. per unit sold, which compares favorably with steam-driven stations. Ignition tubes form a heavy item of the cost. Good results are now being obtained with porcelain tubes, which require only a short time to heat up. The cost of cooling water works out at a low figure, and this is due to the use of a tank of large capacity, which has special cooling arrangements.

The station started to supply current on January 23, 1895, with 2,300 8 candle-power lamps; there are now 13,500 lamps of 8 candle-power connected with the mains.

The following statement shows the quantity of units of electricity generated, sold, etc., from January 23, 1895, to December 31, 1895:

Quantity sold:—

Public lamps.

	Units.	Units.
Private consumers by meter, at 4d. per unit	574	
Private consumers by meter, at 7d. per unit	82,197	
		82,771
Quantity used on works	3,822	
Quantity lost in battery	6,304	
		10,126
Total quantity accounted for		92,897
Quantity not accounted for		2,229
Total units generated		95,126

From this it will be seen that:—

	Per cent.
Total efficiency	= 91.0
Loss in batteries	= 6.7
Loss in main	= 2.3
	100.0

The total maximum supply demanded was 159,000 watts, which is equivalent to 5,300 30-watt lamps.

A STATE LIGHTING PLANT FOR FRANKFORT, KY.

A special dispatch from Frankfort, Ky., says: It has been about definitely decided by the Sinking Fund Commissioners to carry out a supposedly economic enterprise by which the State will light its own public buildings, offices and the public square, and unless present intentions are changed a big electric light plant, to be operated by a trained engineer with the assistance of prisoners, will be placed in the penitentiary, while the wires will be run in to the public buildings and grounds. It is claimed that the State, which uses a great deal of light, will save much on gas and electric light bills by this means, and that the original cost of the plant will soon be more than saved.

The local Gas and Electric Light Company is supposed to have exclusive privileges in Frankfort, and it does not seem to have occurred to the State officials that this company may complain to the council and object to the council's permitting the poles and wires of any other lighting concern being run through any of the streets of the city.

SILVERED INCANDESCENT LAMPS.

Our London contemporary, the "Electrical Review," devotes considerable space to an incandescent lamp which is being introduced by the Improved Electric Glow Lamp Company, Limited. The lamp in question differs from the style generally seen in being about twice the size in diameter, and very much flattened in length, so that the upper surface of the glass which spreads out from the base is in the form of a small oval shade. This upper part of the bulb is silvered or gilded so as to form a reflector which answers the same purpose as the shades in ordinary use. The silvering is varnished over on the outside of the bulb and only the lower half of the lamp remains transparent.

Another point of interest in connection with this lamp is that the filament is placed symmetrically with respect to the silvered surface, or, in other words, as nearly as possible in the optical focus of the mirror. The claim for these lamps is that they give a maximum light on the surface to be illuminated with the least expenditure of energy.

The silver plating on the glass is electrically coated on the outside with copper, and afterwards varnished. The silver plating is thus protected from the direct action of external heat and air, and is said to keep perfectly bright after some thousand hours of lighting. The latter statement, we believe, must be taken cum grano salis, as, unless the efficiency of the lamp is much less than it is said to be, the filament would probably be burnt out considerably under one thousand hours, and the inevitable blackening of the bulb must affect the mirror to some extent long before the lamp is burnt out.

The light from these lamps can be intensified several times in any given direction by the concentration of the direct and reflected light upon a limited area, and one of the special features is the use of this lamp for throwing the light on the ceiling, and thus lighting rooms, etc., with a very soft and diffused light, very pleasant to the user. As far as the silvering of the bulb alone is concerned there is nothing whatever new about it as lamps of the ordinary shape have been silvered for several years by a number of companies; but in regard to the shape of the bulb and the placing of the filament co-axially with it, we should judge these modifications might be of considerable advantage to the lamp for certain purposes. The company report contracts in hand for a very large number of these new lamps, and while their claims for them are certainly extravagant, it is probable, from the testimony of those who have seen them, that these lamps have considerable merit. The claim, however, that a 10 c. p. new lamp gives 25 per cent. more light than an Edison-Swan lamp, and uses 46 per cent. less current than the latter, is certainly in need of further investigation, and undoubtedly, modification.

ICE AND ELECTRIC PLANT AT OSCEOLA, ARK.

Mr. G. N. Borde, of the Electrical Engineering and Supply Company, Memphis, Tenn., informs us that they are installing at Osceola, Ark., a combination ice and electric plant. It comprises a Remington 2-ton ice machine, complete; a 50 horsepower Houston, Stanwood & Gamble engine and 60 horsepower boiler; a Thomson-Houston 500-light self-exciting alternator, and all the fixtures, wiring, etc., for street and private lighting. The building is 32 by 40, of corrugated iron. The water supply is furnished by a Cook deep-well pump putting water into a 3,000-gallon iron tank. The plant is in every respect suitable for a small country town of 2,000 inhabitants, and costs complete about $7,500.

PLANT PROPOSED FOR CUTHBERT, GA.

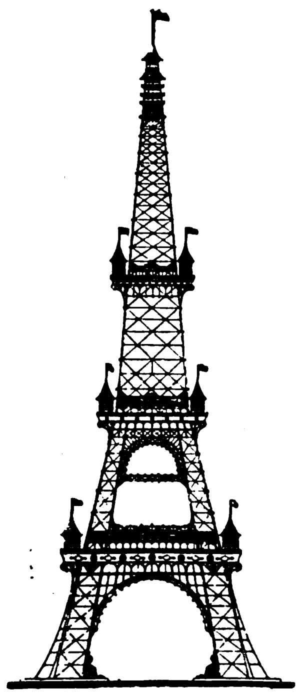
Mr. Robert L. Moye, the mayor of Cuthbert, Ga., informs us that the mayor and council of that city have ordered an election September 18, to determine whether the town shall issue $7,000 in bonds to establish an electric light plant. He says that everything looks encouraging for a favorable vote, with little or no opposition.

News and Notes.

CHICAGO'S CITY TOWER.

A tower has been projected and is in actual course of exploitation in Chicago, which is to be 1,115 feet in height, and whose estimated cost is $800,000. The base of the tower, which will occupy an entire city block is to be 326 feet square.

At the base, from the four corner supports, each of which is 50 feet square, will rise arches 200 feet across and the same in



Proposed Electric Tower for Chicago.

height. These arches will support the first landing, which will have 90,000 square feet of flooring, where 22,000 persons can be accommodated at one time. There is a distance of 225 feet from the ground to this first landing.

At a height of 450 feet there is to be a platform 150 feet square. Six hundred and seventy-five feet above the ground is the third landing, far higher than any building in Chicago. At an elevation of 1,000 feet above the earth is the fourth landing, and from there stairs lead up to the very top of the tower.

Thirty-four elevators are to be used in this tower. They will be operated by electricity, the power being derived from the same plant used in lighting the structure.

The plan of having a United States meteorological bureau has been discussed at Washington and favorably considered by the officials of that department. The most important observations of all on such a tower would be those relating to atmospheric electricity. A few observations at the Washington monument have already shown some remarkable comparisons between the changes at that height and at the earth's surface. There is hardly a point regarding diurnal change, abnormal change or seasonable change of meteorological element that would not be successfully aided by records from such a tower.

SHORT TALKS ON BEARINGS, ETC.

BY M. W. DANIELSON.

ONE of the best kinds of bearings that I have ever had to do with, one giving the least trouble and requiring the least looking after, is the kind with a hollow space under the babbited box, forming an oil well, as shown in Fig. 1.

A mechanic can fix old bearings in this way, if the boxes are of the right kind. Cut a hole in the bottom half of the sleeve at D, and rivet on a piece of brass so as to form the well,C. Solder up the crevices. Put in an oil feed tube at one side so as to fill the well at intervals.

When the shaft is running, the oil will be fed to the shaft, A, by a wick which comes in contact with the shaft by being pushed through a hole in the bottom half (B) of the box and left to hang down into the oil in the well, as shown; this kind of a bearing will run for two months on one filling of the well, and as long as oil is kept in the well there is no danger of the bearings getting hot for want of oil. The wick will feed the oil to the shaft as fast as needed and no faster.

I have recently been troubled with a shaft in which there was a bend, as shown at F, Fig. 2, and this bend frequently made trouble all along the line of shafting. This was repaired one Saturday night without taking it from the hangers, by adopting the plan used to straighten bent files.

First, I set up a post, H, just beneath the bend in the shaft, E, and nailed a pan, G, on top of it. Then I places hot coals in the pan and heated the shaft; afterwards while cooling, pressure was applied to the shaft with chains and weights, which brought it back into line. Shafting will always get out of line if too light for the work put upon it.

There are weak spots in shafting, as well as in everything; "a chain is no stronger than its weakest link," and so with a shaft, its weak spots receive the strain and give way to it until it becomes out of true, and no amount of aligning will make it run true. It is no uncommon thing in mills to find shafting too light for the amount of work required of it.

Referring to another point, I will mention a case in which the backlash of the shaft was severe and as there was no space for another journal at the end of the shaft, I tried the plan shown in Fig. 3, with good results.

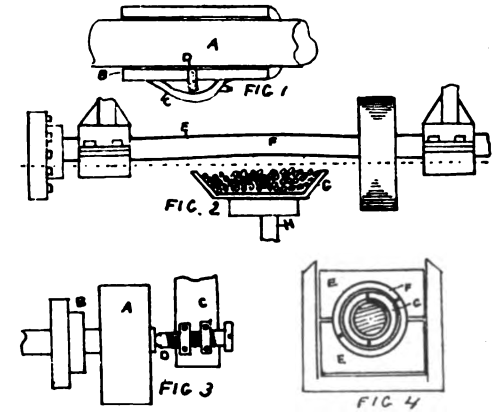
A is a pulley which fitted close to the end of the shaft, as shown. The coupling, B, prevented putting a hanger on the inner side and there was no room further along. I cut a ½-inch hole in the end of the shaft and inserted the pin, D, in it, and supported this pin firmly in place in the casing, C. This served to steady the shaft. If shell rolls are in use, two of a different size will not run together well. All shells should be callipered and put in the right way. Shell rolls are not often used, but we represent a set in Fig. 4, in which the wood casings are marked E E and the shells F G. It can be readily seen that if either of the shells are untrue or mismated that they will not do good service.

Good bearing for machinery is the hard steel ball bearings, which are being run on some makes of machinery with excellent results, greatly reducing the friction on the bearings, and also the danger of cutting in case it should get dry. In setting roller systems there is one precaution to observe. There is a small saddle resting on the middle and back rolls, having a long and a short side. The long side should rest on the middle roll and not the reverse. When this is done, the most weight is on the middle roll, leaving the back roll with very little weight.

Piston Packing.—The variety of methods of packing employed are many. The utility of packing depends, first of all, upon the cylinder, and the care which has been exercised in its construction.

The important thing is to get a cylinder absolutely true and smooth. If this has been accomplished, the matter of packing is relatively unimportant.

If it is necessary to bore, provide a system of boring the cylinder which performs the work with so little labor on the part of any one tool that its cutting edge does not become dulled during the whole process, and with the expenditure of so little



Short Talks on Bearings.

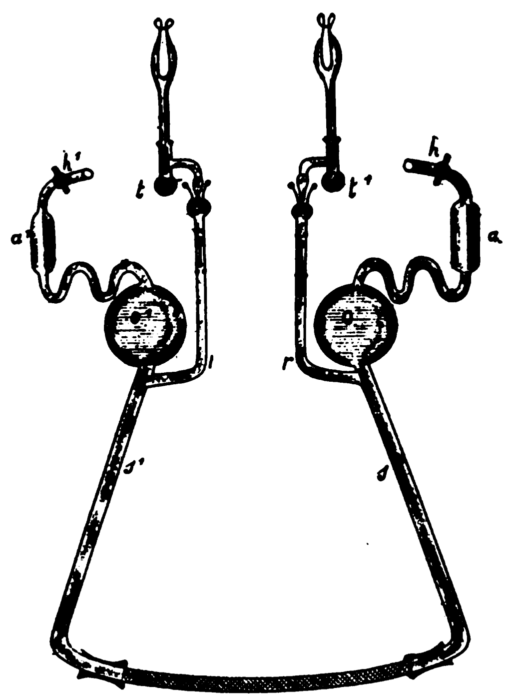
time that no accident is liable to occur from unavoidable stopping of the power.

The process of boring is best performed with the cylinder standing upon its seat, in the position which it will occupy when in actual operation, so that any distortions in the metal, due to the weights of the various parts, however trifling they may be, will have the same effect during the process of boring as they will when the engine is set to work.

DOUBLE ACTING MERCURY AIR PUMP.

THE mercury pump described below was constructed by W. Bähr and E. A. Krüger, of Berlin. Its chief feature is that it operates twice as fast as the ordinary hand pumps.

As shown in the illustration, taken from the "Elektrot. Anzeig.," two Töpler pumps whose riser tubes, s s', were only 40 cms. long, were conected by a rubber tube at their lower ends



DOUBLE ACTING MERCURY AIR-PUMP.

so as to communicate with each other. The pump was mounted on a board so that the bulbs, o' o, were in the position shown.

The usual barometric tube is dispensed with and immediately above the air accumulators, a' a, there is placed a glass cock; no other change is made in the pump. The board on which the pump is mounted is arranged so that it can turn upon a central horizontal axis, the motion on each side being limited by stops.

The pump is supplied with mercury until the bulbs, o o', are filled about one half; the two cocks, h h', are connected to a preliminary pump. The vessel to be exhausted is connected to the drying bulbs, t t', and the preliminary pump set in action; by opening the cocks, h h', the greater quantity of air is removed. Since the air is removed from both sides, the level of the mercury remains constant.

If now the board be turned on its axis, a difference in level ensues, the mercury in the bulb, o, falls below the tube, r', connecting with the vessel to be exhausted, while on the other side it forces the air through the accumulator a', where it is removed by the preliminary pump. On turning the board in the opposite direction the same action is repeated, the mercury now falling in o', and rising in o. The air is prevented from rushing back by the action of the bent capillary tubes, which retain the mercury. The oscillation of the board is continued until the mercury in the bulb touches the mercury thread in the M-shaped capillary tube; that is, until it shows no air space between them.

It will be noticed that with this combination one pump alternately serves as the mercury reservoir for the other; by this means its movement is fully utilized. With ordinary pumps the falling of the mercury must always be awaited before a fresh exhaustion can take place.

According to the designers the pump operates faultlessly and as the oscillation is a slow one, breakage is almost completely prevented. The pump is not patented or legally protected in any way.

NEW CENTRAL STATION AT ATHENS, MICH.

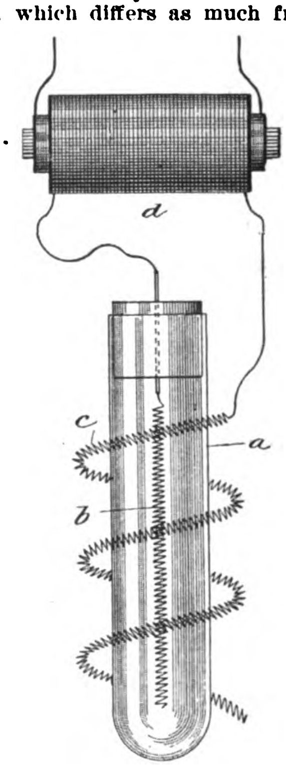
The new central station installed at Athens, Mich., by Rheubottom & Bond, of Union City, Mich., has been put in successful operation and turned over to the Athens Electric Company. The dynamos were furnished by the United Electric Improvement Company, of Philadelphia, the transformers by the Wagner Electric Manufacturing Company, of St. Louis, and the copper wire by the Phillips Insulated Wire Company, of Pawtucket, R. I.

ANDREOLI APPARATUS FOR PRODUCING OZONE.

A METHOD of producing ozone by means of the silent discharges generated by an electric current from points, sharp angles, etc., has been known for several years, and this method has recently been improved by Emile Andreoli, of London, so that ozone and light are produced simultaneously. This is effected by the use of points or sharp angles like the serrated wires shown in the illustration, in connection with tubes containing more or less rarefied gases. The method will be explained by reference to the accompanying drawing which is somewhat diagrammatical.

The tube a is provided inside with an electrode b, consisting of a carbon filament or a metallic wire or rod, or a bundle of small serrated wire, the points of which radiate, so as to face the inside of the glass tube. Outside the tube, and in proximity to it, as shown, some serrated wires, c are fixed. One end of the wire rod b contained in the vacuum-tube is connected with one of the poles of a Ruhmkorff coil d, or of a high-frequency transformer. The external metallic electrode c of the tube is connected with the other pole, and as soon as the electric current passes the inside of the tube becomes luminous, and at the same time on each of the points of the serrated wires, the characteristic glow of the silent discharge appears and is accompanied by a strong smell of ozone.

It is a well-known fact that the silent discharge produces a bluish or violet glow; but there is another luminosity here quite distinct from the glow generated by the silent discharge. In the vacuum-tubes there are both the glow of the silent discharge outside, and luminosity inside. This is scientifically a new phenomenon which differs as much from the disruptive



ANDREOLI'S OZONIZER.

discharge in ordinary vacuum-tubes as the internal luminosity of the tubes differs from their external glow, and it is believed that nothing similar has ever been produced before.

THE OELSCHLAGER-SCHROTTKE LIGHTNING ARRESTER.

WE illustrate herewith a new lightning arrester invented by Messrs. Oelschlager and Schrottke, of Germany. The device consists of two parallel stationary uprights, which are placed within arcing distance for a portion of their length, having their upper ends widely diverging and their lower ends, which are insulated from each other, connected respectively with the circuit and the ground.

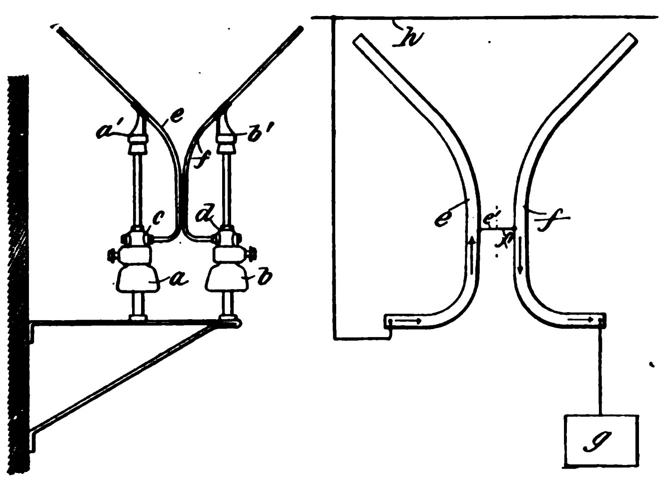
Fig. 1 gives a general view of this lightning arrester and Fig. 2 shows the parts diagrammatically. The metallic caps e and d, which support the lower ends of the uprights e f, are

secured to the insulators a b. These caps are connected respectively to the circuit and to the ground. Within these caps the uprights are adjustable so that the distance between them may be varied according to the voltage of the circuit which the arrester is designed to protect. For a portion of their length the uprights are made parallel and set within a few millimeters of one another, but their ends are widely divergent, the upper portions being supported by additional insulators a' b'. The uprights are identical in form and construction, and are made of copper wire or rods.

When the device is connected for the protection of a circuit, a discharge of lightning will arc across the narrow space separating the uprights and be conducted to ground. Should the arc persist, it will quickly travel upward between the diverging uprights e f until lengthened sufficiently to destroy it. This extinguishment of the arc is the result of thermal and electrodynamic actions. When the arc is established, as at e' f', the surrounding air is rapidly heated, causing an upward current of air at that point, which tends to carry the arc with it. In addition to this cause it is well known that conductors under the influence of an electric current tend to arrange themselves in parallel positions. The arc e' f' being practically at right angles with uprights, the portion e' tends to assume the position of the upright e and acts with the upward current of air in lifting the arc. Similarly the portion f' tends to assume the position of upright f. Thus any arc which may be formed between the uprights is quickly raised to their divergent portions and thereby becomes self-extinguishing, both the above-mentioned causes, the thermodynamic and the electrodynamic, coacting to drive the arc upward and extinguish it.

It is evident that the maximum effect is secured when the thermodynamic influence acts with the electrodynamic to drive the arc upward. This, however, can only be accomplished when the uprights are electrically connected with the circuit and ground, so that the arc is the uppermost part of the path of the current which is flowing. The connections should therefore be made at the lower ends of the uprights, for, if they are made above the arc, the electrodynamic force would act in opposition to the thermodynamic force.

This lightning-arrester has been found to be particularly efficient and certain in its action when connected for the protection of circuits of high voltage. Its parts are stationary. Hence there is absolutely no liability of the device to get out of



OELSCHLAGER AND SCHROTTKE'S LIGHTNING ARRESTER.

order. It is easily adapted for out-of-door service merely by protecting it with a hood, and, when once put into position, it requires no further attention.

PERSONAL.

H. M. LITTELL, THE NEW MANAGER FOR THE METROPOLITAN.

H. M. Littell was elected vice-president and a director of the Metropolitan Street Railway Company of New York City last week, after which President H. H. Vreeland appointed him general manager of the company. Mr. Littell has always been a railroad man. He began work in that line with the Louisville City Railway, in 1874, when he was eighteen years old. From 1883 to 1885 he was general manager of the St. Paul City Railway Company. His next service was with the Louisville and Nashville. He next became general freight and passenger agent of the Chicago, St. Paul and Kansas City Company, and in 1888 he was engaged with the Cincinnati Inclined Plane Railway. In 1893 he was appointed general manager of the New Orleans Traction Company, and in July, 1895, he became president and general manager of the Atlantic Avenue Railroad Company of Brooklyn, holding that place until the line was absorbed by the Nassau Electric Company.

WILLIAM SLOCUM BARSTOW.

In re-electing Mr. Barstow as its secretary, the Association of Edison Illuminating Companies marked its appreciation of faithful and intelligent service. Mr. Barstow was born in February, 1866, and educated at Adelphi Academy, Brooklyn. He then attended Columbia College, entering in 1883 and graduating in 1887. He had a marked taste for electricity and went into the employ of the Edison Machine Works in the summer of 1887, there continuing until May, 1889. He then resigned to become Assistant Superintendent of the Edison Electric Illuminating Company, which was beginning a career of active expansion and needed youthful energy and talent. In September, 1890, he was made General Superintendent of the same company. In July, 1895, he became in addition General Superintendent of the Citizens Electric Illuminating Company and director in it, and thus may be said to have both these large concerns, now united, under his technical and engineering direction. Mr. Barstow takes great interest in general electrical matters and is vice-president of the Electrical Department of the Brooklyn Institute. To his ability as a mechanical and electrical engineer the success of the Brooklyn stations and his frequent contributions to the technical press bear abundant witness.

W. S. BARSTOW.

MR. PATRICK B. DELANY has been awarded the Elliot Cresson gold medal by the Franklin Institute of Philadelphia for his ingenious system of machine telegraphy.

MR. H. GORDON STOTT, electrical engineer of the Buffalo General Electric Company, has been a visitor to New York recently, inspecting local central stations and enjoying the pleasures of the seashore at Bay Ridge.

Mr. MAX OSTERBERG, E. E., A. M., has opened an office at 27 Thames street as Consulting Engineer and Electrical Expert. He will continue to devote considerable time to the Röntgen rays, being busy at present making complete installations in several hospitals. He will make a specialty of gas engine plants for private residences and isolated plants.

POWER SUPPLIES WANTED FOR MARE ISLAND NAVY YARD.

The Navy Department, through the Bureau of Supplies and Accounts, is inviting proposals until September 8, for furnishing the Mare Island Navy Yard, with 175 kilowatt dynamos, one switchboard and instruments; two 5 horse-power stationary motors; three 2 horse-power, portable drills; four ¼ horse-power electric blowers; seven switch boxes; 125 insulators, special cable, L material; 125 locust pins; 3,800 feet B. & S. cable, copper wire; 5,000 feet cable copper wire; 400,000 circular mill sections; 150 lamps, 16 candle-power; 110 volt T. & H. sockets, porcelain fittings; 900 feet twin conductors, rubber insulated flexible cable.

Prospective bidders can obtain additional particulars by addressing Edwin Stewart, Paymaster General U. S. Navy, Washington, D. C.

READING, PA.—The prison inspectors have decided to equ'p the Berks County Jail with an isolated electric light plant.

Society and Club Notes.

EIGHTEENTH ANNUAL CLAM-BAKE OF THE AMERICAN ELECTRICAL WORKS, PROVIDENCE R. I.

CLAMBAKES for electricians at Providence now number eighteen, and the latest always seems the best.

When the invitations to the eighteenth annual clambake of the American Electrical Works, were received this year, they attracted more than usual interest, as it was seen at once that Mr. Phillips had once more selected another club at which to entertain his guests, and the picture on the card representing the clubhouse showed it to be a building of superior and commanding site and architectural attractions. Nor were the hopes of the visitors disappointed, as on arrival at the Pomham Club, it was at once seen that the house occupied a site of unusual beauty, on a bluff opposite Pomham Light, commanding an uninterrupted view of the whole Providence River. The house itself also possesses great attractions of its own, having been built for a permanent institution and with every provision for entertainment self-contained. The entire ground floor is occupied by the dining room, surrounded by a wide piazza equipped with numerous easy rocking chairs, in which we could enjoy the balmy breezes from Narragansett Bay and as beautiful a panorama as the eye could desire. On the second floor were to be found a large billiard room equipped with four tables, and a large music and card room, and a smaller room which was liberally patronized containing the famous Phillips' punch bowl. A short distance away from the main building is situated a very complete bowling alley, in which the visitors soon made some startling scores.

When the morning dawned, it looked anything but promising, and in the early hours it was raining heavily. Those who knew best, however, did not lose hope, as good weather has come to be considered a regulation feature at these annual entertainments, and there seems little doubt that Mr. Phillips has some secret understanding with the weather clerk, as it never fails. And so by the time breakfast had been served, the clouds began to ascend, ceased from their anxiety to water the earth for that day, and then proceeded to afford a very grateful shade from the fiery glances of the sun, which, however, could be seen smiling between the drifts, on the merry doings of some two or three hundred busy business men, let loose for one day to enjoy the entertainment provided for them.

Of the dinner itself, it is almost unnecessary to write. It was of the same excellency that has always characterized them, and was enjoyed by about 225 guests, who pronounced everything good from the opening course of clam chowder (and there is no better chowder to be procured anywhere in this wide world), down to the watermelon, ice cream (which, by the way, is a distinct but very welcome innovation at these dinners), coffee and cigars. Towards the close of the feast Mr. Phillips called upon Col. Ballou to act as chairman and toastmaster, which he did with great thoroughness and satisfaction.

The first toast proposed was the "Electrical Press," an honor rather unusual so early in the proceedings, which was gracefully responded to by Mr. R. F. Ross, who spoke feelingly of the esteem and love which was universally felt for the host of the day, and then alluded to the mutuality that should always exist between the electrical manufacturer and the electrical press. Mr. Phillips then read a number of names of departed friends, and a silent toast was drunk to their memory. The toast of telegraphy and telephony was replied to by Mr. Thomas D. Lockwood, who was in a particularly happy vein, and succeeded well in holding the attention of his auditors with an amusing talk on almost anything but the subject of the toast, which he claimed to be every after-dinner speaker's privilege. The speech of the day, however, was undoubtedly made by Col. J. C. Wyman, in response to the toast of "Love and Duty." Col. Wyman is an able orator, and he held the attention of the audience rivetted, with a graceful flow of language on the beauty of love, while he convulsed them with laughter, when he acknowledged that his own loves were so numerous that he could not keep any record of them. The day has gone by he said, for the one love of a life time; one has to love often to fully appreciate what it is. It was, however when he came to Duty that he aroused the audience. Duty, he said, was not nearly so pleasant a theme to deal with, but it had to be recognized, and after some stirring phrases, he wound up by an eloquent appeal for every man to do their duty at present in this great financial crisis that is upon us, by a careful study of the situation, and a determination to preserve the nation's credit at any cost.

Mr. H. B. Cram, in his usual happy way replied to the toast of the "Electric Light," and Capt. Brophy made a few happy remarks on the wonderful progress of the electric railways in response to the toast to that branch of the business. After a rousing vote of thanks to the American Electrical Works and to Mr. Phillips, the party broke up, well satisfied with their day's outing.

The usual photograph was taken just before the dinner. and a little memento of the occasion was distributed during the dinner in the menu card, on which was represented the clam digger at work, and to which was attached a silver model of the familiar hoe, with the words, "Don't be a clam," "Hoe your own row."

Mr. Phillips is to be congratulated upon the selection of the Pomham Club for his annual entertainment, as it would be difficult to concieve of a place more perfect in itself, and occupying a site so that even to do nothing but to "sit and look" becomes a pleasure.

ST. LOUIS MEETING OF THE AMERICAN STREET RAILWAY ASSOCIATION.

THE following papers have already been promised for the St. Louis convention:

"Track and and Track Joints, Construction, Maintenance and Bonding," by M. K. Bowen, superintendent, Chicago City Railway Company, Chicago.

"Trucks," by Jno. N. Akarman, superintendent, Worcester Consolidated Street Railway Company, Worcester, Mass.

"How can the Revenue of Street Railways be Increased, Taking into Consideration the Collection of Fares, Method of Registry, Transfers, Use of Tickets or Cash Fare and Attractions Along the Line of Road," by C. Densmore Wyman, general manager, Milwaukee Street Railway Company, Milwaukee, Wis.

"The Modern Power House," by Richard McCulloch, engineer, Citizens Street Railway Company, St. Louis, Mo.

"Modern Overhead Electric Construction," by B. Willard, superintendent, New Orleans City and Lake Railroad Company, New Orleans, La.

"Selection and Management of Employés," (to be read at Executive Session), by W. F. Kelly, general manager, Columbus Street Railway Company, Columbus, Ohio.

The following applications for space in the exhibit hall have been made: Shickle-Harrison & Howard Iron Company, Commercial Elec. Supply Company, Street Railway Review, National Lead Company, American Electric Heating Corporation, Consolidated Car Fender Company, Missouri Car & Foundry Company, Missouri Malleable Iron Company, General Electric Company, The Johnson Company, Mica Insulator Company, Heine Safety Boiler Company, St. Louis Register Company, Devlin Street Car Brake Company, Sterling Boiler Company, Hartford Woven Wire Mattress Company, Standard Air Brake Company, Leschen-Macomber-Whyte Company, Meaker Manufacturing Company, H. W. Johns Manufacturing Company, The Diamond Truck Company, Paige Iron Works, J. G. Brill Car Company, The Peckham Motor Truck & Wheel Company, E. T. Burrowes Company, Scarritt Furniture Company, The Sargent Company, Wm. Wharton, Jr., & Co., The Creaghead Engineering Company, Theodore Fletcher, Chas. G. Smith, Munson Electric Conduit Company, Partridge Carbon Company, The Graham Equipment Company, Safety Car Heating & Lighting Company, American Car Company, Consolidated Car Heating Company, Central Union Brass Company, Walker Company, The Trojan Button Fastener Company, Given Campbell, The Adams & Westlake Company, R. D. Nuttall Company, Schultz Belting Company, Western Electric Supply Company for the Ohio Brass Company, International Register Company, Gold Street Car Heating Company, Bundy Manufacturing Company and the Brussels Tapestry Company.

Applications from those wanting space should be made at once to Mr. G. W. Baumhoff, Lindell Railway Company, St. Louis, not later than October 1. The applications already received require about 30,000 square feet.

SOCIETE INTERNATIONALE DES ELECTRICIENS.

The above society, whose headquarters have hitherto been established at 44 Rue de Rennes, Paris, will hereafter be located at the Central Electrical Laboratory, 12 and 14, Rue de Stael, where all communications should be addressed.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Railways:

OVERHEAD AND UNDERGROUND ELECTRIC ROADS.—By Mr. Braun. After a short discussion of the advantages and disadvantages of the cable and steam roads for large cities, the author discusses and explains the following electrical roads: City and South London R'way, Waterloo and City R'way, Central London R'way, Budapest and Boston Underground roads, Overhead R'way in Liverpool, Metropolitan West Side Elevated R'way, Chicago.—"Elektrotechn. Zeitschr.," Aug. 6, '96.

WALKER COMPANY'S SERIES-PARALLEL CONTROLLER SYSTEM.—By William Baxter, Jr. The description is accompanied by a diagram of the Walker Controller connections.—"Elec. World.," Aug. 15, '96.

LIGHTING EXPRESS RAILWAY SERVICE.—A peculiarly built railway, the invention of F. B. Behr, said to make a possible speed of 150 miles an hour, is illustrated and described in Lond. "Elec. Rev.," Aug. 7, '96.

COST OF MOTOR MAINTENANCE.—Fifty-two railroad plants have been investigated and a table gives the following data: Number of report; number of cars operated daily; men employed on motors, tracks and electrical equipment; day men; night men; monthly pay roll; inspection and repairs of trucks and motors; cost per car, mile; repair and inspection labor (this item varies from $.0185 to $.0013); average monthly mileage—motor cars; cost repair labor per car per month; cars inspected; cars overhauled.—"Street Railway Rev.," Aug. 15, '96

FREIGHT HAULING BY ELECTRICITY.—By F. W. M'Clement. The Winston-Salem (N. C.) railway has made successful use of its charter for hauling freight.—Prices are given in "Street R'way Rev.," Aug. 15, '96.

ELECTRICAL DEVELOPMENTS IN JAPAN.—Various rules and regulations concerning insulation, pressure, franchise, etc.—Lond. "Engineering," July 31, '96.

Measurements:

STANDARDIZING INSTRUMENTS.—By K. Wilkens. Method for standardizing alternating and polyphase instrumentsof the Allg. Elektr. Ges.—"Elektrot. Zeitschr.,, Aug. 6. '96

MEASUREMENT OF INSULATION RESISTANCE.—By A. O. Benecke. Author gives a theoretical solution for the measurement of insulation and resistance of any continuous current distributing system during operation.—"Electricity.," Aug. 19, '96.

Telephony, Telegraphy, etc:

STOCKHOLM SYSTEM OF LONG DISTANCE TELEPHONY.—By Hemming Johansson. A detailed description of the entire system.—"Elektrot. Zeitschr.," Aug. 6, '96.

HESS-RAVEROT-WEST SYSTEM OF TELEPHONE EXCHANGES.—By J. H. West. Reproduced from "Elektrotechn. Zeitschr." A new system which makes a minimum number of central stations and trunk lines possible.—Lond. "Elec. Rev.," Aug. 7, '96.

Central Stations:

ELECTRICITY WORKS AT HANOVER.—Annual report.—"Elektrot. Zeitschr.," Aug. 6, '96.

Biographical:

A BIOGRAPHICAL HISTORY OF ELECTRICITY.—Portrait of Franklin with a description of some of his experiments.—"Am. Elec.," Aug., '96.

Storage Batteries:

ACCUMULATOR ACCESSORIES.—Various forms of automatic switches are explained in Lond. "Electricity," Aug. 7, '96.

Isolated Plant:

BATTLESHIP "INDIANA."—An illustrated description of some electrical features.—"Elec. World.," Aug. 15, '96.

Dynamos and Motors:

LOAD LOSSES IN DYNAMOS.—By Otto T. Bláthy. Further experiments with energy losses in electric machines due to the armature currents lead author to conclude that it appears to be work spent in reversing the magnetization, of the iron, and consists of Foucault currents and hysteresis.—Lond. "Elec.," Aug. 7, '96.

Electro-Physics:

DISPERSION.—By Oliver Heaviside. A mathematical paper in which the author points to some apparent obscurities and inconsistencies which he found in Helmholtz's theory.—Lond. "Elec.," Aug. 7, '96.

Roentgen Rays:

ROENTGEN RAYS.—By J. J. Thomson, F. R. S. Rede Lecture delivered June 10, '96. A general review of the subject.—"Electricity.," Aug. 19, '96, and subsequent issue.

ROENTGEN RAY APPARATUS OPERATED FROM ALTERNATING CURRENT CIRCUITS.—By E. J. Houston, Ph. D., and A. E. Kennelly, Sc. D. The primary of the induction coil is connected to the alternating current mains through a resistance, the secondary is in series with a condenser and the primary of a Tesla coil and in multiple with a spark gap.—"Am. Elec.," Aug., '96.

Lighting:

RECTIFIERS FOR ARC LIGHTING.—By John Hesketh. Paper read before the Nor. Soc. of Elec. Eng's. The various ecomomies obtained by the use of the rectifier are discussed.—Lond. "Elec.," Aug. 7, '96.

ELECTRIC LIGHTING IN BELFAST.—By Victor A. H. McCowan. Paper read before the Inst. of Mechan. Eng's. Complete description of plant in which gas engines are used, driving dynamos of low tension.—Lond. "Elec.," Aug. 7, '96. "Electricity," Aug. 12, '96.

NEW LAMPS FOR OLD.—A new lamp has just been put on the market which seems to possess various advantages over the old types. The top end of the glass globe is silver plated and is shaped in such a way as to form a reflector.—Lond. "Elec. Rev.," Aug. 7, '96.

FUSES AND MAGNETIC CIRCUIT BREAKERS.—By Wm. Baxter, Jr. Author claims that the only proper place for fuses is in branch circuit.—"Elec. Eng'r.," Aug. 12, '96.

Power Transmission:

ELECTRICITY IN THE UNITED STATES NAVY.—By Frank W. Roller. Author states the requirements and methods pursued in laying out a plant for the various ships.—"Am. Elec.," Aug., '96.

ELECTRICAL DEVELOPMENT IN EUROPE.—The following figures are taken from "L'Industrie Electrique:" There are 560 miles of electric roads in Europe, which is an increase of 125 miles in one year. The number of electric cars has increased from 1,236 to 1,747 in the same time. Germany has 250 miles of electric roads and 857 motor cars. France has 82 miles and 225 motor cars. Great Britain has 65 miles, with 168 cars, and Austria-Hungary has 45 miles, with 157 cars. Next come Switzerland, Italy, Spain and Belgium in the order given, while Russia has but one electric railroad, with six miles of track and 32 motor cars, and Portugal ends the list with 1⅞ miles. Of the 111 European lines 91 are overhead trolleys, of which there were 35 in Germany, 12 in Switzerland, 10 in France and 7 each in England and Italy, and 6 in Austria-Hungary, etc. Of electric railroads with underground current there were but three at the beginning of this year, one each in England, Germany and Hungary. Nine lines are provided with an insulated central track, through which the current is conducted, eight of these railroads being in Great Britain and one in France. The remaining eight lines are provided with accumulators. Of these four are in France and two in Austria, and one each in England and the Netherlands. "Railroad Gazette.," Aug. 14, '96.

TRANSMISSION OF POWER IN MINES.—By Rankin Kennedy. The first of a series of papers in which a comparative study is made of steam and compressed air versus electricity. —Lond. "Elec. Rev.," Aug. 7, '96.

ELECTRICITY AND WATER POWER.—By Mark A. Replogle. Part II of this series deals with power at the falls of the Willamette, Oregon City, and with the power in Ottawa, Ont.—"Elec. Rev.," Aug. 19, '96.

TRANSMISSION AT RHEINFELDEN.—By Erich Rathenau. Abstract of a paper read before the Verband Deutscher Elektrotechn. This plant has been described in detail in "Elektrotechn. Zeitschr.," July 2, '96. "Elec. Eng'r.," Aug. 12, '96.

Electro-Chemistry:

WOLFRAM (Tungstate) ORE.—By R. Helmhacker. A description of where it is found and how it is utilized. Of interest at present on account of the fluoroscope.—"Engineering and Min. Journ.," Aug. 15, '96.

A NEW ELECTROLYTIC GENERATOR FOR OXYGEN AND HYDROGEN.—By W. S. Franklin. Preliminary tests made are recorded from the "Journal of the Franklin Inst." in Lond. "Elec. Eng'r.," Aug. 7, '96.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED AUGUST 18, 1896.

Alarms and Signals:—

SIGNALING APPARATUS. A. P. Smith, Springfield, Mass., 565,933. Filed March 10, 1896.

A system and apparatus by which it may be clearly indicated at certain predetermined points whether a certain section of track is open or not, and to indicate also the direction in which a car has entered upon such section.

WATER ALARM FOR TANKS OR BOILERS. G. V. Sheffield, New York, 566,235. Filed April 10, 1896.

An electric circuit and sounding devices whereby an engineer may be instantly notified when the water in a boiler or tank shall have reached the low water line.

AUTOMATIC SIGNAL LAMP FOR ELECTRIC RAILWAYS. D. O. Beckwith, St. Louis, Mo., 566,283. Filed April 29, 1895.

Signal lamp operated by contact device placed on trolley wire.

Secondary Batteries:—

ELECTRODE FOR ELECTRICAL APPARATUS. W. Schafer and A. Heinemann, Berlin, Germany, 566,231. Filed Oct. 8, 1894.

A process for producing an active material for electrodes for storage batteries, subjecting a lead glycerate to the action of an electric current in presence of an acid containing a permanganate of a metal of the alkalies.

Conductors, Conduits and Insulators;—

INSULATOR SUPPORT. C. P. Toward, Putnam, Conn., 565,944. Filed April 13, 1896.

Details of construction.

INSULATOR FOR ELECTRICAL PURPOSES. A. J. P. Whitaker and F. G. Treharne, Llanishen, England, 566,045. Filed Sept. 3, 1895.

Details of construction.

INSULATION PROTECTION. G. B. Damon, Lowell, Mass., 566,064. Filed July 8, 1896.

A shell to cover the length of wire to be protected.

Dynamos and Motors:—

CONSTRUCTION OF DYNAMO ELECTRIC MACHINES. S. H. Short, Cleveland, O., 565,930. Filed May 4, 1896.

A construction of dynamos wherein access to the field bobbins or to the armature for inspection and repair is facilitated.

ARMATURE WINDING. S. H. Short, Cleveland, O., 565,931. Filed May 4, 1896.

The combination with a core, provided with peripheral seats, of coils bent to form end and side portions, said side portions arranged to be received and said seats and said bends arranged at a fixed distance from the axis of said armature.

POWER GEARING FOR ELECTRIC OR OTHER MOTORS. E. A. Sperry, Cleveland, O., 565,936. Filed June 29, 1894.

The combination with two revolving shafts, of cross-arms attached to said shafts, links connected to said arms and to each other, and comprising a resilient portion, and ball-and-socket joints at the junction of the links.

ELECTRIC GENERATOR OR MOTOR. C. E. F. Ahlm, Cleveland, O., 566,120. Filed May 16, 1896.

A self-contained machine having an attachment by means of which it may be hung upon the wall or ceiling without inverting the machine.

Lamps and Appurtenances:—

ELECTRIC ARC LAMP. H. J. Fisher, London, England, 565,971. Filed Feb. 26, 1896.

Means for economizing the current required for automatically controlling and regulating the carbon-feeding mechanism, for using at will with either continuous or alternating currents.

EXTENSION ELECTRIC LAMP HOLDER. E. C. Kuenneth, G. Schreier and C. Kuenneth, Mt. Olive, Ill., 566,193. Filed Jan. 21, 1896.

An extension holder for holding an electric lamp in different positions.

ELECTRIC INCANDESCENT LAMP. F. M. F. Cazin, Hoboken, N. J., 566,285. Filed July 24, 1893.

The material intended to become incandescent is supported upon one side or face throughout its entire length by solid material having a high point of fusion.

COMBINED GUARD AND STAND FOR INCANDESCENT ELECTRIC LAMP. E. Gahlau, Detroit, Mich., 566,287. Filed Dec. 27, 1895.

Consists of a wire frame.

Miscellaneous:—

APPARATUS FOR PRODUCING OZONE AND LUMINOSITY BY ELECTRICITY. E. Andreoli, London, England, 565,952. Filed April 3, 1895.

For description see page 210.

APPARATUS FOR INDIRECT ELECTROLYSIS. E. Andreoli, London, England, 565,953. Filed April 9, 1895.

The solution to be treated by the indirect electrolysis is contained in or passed through a compartment situated between the anode and cathode compartments.

SYSTEM FOR ELECTROPLATING VESSELS. J. H. George, New York, 565,975. Filed Aug. 21, 1895.

The combination of one or more portable baths, a pump for providing a continuous supply of solution thereto, and an air exhauster for producing suction against said bath.

HAIR CURLING IRON. E. B. Jacobson, Boston, Mass., 565,991. Filed March 12, 1895.

Comprises an electric lamp and bracket, electric wires within the bracket, one of said wires being broken, a spring connection whereby said break is bridged, and a curling iron provided with electric wires which are connected with insulated plates.

LIGHTNING ARRESTER. E. G. P. Oelschlager, Charlottenburg and K. O. F. Schrottke, Berlin, Germany, 566,011. Filed April 17, 1896.

For description see page 210.

ELECTRICAL ADVERTISING DEVICE. J. J. McCormack, Brookline, Mass., 566,087. Filed Jan. 25, 1896.

Method of revolving incandescent lamps within a stationary box.

ELECTRIC DENTAL APPARATUS. H. F. Waite, New York, 566,103. Filed April 16, 1896.

A switch arm provided with a stem carrying a contact device having variable diameters, a spring controlling the normal position of the contact device with relation to the arm, and means permitting a partial rotation of the contact device.

Railway Appliances:—

ELECTRIC CAR LIGHTING. W. J. Morden, deceased, L. H. Morden, executrix, Chicago, Ill., 565,918. Filed Oct. 22, 1895.

A trailing traction motor connected to a vehicle, a dynamo mounted on the frame and having a revolving armature driven from the motor wheels, and means for conveying the current from the dynamo.

ELECTRIC BRAKE. E. A. Sperry, Cleveland, O., 565,937. Filed Feb. 16, 1895.

A circular magnet constructed in parts, means for securing the parts together, a coil, a groove narrower at its face for the coil in one of the parts of said magnet opening into the joint between the parts.

POWER TRANSMITTING GEARING FOR ELECTRIC RAILWAY TRUCKS. E. A. Sperry, Cleveland, O., 565,938. Filed April 13, 1896.

A flexible coupling consisting of two discs, arms on said discs interlocking with each other, and elastic cushions interposed in, but not filling, the space between said arms.

CONTROLLER FOR ELECTRIC RAILWAY CARS. E. A. Sperry, Cleveland, O., 565,939. Filed April 23, 1896.

The combination, with its operating handle, of connections for closing the motor in a local circuit, brake magnets in said circuit, an automatic circuit-breaker in series with the brake magnets, and a shunt circuit, including an automatic circuit-breaker.

UNDERGROUND TROLLEY SYSTEM. J. Hoffman, Schenectady, N. Y., 565,985. Filed Sept. 20, 1895.

The current carried by an underground feeding wire is automatically switched onto a section of the contact rail by means of electro-magnetic circuit-closing devices, which respond to the attracting force of magnets carried by the car.

CONTACT DEVICE FOR CONDUIT ELECTRIC RAILWAYS. M. Stobrawa, Dresden, Germany, 566,035. Filed April 10, 1896.

A contact lever hinged or pivoted to a car adapted to be swung into the conduit, said lever carrying upon the lower end a contact arm and shoe to form electric contact with the conductor.

TROLLEY WHEEL. M. C. Furstenau, Detroit, Mich., 566,161. Filed Feb. 24, 1896.

Means for attaching or detaching the wheel to or from the pole, for lubricating the bearings, and for taking up the wear.

TROLLEY POLE FOR ELECTRIC CARS. S. H. Short, Cleveland, O., 566,237. Filed Feb. 17, 1896.

For description see page —.

TROLLEY FOR ELECTRIC RAILWAY CARS. J. Van Hoogstrate, Chicago, Ill., 566,252. Filed March 31, 1896.

A trolley and pole for electric railway cars, which efficiently take up slack in the controlling rope, prevent sudden upward motions of the pole, permit it to stay on the trolley wire, and sound an alarm when the trolley "jumps" the wire.

Regulations:—

APPARATUS FOR CONTROLLING MOTORS. S. D. Field, Yonkers, N. Y., 566,070. Filed June 18, 1892.

The combination of an electric elevator electromotor and its switch of a fluid switch, and means for actuating the switch motor from the cage, an outlet for a regulated leakage from the switch motor and means for supplying fluid to the switch motor.

METHOD OF CHANGING FREQUENCY OF PERIODIC CURRENTS. L. Gutmann, Chicago, Ill., 566,076. Filed Oct. 22, 1894.

Method of winding.

Telephones:—

TELEPHONE REGISTERING DEVICE. J. Curran, San Francisco, Cal., 565,965. Filed July 1, 1895.

A device, by means of which the subscriber to the telephone or the user of the telephone is enabled to register in his own office each time the telephone is used or a switch is made by the central office.

TELEPHONE SYSTEM. G. F. Durant, W. W. Dean, St. Louis, Mo., and W. A. Childs, New York, 565,968. Filed April 10, 1896.

A telephone trunking system between central offices, whereby a subscriber at one central office may be connected with a subscriber belonging to another central office, and signals given to the operators at the two central offices of the condition of the trunking wires.

TELEPHONE. C. A. E. Ruebel, St. Louis, Mo., 566,022. Filed July 25, 1895.

In a microphone transmitter, a suitable diaphragm connected to one terminal of a primary circuit, and a series of circumferentially grooved rods of suitably conductive material with which said diaphragm makes variable contact, connected with the other terminal thereof.

LEGAL NOTES.

TO REVOKE THE NORTHWEST GENERAL ELECTRIC CHARTER.

An application for quo warranto proceedings was filed on August 11, at St. Paul, Minn., with the attorney general by Selden Bacon, of New York, asking that the charter of the Northwest General Electric Company, of St. Paul, be revoked on the grounds that the concern had withdrawn from the State and had not maintained an office here since 1893. The attorney general took the case under advisement.

DISPUTE OVER A TROLLEY BRIDGE CROSSING.

A temporary injunction has been granted restraining the Long Island Electric Railway from laying rails over the wooden bridge at the Washington Avenue crossing of the Long Island Railroad in Jamaica, L. I. The writ was obtained by the Board of Village Trustees. The Trustees claim that the company agreed to build an iron bridge, and they say that when that bridge is constructed the tracks can be laid, and not before. Previous to the granting of the temporary injunction a force of deputy sheriffs was at the bridge, and they prevented the laying of the tracks. Officers of the road say they will build a new bridge, and that they want to use the present bridge for only thirty days.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

INCANDESCENT LAMP ADJUSTER.

THE INCANDESCENT LAMP ADJUSTER COMPANY, of Abingdon, Ill., have recently put upon the market a very handy device for adjusting the height of incandescent lamps, which are suspended from flexible cords. This device is illustrated in the accompanying engraving and is so simple that a printed

INCANDESCENT LAMP ADJUSTER.

description is hardly necessary to explain the manner in which it is applied. With this adjuster it is apparent that the height of the lamp may be regulated through a long range, and all necessity of putting knots in the flexible cord is avoided. The device is easily attached, durable, ornamental, and will be found of great convenience wherever flexible cords are in use.

THE WESTERN TELEPHONE CONSTRUCTION CO., CHICAGO.

This company reports that in spite of the hard times, orders are pouring in to such an extent that although they are working their factory to its utmost capacity they cannot keep up with them. The 900 capacity switchboard for La Crosse, Wis., has just been shipped. This board embodies the latest and best inventions and designs of the experts connected with this company. Orders from Fort Wayne, Ind., and Richmond, Va., telephone companies for increased capacity have been received almost before their original orders were filled.

Among the most recent contracts secured by this company are Carmi, Ill., 100 drop switchboard and telephones; Olney, Ill., 100 drop switchboard and telephones; Globe Telephone Company, Winchester, Ky., 100 subscriber equipment complete; Sandersville and Tennille, Ga., one 50 subscriber and one 40 subscriber equipment complete; Dunning Institute, the Insane Asylum of Cook County, 30 subscriber installation complete; Washington, Ia., 200 equipment; Fort Kent Telephone Company, Fort Kent, Mo., 50 capacity switchboard and Normal, Ill., 50 drop switchboard and telephones.

DIXON'S GRAPHITOLEO.

Dixon's Graphitoleo is a preparation of a very finely pulverized and very choice graphite and a pure petrolatum warranted not to gum or become rancid.

The merits and wonderful lubricating power of Dixon's flake graphite are well known to almost every engineer and machinist throughout the world. It has been tested by professors at the leading mechanical institutes, and also by the mechanical experts of the great railroad companies throughout the country, and declared to be the finest and best natural lubricant known.

An article combining a perfect lubricant and rust preventive, put up in convenient form, is something desired by every bicyclist, hunter and yachtsman, as well as by every office and household.

To all such and many others Dixon's Graphitoleo will be not only welcome, but indispensable. It is manufactured only by the Jos. Dixon Crucible Co., Jersey City, N. J.

NEW YORK NOTES.

OSCAR F. EHRLE, 652 Hudson street, New York, is busy on experimental work, gear cutting, electrical instruments, the building of arc lamps, etc.

WALSH SONS & CO., Washington street, Newark, have a large and varied line of second-hand electrical supplies and machinery on hand. At present they offer as a special bargain a fine Westinghouse Voltmeter almost as good as a new one.

M. T. DAVIDSON, 133 Liberty street, New York, has about completed the entire pump and condenser outfit for the Baltimore and Catonsville Electric Street Railway; included in this work are four of the Davidson vertical twin air pumps. The Detroit Electric Street Railway Company have also been recently fitted up with several large steam pumps of Mr. Davidson's make.

THE AMERICAN STOKER COMPANY has recently furnished the following stoker equipments: Pennsylvania R. R. Company Shops, Columbus, O., second order; Davis & Egan Machine Tool Company, Cincinnati, O.; Toledo Brewing & Malting Company, Toledo, O.; Michigan Carbon Works, Detroit, Mich., second order; John C. Roth Packing Company, Cincinnati, O., and Cleveland City Water Works, Cleveland, O.

THE PRENTISS CLOCK COMPANY, 49 Dey street, New York, are supplying a system of clocks for the new silver work factory of Messrs. Tiffany & Company at Forrest Hill, N. J. Thirty-three clocks were recently installed by this firm in Public School No. 1, Elizabeth, N. J. The Prentiss clock can be found throughout the country in many of the largest electric factories, stations, power houses, public buildings, etc.

THE HAMMERSCHLAG FIRE.—Although the recent fire in their factory severely handicapped Messrs. Hammerschlag & Company, Liberty street, they are fast getting matters into shape and running order. The dynamo brushes manufactured by them can be found in the pressrooms of the Southbridge Printing Company, Southbridge, Mass.; the St. Louis "Chronicle," St. Louis, Mo.; the "Evening Press" and "Chicago Mail," Chicago, Ill.; in the Vanderbilt Building, New York City; the Mathieson Alkali Works, Saltville, Va., and many other large plants.

THE FERRACUTE MACHINE COMPANY, Bridgeton, N. J., manufacturers of presses and dies, are running their works full-handed and on full time. They are quite busy and have a large number of orders in at the present time. In addition to an order from the Chinese Government for mint machinery they are fitting up three or four large outfits for bicycle factories and two or three for electrical factories. They have just shipped two large presses to Budapest, for an electrical works, and are shipping other foreign orders to India, Germany, England, etc. Mr. Fred. F. Smith, the secretary of the company, sailed on the St. Paul last week for Southampton, and will look up trade in England, France and Germany during his visit abroad.

THE EMPIRE SELF-LIGHTING OIL LAMP COMPANY have recently opened fine showrooms at 766 Broadway for the sale of their lamps. The line is a large and varied one, from plain to the most artistically designed goods and prices to accommodate the modest as well as the most fastidious purchaser. As explained in one of our previous issues, this oil lamp is lighted by electricity generated from dry batteries concealed in base of the lamp. The company is now putting on the market also the Empire Self-Lighting Bicycle Lamp. This ingenious invention enables the bicycle rider to light his lamp without dismounting. By simply pushing a button on the tool bag, in which are concealed the dry batteries connected with the lamp, it is lit at once. The lamp burns kerosine oil, gives a brilliant light and does not jar or blow out. The outfit sells for $6.00 complete. The salesrooms of The Self-Lighting Oil Lamp Company are in charge of Mr. W. H. Seidel, vice-president, and Miss Russell.

PHILADELPHIA NOTES.

F. E. BAILEY & CO., of Philadelphia, have received the franchise and contract for the lighting of Birdsboro, Pa.

THE NANTICOKE, PA., LIGHT COMPANY, through F. E. Bailey & Co., of the Betz Building, Philadelphia, have placed an order for a 600 horse-power Armington & Sims engine.

MACAU & COMPANY have been formed under the laws of Pennsylvania, as manufacturers of insulating materials. The incorporators are: W. H. Macau, R. W. Lysle, J. B. Tompkins,

A. Greene, G. D. Macau, E. Rice and H. M. Suple, of Philadelphia. The capital stock is $50,000.

The company proposes to maintain its patent rights and suit has already been begun in the U. S. Circuit Court against an alleged infringer.

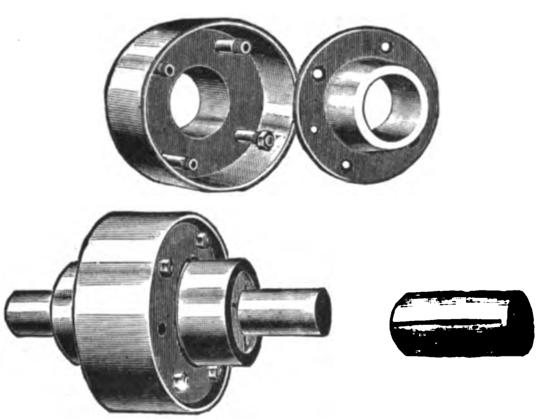
THE A. A. A. S. AT BUFFALO, N. Y.

During the current week, the American Association for the Advancement of Science will hold its annual meeting at Buffalo. The headquarters will be at the Hotel Iroquois. The president-elect is Professor E. D. Cope ,the naturalist. Several papers in electro-physics are promised.

The occasion has been seized for the holding also at Buffalo, during the past week, of the annual meeting of the American Chemical Society; and the week was also availed of for the annual meeting of the Society for the Promotion of Engineering Education.

THE SHAW COMPRESSION SHAFT COUPLING.

Messrs. Patterson, Gottfried & Hunter, Limited, 146 Center street, New York, are advertising the Shaw patent compression shaft coupling for which they are the agents. We herewith give a brief description of the accompanying cuts representing this ingenious invention. The sleeve, Fig. 1, is tapered from the middle down to each end; it has six slots running nearly its entire length, three from one end and three from the other end, in alternation, and holds the ends of the shafts by compression. The outer shell, Fig. 2, has a bore tapering from the middle outward, the taper corresponding with the taper on the sleeve, the diameter of the bore being slightly less than the diameter of the sleeve. It is divided in two, the halves being drawn together with four bolts and nuts, one-half having two pin holes in it. When the halves of the shells are drawn together by tightening the nuts on the bolts the pressure of the tapering bore on the tapering sleeve, which is compressible on account of the slots in it, causes the sleeve to grip the shaft. When in



FIGS. 1, 2 AND 3.—SHAW SHAFT COUPLING.

place, the flanges extend beyond the nuts and the heads of the bolts. When the coupling is to be taken down, after the nuts are taken off of bolts, the halves of the shell can be easily driven apart by drawing a pin through the pin holes. Fig. 3 represents a coupling fitted to a shaft. Among the many advantages gained are, that keys are done away with—key seating is done away with—shafts do not need to be centered, even if there be a slight variation in diameter; couplings do not need to be faced; a lack of alignment becomes evident at once; and a gripping power is obtained that will break the shaft before slippage takes place. There is an equally distributed bearing over the entire surface, covered by the coupling. Clothing and belting are not liable to be caught; shafts of different diameters may be united (with reduction coupling) without any cutting down.

These are among the most essential points in favor of the Shaw patent compression shaft coupling, which is certainly of such excellent merit as to commend the coupling to all having use for it.

Aside from handling the foregoing and many other specialties Messrs. Patterson, Gottfried & Hunter, Limited, carry a full line of machinery, metals, hardware, tools and supplies suitable for the electric as well as other trades. They are located at 146-150 Center street, New York.

NEW MODEL GRENET BATTERY.

Mr. M. R. Rodrigues, 19 Whipple street, Brooklyn, has brought out a new model Grenet battery, which he proposes to retail at the low price of 50 cents. The jar is 2½ inches square by 4½ inches deep. The cover is made in such a way that it serves to hold the carbon plates at the same time, the zinc being suspended at the center. For small motors and light experimental work, where large cells are out of the question, these new cells are useful. One of them will run the Rodrigues "Baby Motor," or the "No. 1 Premier Motor" two or three hours on one charge.

WESTERN NOTES.

THE ELECTRIC APPLIANCE COMPANY have made special arrangements for the manufacture of cross-arms for telephone work; i. e., an arm 2¾ by 3¾, with holes for 1¼ inch pins. On these goods the Appliance Company are prepared to make specially low prices, and prompt shipments.

W. H. McKINLOCK, president of the Metropolitan Electric Company, Chicago, reports a decided improvement in business, especially in the telephone line. The Gordon cell, for which they are Western agents, is rapidly coming into favor with telephone, telegraph and railroad companies. The No. 1 Gordon cell is specially adapted for track circuit work, and the No. 2 for telephone work.

THE ELECTRICAL MAINTENANCE COMPANY of New York have opened a Western office at 1200-1202 Fisher Building, Chicago, where their interests will be taken care of by Mr. W. R. Mason, of the Mason Electric Equipment Company, and Mr. Wm. Sharpe. This young and enterprising company, although established only about two years, has met with great success in its unique style of business, which consists chiefly in keeping up and maintaining electric lighting plants in good working order at a small yearly cost to their owners. This company has amongst its regular customers several concerns and buildings in which there are large isolated plants, and the favor which this method has met with has prompted the company to extend their operations to the West, where there is a large field for this new line of business. Messrs. Mason and Sharpe, who have a thorough knowledge of the electrical trade, are quite sanguine that they will very shortly be able to add considerably to the number of customers which the company have already secured in the East and, although they have not yet got fairly started, they feel greatly encouraged with the favorable reception that has been accorded to the new undertaking by those whom they have seen on the subject.

NEW ENGLAND NOTES.

LEO T. LEVY has been appointed the agent for the Massachusetts Fan Company, manufacturers of the well-known Davidson and Starbuck exhaust fans. His address for the present is 169 West Fifty-seventh street, New York City. He is prepared to fill all orders relating to his specialties.

DODGE WOOD-WORKING POWER TESTS.—We are informed that the tests made by Prof. Dodge on power required by wood-working machinery, recently published in our columns, were collected by the "American Machinist" at heavy expense. We were in no wise aware of this fact, but hasten to give our esteemed contemporary credit and to felicitate it upon its judicious enterprise in setting such an investigation on foot.

ARMINGTON & SIMS ENGINE COMPANY.—The sudden death of Mr. Henry C. Cranston, the assistant treasurer of this company, who had charge of the financial management of the business, placed the company's affairs not long since in a very unsettled condition. Mr. G. C. Sims was elected treasurer about June 1, and since that time he has been working incessantly to get matters straightened out, and to get the business on a solid basis again. At a meeting of the creditors on Aug. 19, a proposition was made which will doubtless allow this concern to go on as before, a result that gives unbounded pleasure in every quarter. It is due to the untiring efforts of Mr. Sims that this decision has been reached, and it is satisfactory to learn that after a period of terrible strain, he has been able to break away for a few days' rest. The company has built up a world-wide reputation, and has doubtless before it a period of success and prosperity equal to any it has known in the past. Its services in the early days of electric lighting will not readily be forgotten.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

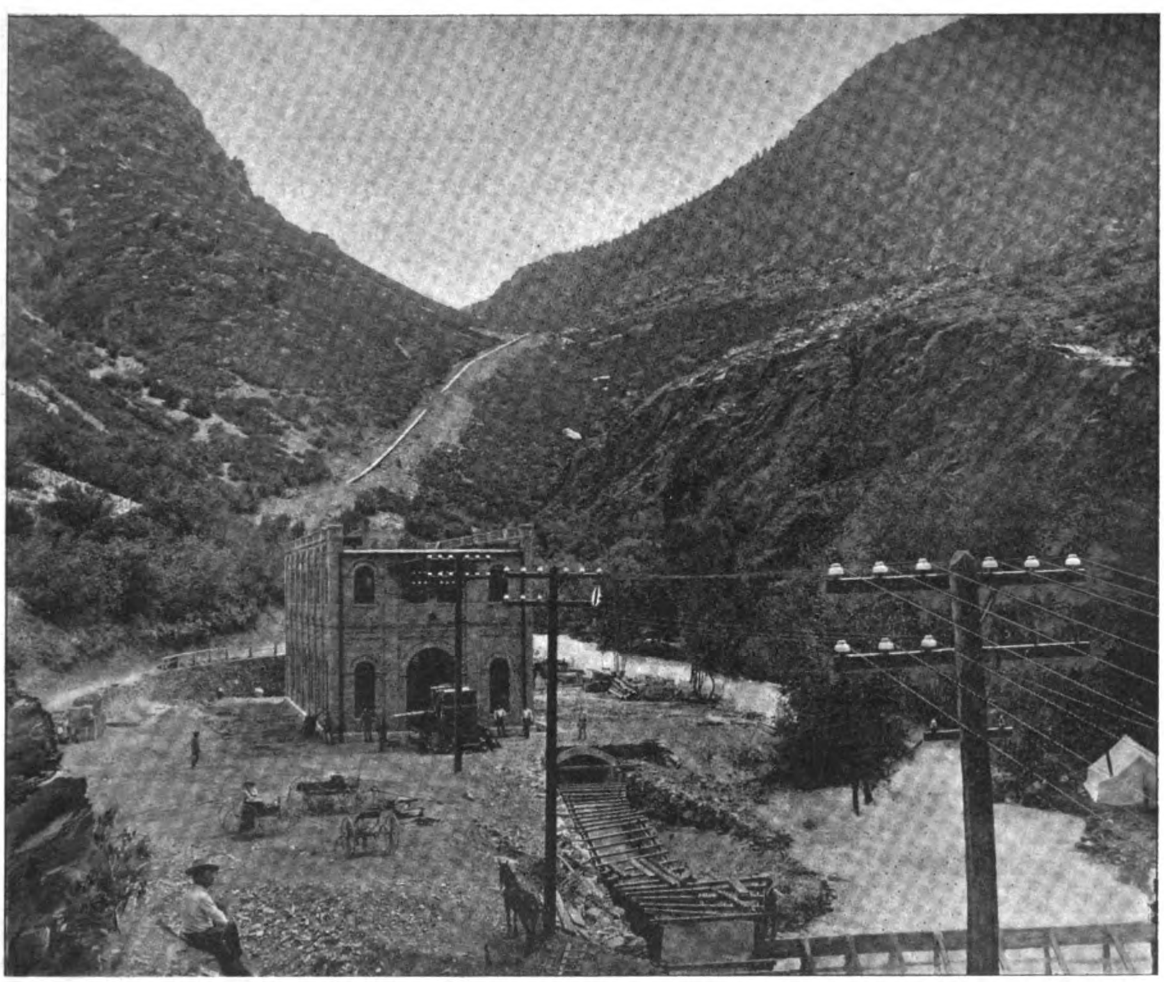
Vol. XXII. SEPTEMBER 2, 1896. No. 435.

Power Transmission.

THE BIG COTTONWOOD POWER TRANSMISSION, UTAH.

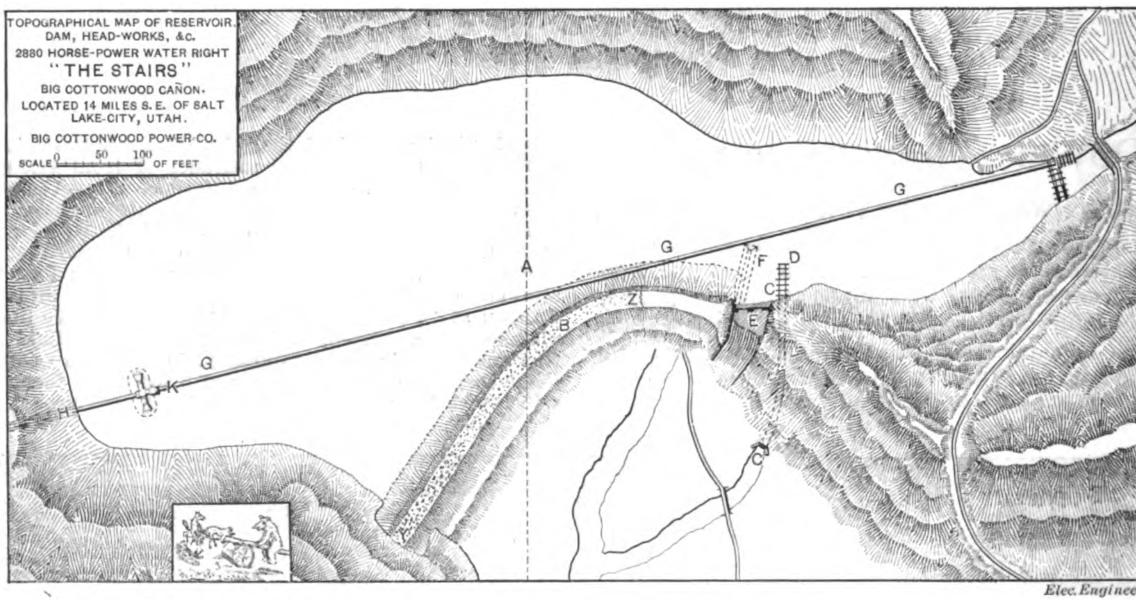
NEARLY a year ago, some interesting details were given in The Electrical Engineer (Sept. 11, 1895), of the work about to be done by the Big Cottonwood Power Company in utilizing electrically the water power of eight of the lakes in the Wahsatch Mountains and distributing it throughout the valley around Salt Lake City. We are now glad to report that the plans as first proposed by Mr. R. M. Jones and his associates have been carried out and that the plant is to-day in successful operation. A few notes and illustrations of this plant will, therefore, be in order. Events have moved quickly since we first brought the scheme to notice, and last Fourth of July witnessed the entrance of the State of Utah into the Union, when Salt Lake City, with its population of between fifty and sixty thousand celebrated the event with appropriate rejoicing. One feature was the hanging of a huge American flag as a canopy in the big tabernacle, its size being 125 feet by 75, and the forty-fifth star in it, typical of Utah, was a dazzling incandescent lamp.

It should be premised that the lakes emptying into the Big Cottonwood Canyon, lie at altitudes of from 11,000 to 13,000 feet above the sea, so that the difference of level is considerable even when the water is made to give up its energy at a point some thirteen miles southeast of Salt Lake City. As a matter of fact, the company has available over 1,000 feet of fall, in various spots, but at present is using less than 400. The power station to which we now direct attention is situated in the Canyon at "The Stairs," about 14 miles by pole line from the distributing or "step-down" station of the Salt Lake and Ogden Gas and Electric Light Company, in Salt Lake City. At this point there is a minimum flow of 3,400 cubic feet per minute, which, working under 380 feet head, produces 2,447 horse-power any and every hour in the year. During nine months of each year, it will give nearly 4,000 horse-power. The storage reservoir at the head of "The Stairs," has an available capacity of 24 hours' continuous flow of the stream, making all of the water available by using an excess during maximum loads and allowing the reservoir to accumulate during minimum loads. 58,800 horse-power hours per day of 24 hours, is looked for from this source, of which 68 per cent. can be delivered in Salt Lake City in contract form, making 40,000 horse-power hours net daily. The 68 per cent. efficiency is derived from: Pelton water wheels 80 per cent., General Electric Company gener-



Power House and Pipe Line, Big Cottonwood Transmission.

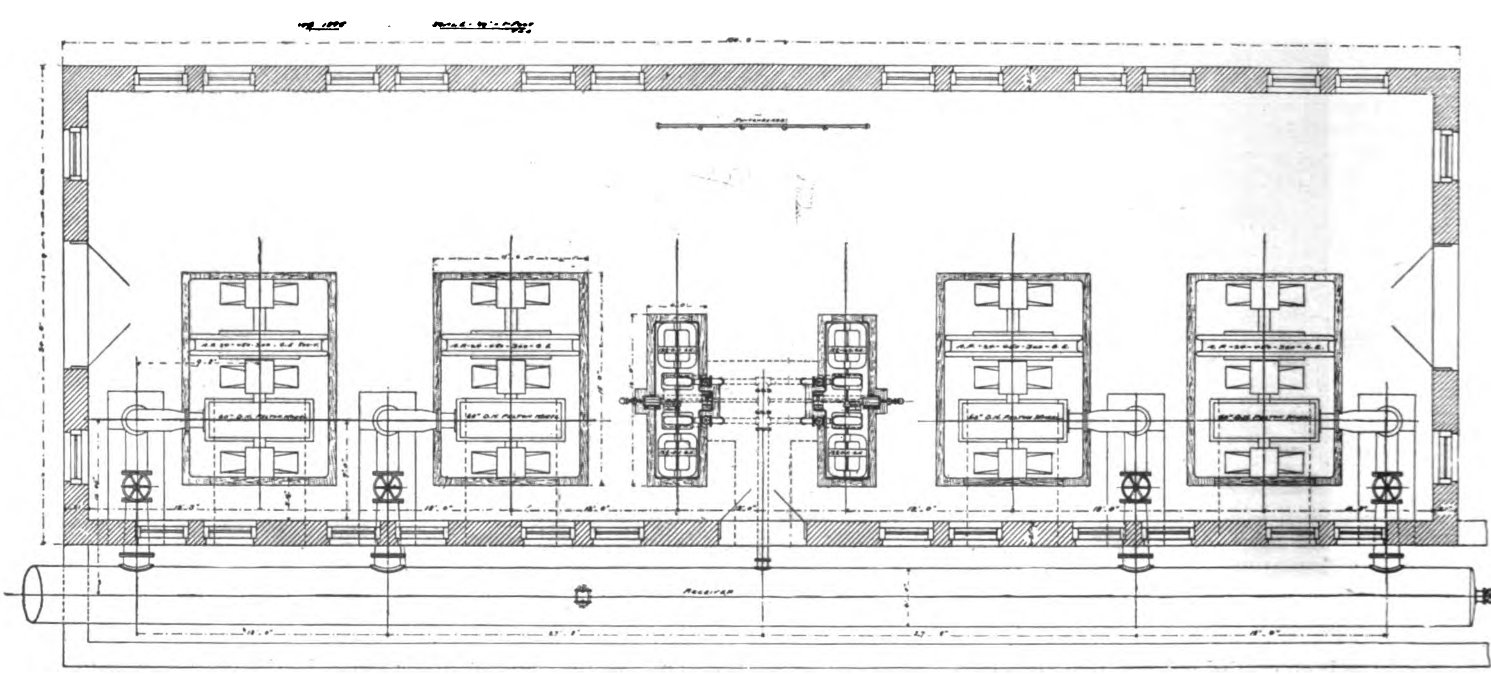
ators, 94 per cent., G. E. transformers (raising) 97½ per cent., line transmission 95 per cent., G. E. transformers (reducing) 97⅞ per cent., or a total of 68½ per cent. The map of the reservoir shows a pipe line extending from the head gates, submerged in the bottom of the reservoir, to a penstock or receiver wood housing with "grizzlies" located just below the bridge. tion and economical use of water are secured. Each nozzle at 370 feet effective head, produces 310 mechanical horse-power, and drives the wheel at 300 revolutions per minute, its economical speed. The water wheel is keyed directly on the armature shaft, in lieu of a pulley. In addition to the generators named, four 12½ kilowatt exciters are connected together



TOPOGRAPHICAL MAP OF BIG COTTONWOOD RESERVOIR: B Z, DAM; E, OVERFLOW GATE; G G G, SUBMERGED PIPE LINE; K, "GRIZZLIES."

This pipe, of steel-banded redwood, is anchored to the bottom by rock piles, and is to be used in the event of its being necessary to drain the reservoir, without interfering with the running of the station. This is accomplished by closing the head-gate valves, and the station can thus be supplied from the natural flow of the stream, during such time as the reservoir might be empty.

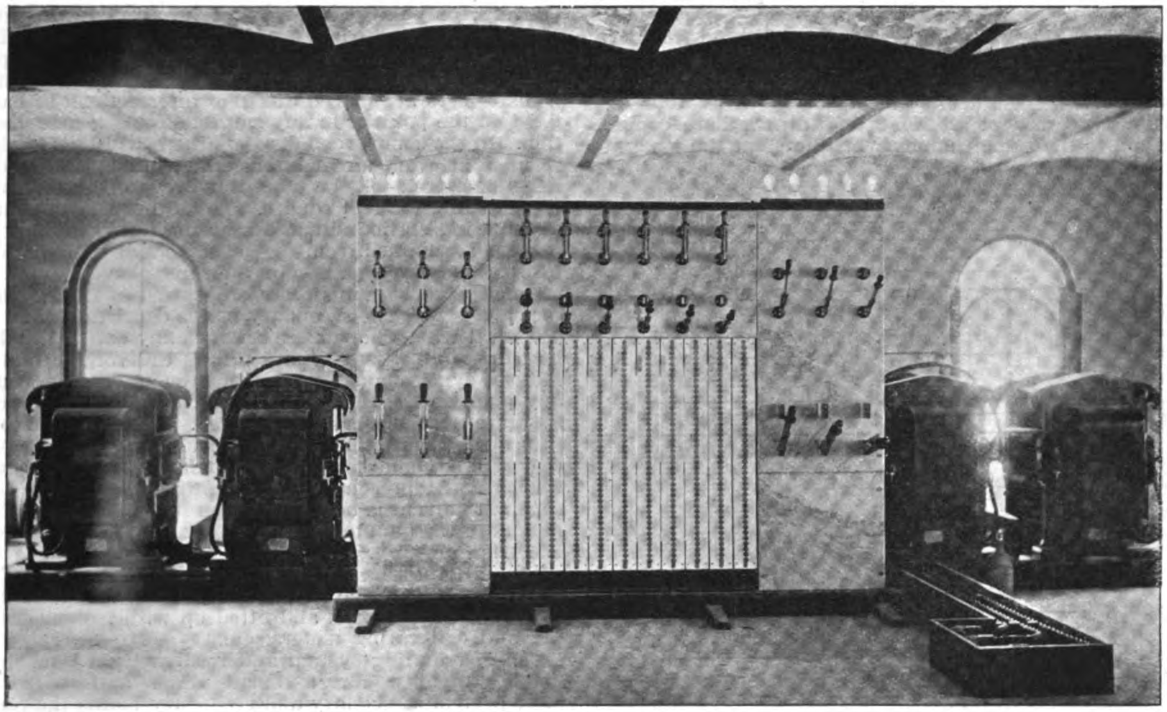
The outside dimensions of the generating station are 34 feet in pairs by couplings, each set being driven by a 14-inch Pelton wheel, with cast housings. Each set consists of two generators and two wheels, built up on a cast-iron base-plate, making a rigid and direct connection. This application provides exciting energy in two units, and at all times either one or two exciters are in reserve. The exciters are to be run in multiple, and all connected to one common "bus line" on the switchboard. The three-phase generators are also operated in



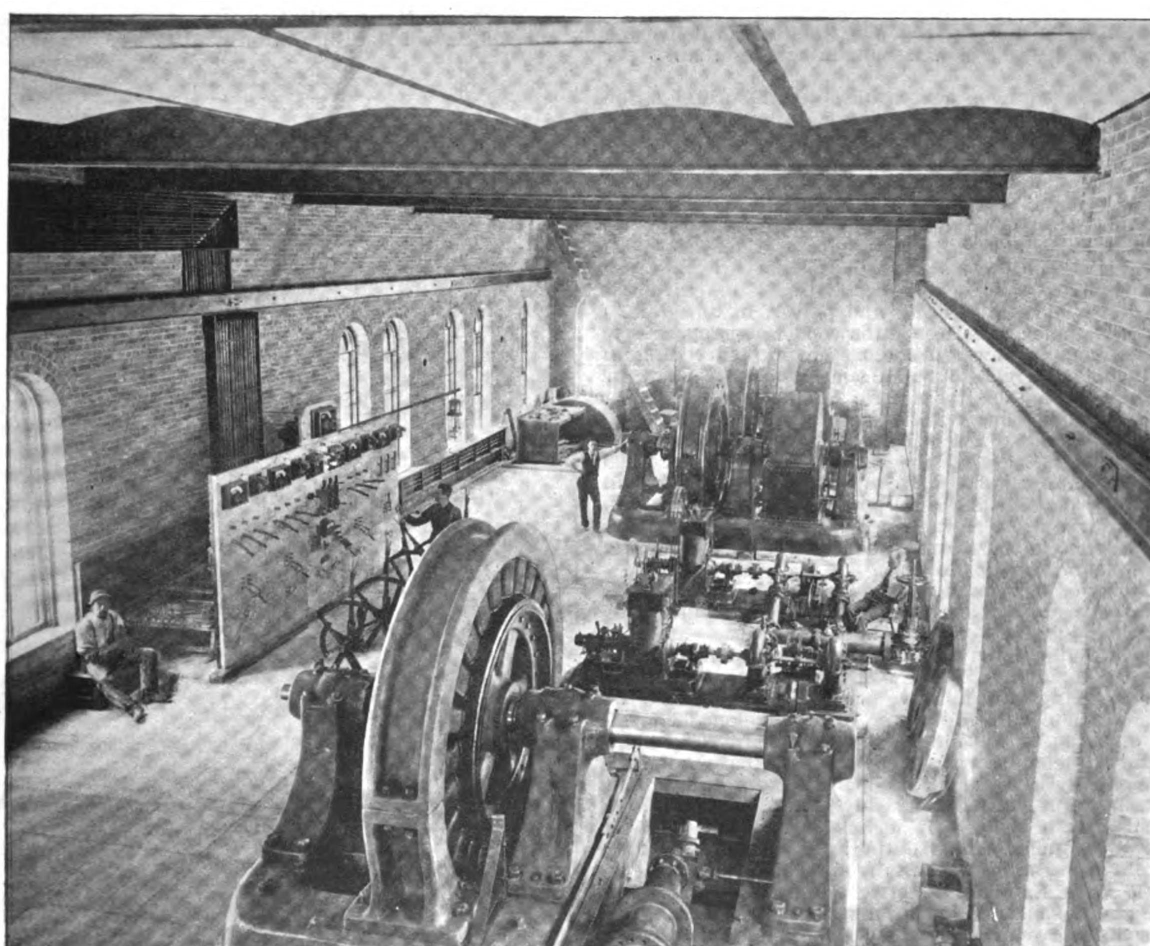
PLAN OF BIG COTTONWOOD POWER HOUSE.

by 100 feet. The generating plant consists of four 450 kilowatt three-phase 60-cycle General Electric generators, separately excited, non-compounded, set with armatures parallel to each other, facing up in true line in the building as shown in plan and in elevation on page 220. Each generator is driven directly by one heavy special Pelton wheel, 60 inches in diameter, provided with two nozzles of 3¼ in. diameter. The nozzles are provided with hood valves for shutting off, so that both good regula- parallel. There are six raising transformers, 265 kilowatts each, of General Electric make.

The station switchboard consists of 5 panels with complete controlling and indicating apparatus, and there is a 3-panel raising transformer switchboard. At the step down or distributing station, there is a 3-panel reducing switchboard, with proper regulating apparatus. The apparatus is protected by ball lighting arresters, and the transformers are cooled by two



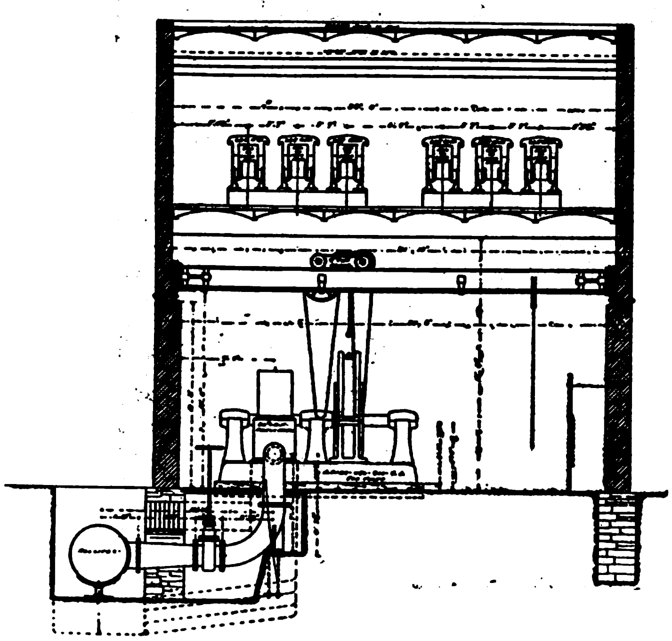
TRANSFORMER ROOM, BIG COTTONWOOD TRANSMISSION, SALT LAKE, UTAH.



GENERATING ROOM, BIG COTTONWOOD POWER TRANSMISSION PLANT.

Sturtevant exhaust fans driven by two 5 horse-power induction motors.

The 915 poles for the line construction were selected from live growth of Sand Point (Idaho) cedar. The smallest are 40 feet long, and 8 inches in diameter at the top. They are placed 100 feet apart. The line conductors consist of 12 wires, four circuits of three wires each; all No. 2, soft-drawn bare copper, and connected to the same common "bus line," at the generating and at the distributing station. The line loss, in delivering 1,520 kilowatts at 10,000 volts, is something less than 5 per cent.



Transverse Section of Big Cottonwood Power House.

The transmission line from generating to distributing station is 14 miles by pole line. The distributing station is owned by the Salt Lake and Ogden Gas and Electric Light Co., who rent it to the Big Cottonwood Power Company at a nominal rent. It contains, for "step-down" transformation, nine 160 kilowatt air blast transformers, from the secondary side of which the Electric Light Company buys the current wholesale by meter. This arrangement is a most convenient one for both companies. The actual terms of the contract are that the electric light company is to be supplied with all the current it can dispose of for electric lighting and power, in units of 10 horse-power, and under, the Big Cottonwood Company reserving the right to supply power to motors in units exceeding 10 horse-power, and the right to reach such wholesale users of power by wires erected on the electric light company's poles, throughout all the districts within the city limits. The contract dates from January 1, 1896, and runs for a term of five years. Its conditions are that the current is bought at 2,000 volts, three-phase, at a stipulated price per k.w. hour, which will be used to supply electric light and power for any purpose up to 10 horse-power, and for elevator service up to any limit desired by the lessees. 2,000,000 units annually is the minimum limit of the consumption of current.

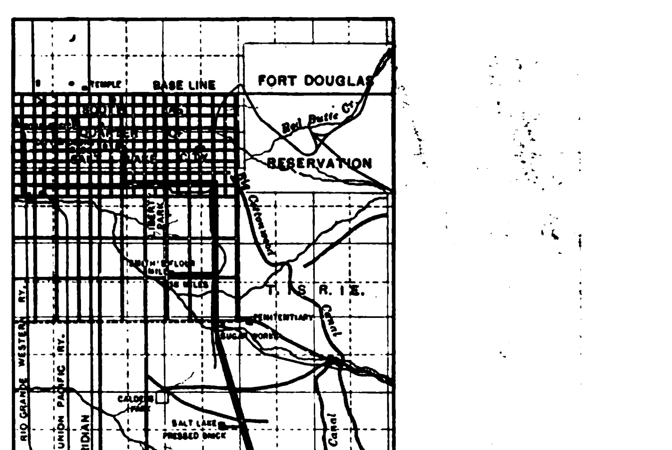
The final cost of the complete development is estimated at $300,000. An estimate of $300,000 for the original outlay for "The Stairs" would give for construction expenses—at 2,258 horse-power—$132.72 per net horse-power delivered in the city ready for use. The future of the company seems to be well assured. The company's affairs have been so well administered that much more than half the power to be developed has already been disposed of absolutely, and the guaranteed total revenue from completed contracts is over $100,000 annually. Although the company is confining its operations for the present to "The Stairs" supply, it has, as already stated, other valuable water rights partly developed by means of which it could at any time largely supplement its output.

In order to secure the best results from the three-phase current the Salt Lake Gas and Electric Company, originally a single-phase plant, has modified its distribution system. The new system consists of a network of primary mains with a network of low tension secondaries, wherever the houses are in close proximity to each other. The primary mains are at 2,000 volts. They run along every street east and west and have equalizing cross mains on several streets running north and south. There will eventually be ten feeding points, though at first only six are required. Secondary mains are used almost entirely; only when the houses are very scattered separate house transformers are used. In the commercial district, the secondary and primary mains will eventually be put underground, though this is not immediately contemplated. The transformers are placed at street intersections in banks either fixed on the poles or in any suitable location near the intersection. In the commercial districts there will be a bank of transformers at every street intersection; but in the incidental districts one bank will be placed at every other intersection, the blocks being 792 feet square. The feeders are brought from the distributing station situated near the center of the town. The current is supplied from the generators of the Big Cottonwood Power Company's station on the three-phase system. The feeders and primary mains therefore consist of three wires each of the same size. The secondary mains consist of three wires and a neutral wire. The voltage between any one of the three wires and the neutral is 115, and this is the voltage of the lamps. Motors, synchronous or non-synchronous, can be connected at any point to the secondary mains, or, when the motor is large, separate transformers will be used. It is intended to eventually use the alternating current for all arc lamps, in which case they will be connected to the secondary mains with small transformers. At present the arc lighting of the city is done by constant current generators driven by three-phase synchronous motors in the old steam power house of the Salt Lake Gas and Electric Company.

The distributing station is a substantial fireproof building, with a room for the 10,000 volt step-down transformers, the 2,000 volt switchboard and fitted up with instruments for testing and calibrating meters, etc.

The distributing system and feeders have been designed of ample capacity for a small drop, and with the complete system of primary and secondary mains the regulation is perfect. By cutting out transformers during times of light load, it is expected to obtain a very high distribution efficiency. The Stairs plant of the company was completed in time to deliver current in Salt Lake City by June 1. A few days after, the greatest flood seen in thirty-five years rushed through the canyon, thus testing in the severest manner the strength of the construction. Not a dollar's worth of damage was done.

The officers of the Big Cottonwood Power Company are John

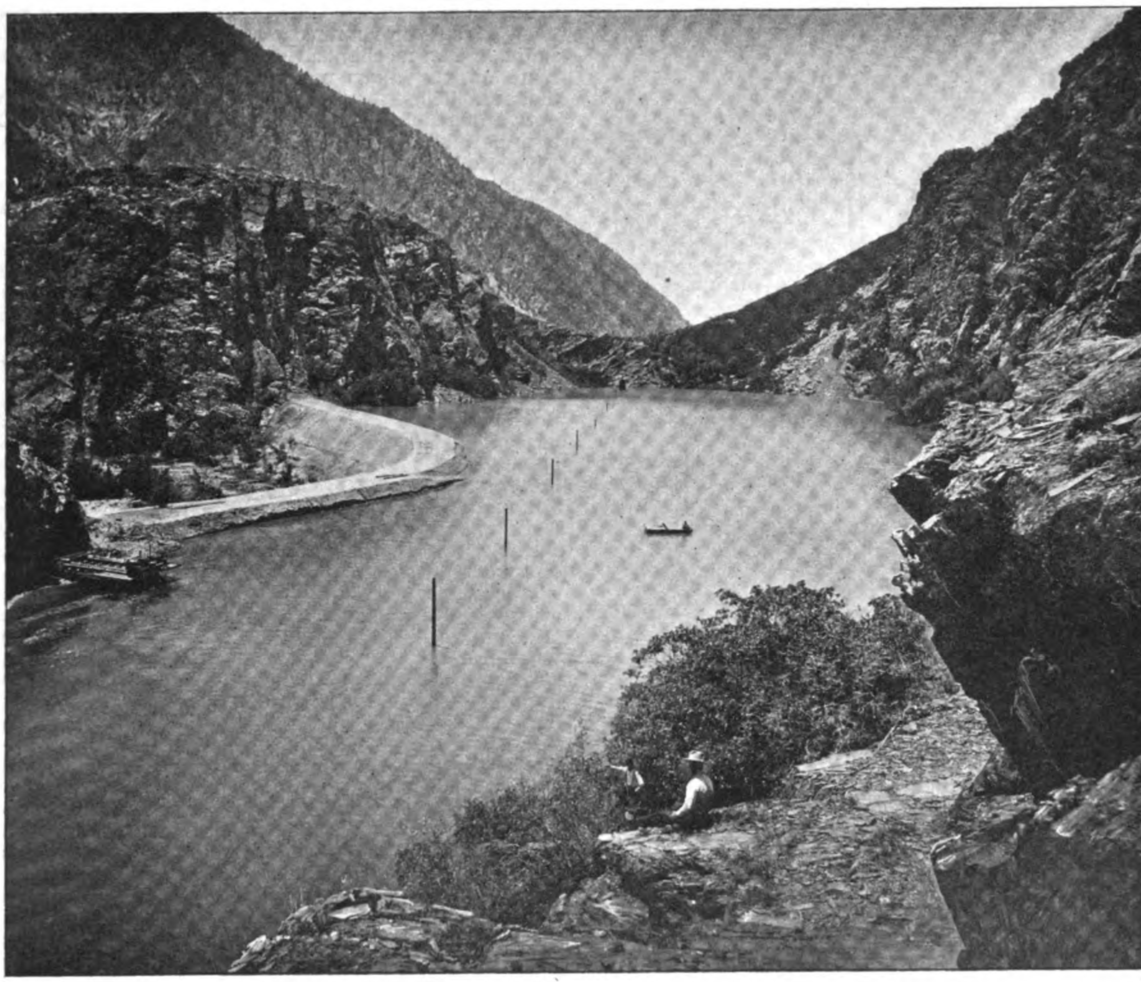


Map Showing Big Cottonwood Power Line.

W. Donnellan, president (cashier Commercial National Bank, Salt Lake); W. H. Rowe, vice-president (president Bear River

Canal Company); Geo. M. Cannon, secretary (cashier, Zion's Savings Bank, Salt Lake); G. M. Downey, treasurer (president Commercial National Bank, Salt Lake); R. M. Jones, engineer and manager, Salt Lake; Jos. W. Summerhays, director, Salt Lake. The Old Colony Trust Company, of Boston, is its trustee.

At the present time, The Stairs plant, at ruling rates for current, can earn $200,000 per annum, and it would seem that a ready market exists for light and power now, some 27 concerns using over 2,000 horse-power. Many of these establishments work every day the entire year, and their steam power has cost them from $90 to $145 per horse-power per year.



DAM AND RESERVOIR, BIG COTTONWOOD ELECTRIC POWER TRANSMISSION.

TONAWANDA FRANCHISE FOR THE NIAGARA FALLS POWER CO.

The Tonawanda Common Council has granted a franchise to the Niagara Falls Power Company. It gives them permission to construct, maintain, and operate conductors for the Niagara Falls electric power, subject to the inspection and approval of the trustees or the engineers appointed by them. The franchise contains the usual stipulations for the welfare of the village. The company agrees upon the application for 500 electrical horse-power to distribute it within the village limits at a price not to exceed that paid by North Tonawanda or Buffalo and further agrees to have power transmitted within a year from date or forfeit the franchise. The route of the transmission line is in general a strip thirty feet wide.

ELECTRICITY FOR STOCKTON, CAL. AND THE MOTHER LODE.

The California Exploration Company, of which Prince Poniatowski is president and Will H. Crocker treasurer, has completed a contract with the Blue Lakes Water Company, by which the former secures from the latter 5,000 horse-power, to be increased as may be required. The immediate field to be exploited is Stockton and the mines on the mother lode. The company expects to furnish power to operate every street car line, flour mill and factory in San Joaquin district. The Exploring Company, itself, is going into mining. It has bonded three miles of ground on the mother lode, extending in a southeasterly direction from the Mokelumne River, through Calaveras County. Sinking operations are to be commenced at once. The plant is to be completed for at least 1,500 horse-power within nine months. Percy Tarbutt and Edmund Davis of London, are largely interested in the scheme. Jesse W. Lilienthal is counsel for the Blue Lakes Company and W. S. Goodfellow and Morrison & Foerster for the Exploration Company. Richard A. Parker of Boston and John Hays Hammond will have charge of the operations.

ELECTRICITY AT VANDERGRIFT, PA.

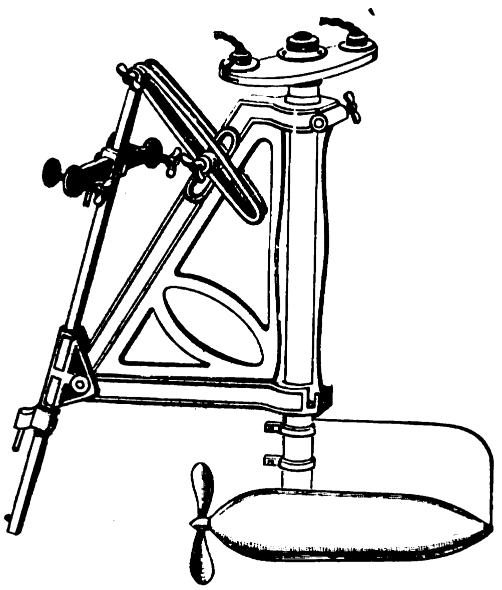
Electricity performs a very large part in the new steel plant of the Apollo Iron and Steel Works, at Vandergrift, Pa. The electrical power plant consists of three 400 horse-power side crank medium speed engines of the latest type recently brought out by the Ball Engine Company, Erie Pa., which are direct connected to Westinghouse generators. These generators deliver current to 36 different power motors operating various machinery, including the electrical centrifugal pumps furnishing the water supply of the steel works, which comes from the river, 1,200 feet away.

MR. JOHN FINLAY, of Holywood, Ireland, an English electrical engineer, is inspcting the mining camps of Colorado, and is said to be collecting data as to the use of electrical power in getting out low grade or deep ore by means of electrical power. The work done in America in the department of electric mining is attracting the attention of mining engineers throughout the world.

Electric Transportation.

THE NEW & MAYNE ELECTRIC BOAT.

A REPORT from Brighton, England, states that the New & Mayne electric motor rudder boat has made a trial trip to sea with very good results. The boat is 30 feet in length, with a

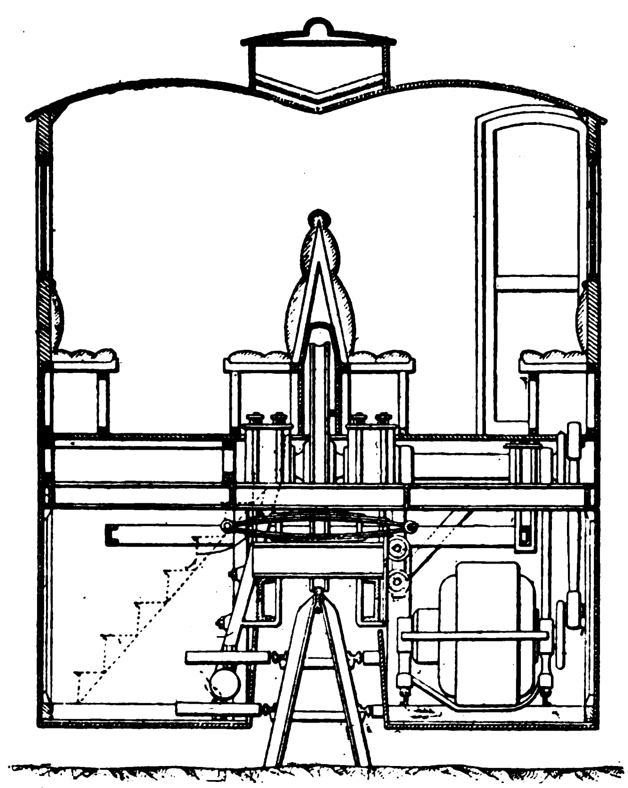


New-Mayne Rudder Motor.

beam of 6 feet, and is fitted with the electric motor close to the keel. The motor is driven by accumulator cells, which fit neatly into the waist of the boat.

BEHR'S HIGH-SPEED RAILWAY.

CONSIDERABLE attention is being given by the English technical press to a system of lightning express trains invented by Mr. F. B. Behr. The method proposed provides for



The Behr Single Rail High Speed Road.

a speed of from 100 to 150 miles per hour, and it has also been before the public for several years, but without meeting with any practical application heretofore. It is now about to be put on trial at Brussels, where a line about three and one-eighths miles long and oval in form will comprise one of the attractions of the 1897 exhibition to be held in that city.

A cross section of the car and general arrangement of the track is shown in the illustration. It will be seen that four guide rails are necessary, and the top rail which bears the weight of the train is supported at from 40 to 60 inches above the ground. Each carriage is supplied with its own motive power, so that little strain is put upon the couplings.

On the Brussels line the guarantee of 95 miles per hour has been given for running over the curves of only 550 yards radius. The mechanical stress when running at 95 miles per hour on the above-mentioned curves reaches an alarming amount. Thus, the centrifugal force tending to throw the cars outwards reaches the respectable figure of 20 tons. This stress is to be taken by the guide wheels on the inside.

The following are the improvements claimed by Mr. Behr, the mention of which may be of interest to our readers.

Firstly, the carriages have a considerable total length to enable them to pass readily round sharp curves. This is effected by constructing the carriage in two or more separate parts, joined together by a pivot or universal joint. A flexible enclosure covers a platform between the two adjoining parts, from which access is gained to each part. Each half is supported on the rail by two driving wheels, placed as close as practicable together so as to obtain a comparatively small fixed wheel base.

Secondly, the center of gravity of the carriage is kept below the level of the line of rail, even when the entire floor for the passengers is raised above the line of rail. This is effected by placing the motors that propel the carriage at the bottoms of the two lower parts of the vehicle, and so arranging them that although they partake of the vertical motion of the carriage body upon its springs, the distance between their driving shafts and the driving wheel axles, by which they are connected by driving gear, shall always remain constant.

Thirdly, the carriage body, though having a vertical motion on springs, is so guided that it cannot move laterally; this is effected by constructing the framing carrying the driving wheels and bogie entirely separate from the framing of the carriage body and guiding the former in a vertical position by means of guide wheels running on lateral guide rails on the line rail supports. The framing of the carriage body, which rests upon the wheel framing with springs, is prevented from lateral motion by providing the wheel frame with vertical rails, against which bear rollers attached to the carriage body.

Fourthly, two guide rails are provided, situated one above the other, against which bear two corresponding guide wheels on each side of the wheel frame of the carriage. In order to ensure that both wheels shall always be kept automatically in contact with both the guide rails so as to distribute the lateral strains on the carriage uniformly over both, the guide wheels are mounted upon vertical arms projecting upward and downward from a horizontal axis that can turn in bearing in brackets on the wheel frame.

TROLLEY CAR COASTING ON CATOCTIN.

A car with a capacity of 48 passengers, but carrying 110, had some lively experiences on the Catoctin Mountain section of the Fredericksburg and Braddock Heights trolley road on August 23. Soon after leaving the mountain crest, the motorman lost control of his car, the brakes would not work, and the car went coasting. It managed to cross a trestle 400 feet long and 45 feet high, but soon struck a curve and ran about 100 yards on the crossties. It then fell over an embankment seven feet high and landed on its side. Marvelous to tell, nobody was killed, but nearly forty people were injured.

NEW ENGLAND RAILWAY CO. SEEKS TO RESTRAIN TROLLEY COMPETITION.

Counsel for the New England Railway Company have filed in the Superior Court at Hartford, Conn., an amended complaint against the Central Railway and Electric Company, of New Britain, the Newington Tramway Company, and the Hartford Street Railway Company, in its suit to restrain those companies from building a trolley road between this city and New Britain. The original writ was filed in June. In the new complaint the New England Road alleges that on March 21, 1896, the Hartford Street Railway Company and the Central Railway and Electric Company, of New Britain, entered into a conspiracy to defraud the New England Road of its just rights by building a trolley road to carry freight and passengers between New Britain and this city. The complaint further alleges that in furtherance of this conspiracy 121 shares of the Newington Tramway Company were illegally transferred to four directors of the Hartford Street Railway Company. All this is denied in the reply.

TWO HUNDRED HORSE-POWER BALDWIN-WESTINGHOUSE ELECTRIC MINE LOCOMOTIVE.

THE Baldwin Locomotive Works have recently delivered to the Crozer Coal and Coke Co., at Elkhorn, W. Va., the largest electric mine locomotive ever built. The common electric mine locomotive has about 50 horse-power capacity and seldom exceeds 80. In this case the work was so heavy that a special steam locomotive was designed to be substituted for an inadequate electric locomotive formerly used in the mine. The Baldwin company offer the same guarantees for both steam

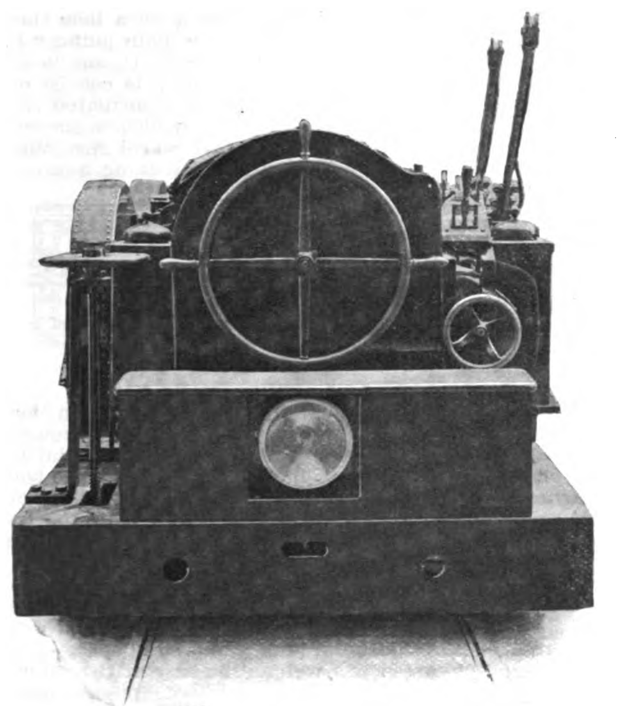


FIG. 2.—END-VIEW, SIX WHEEL MINE LOCOMOTIVE.

and electric locomotives and of the two kinds the Crozer Coal and Coke Company finally took the electric.

The requirements were a six-wheel connected locomotive, weighing about 43,000 lbs., and guaranteed to haul 40 cars up a grade of 2 per cent. at the rate of six miles an hour, and developing a drawbar pull of 10,000 lbs. using sand. Radius of sharpest curve, 60 feet; weight of rails, 40 lbs. per yard; gauge 44 inches. Locomotive to pass through an opening 6 feet 11 inches high above rail, 10 feet wide at bottom, and 8 feet wide at top.

The general dimensions and specifications are as follows:

Diameter of driving wheel	33 in.
Total wheel base	6 ft.
Extreme width, not over	6 ft. 2 in.
Extreme length over all, about	18 ft.
Weight in working order	44,000 lbs.
Extreme height	5 ft. 6 in.

Two 100 horse-power consequent pole motors, with steel fields wound for 500 volts. Gears of cast steel, acurately cut. Gear cases of sheet iron, oil tight at bottom, and completely surrounding gears. Top field with hinged lid for reaching armatures and commutators. Rings in top fields for hoisting.

Driving axles of best hammered iron with journals 5½ inches in diameter by 6½ inches long. Axles turned all over.

Driving wheels of cast-iron, spoke type, keyed to axles. Tires of open-hearth steel, 5 inches wide and 2½ inches thick.

Parallel rods of hammered iron with brass bushings and oil cups.

Crank pins of steel accurately turned and pressed into wheels with hydraulic pressure.

Frames of wrought iron, with wrought-iron jaws. Jaws protected from wear of boxes by cast-iron shoes.

Foot plates of cast-iron bolted to frames.

This locomotive has two sand boxes, front and back, two electric headlights with parabolic reflectors and brakes operated from both ends and of sufficient power to slip drivers when necessary, one electric controller operated from both ends and suitable for two 100 horse-power motors. All electrical apparatus, including rheostats, controller poles and switches, are provided to operate the locomotive. The workmanship is equal in all respects to that given to steam locomotives. All similar parts are interchangeable and all turned bolts to have a driving taper fit.

The gauge of the track being but three feet, it was impossible to get the 100 horse-power motor's dome between the wheel flanges. This fact, together with the slow speed at which the locomotive was required to develop its rated power, compelled the use of intermediate gearing.

This locomotive was built to the specifications of Mr. F. W. Darlington, who was the consulting engineer for the Crozer Coal and Coke Company. Mr. Darlington has made a specialty of these problems and it will be remembered, was engaged on the experimental work of the Pennsylvania Railroad Company on their Mount Holly-Burlington branch.

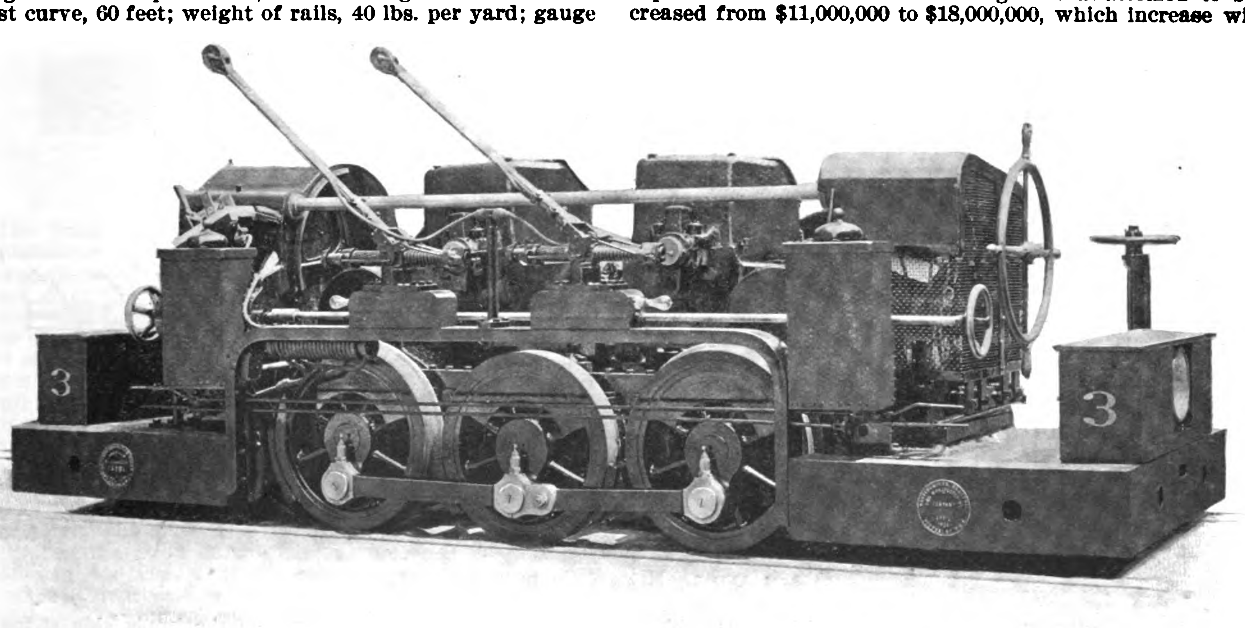

FIG. 1.—SIX-WHEEL MINE LOCOMOTIVE, 200 H. P., FOR NARROW GAUGE.

CONSOLIDATION IN CINCINNATI AND SOME RESULTS.

On July 29 the Cincinnati Street Railway Company absorbed the Mount Adams and Eden Park Inclined Railroad and the Mount Auburn Cable Railroad, and now controls and operates the various lines formerly owned by those companies. The capital stock at the same meeting was authorized to be increased from $11,000,000 to $18,000,000, which increase will be used from time to time as it is required. The elective officers of the Cincinnati Street Railway Company are as follows: John Kilgour, president and general manager; Jas. A. Collins, sec-

retary and assistant general manager; Robert A. Dunlap, treasurer; John Harris, superintendent.

The consolidation has led to a new contract between the city and the railroad, and the terms have just been accepted by President Kilgour. They are very interesting and noteworthy.

The City Board of Administration has eliminated the trouble in existence in regard to transfers. As it is now the passenger must demand the transfer upon payment of fare. Under the consolidation resolution he has three minutes in which to secure the transfer. That is, any time within three minutes after paying his fare he is entitled to a transfer. The board, in case any one has been overlooked, may within six months make additional demands in regard to transfers or make such changes as they see fit.

The Street Railway Company must within one year remove the tracks from the sidewalks on Clifton avenue and relay them in the center of the avenue and widen the roadway and set new curbs along the sidewalks and expend $7,000 in improvements on the avenue. The railroad company must pay $7,000 towards improvement of the Liberty street viaduct.

Although the rate of fare is 5 cents, the fare for children under 10 has been made 3 cents.

The inclines must sell tickets to ride on the trucks ten for 25 cents, or two and one-half cents per trip. This means much to those who simply ride to the hill top, working not far away, but down the hill.

One of the greatest advantages secured is the all-night service, which will give the suburbs continuous connection with the downtown portion of the city.

The heating of cars in the winter and the running of summer cars is provided for.

A point secured is that the extension of the franchise does not give the street railroad the privilege of a 5-cent fare for fifty years, but really only for fifteen years, when the B. of A. or the regular constituted body of the city, may consider again the question of fares.

The consolidation terms also provide for illuminated signs, and the municipal inspection of all cars. The Board of Administration can adjudge a car unfit for service and recommend such improvements on it as they think best. The new terms go into effect the middle of September.

THE MUNSON ELECTRIC CONDUIT RAILWAY.

THE Munson Electric Conduit Company have established offices at the Rookery, Chicago, to promote a new electric conduit system for railway car propulsion, and have equippeu a practical working model in their offices, consisting of 70 feet of track and an electric motor car which is exactly one-quarter the dimensions of a regular 28-foot car. The track, which is partly level, also contains a grade and a sharp curve of seven-foot radius.

The level portion of the track is submerged in water, and the car runs, stops and starts on the level (while the electrical contacts and collector are under water), without any hitch, flickering of the lights in the car or sparking at the motors. The system shows a high insulation test, and its promoters believe that it obviates all the troubles common to the overhead trolley and underground conduit systems. The seventy-foot model shows the details of the construction of the track which is adopted to either crowded city streets, suburban railways or elevated structures and steam roads. The construction is specially applicable to suburban traffic on existing steam roads, and it is sufficiently flexible to be applied even to cable road conduits. The details of the system will be unuerstood by reference to the accompanying illustrations.

The conduit consists of a wooden box placed under the rail H. Fig. 1. This conduit contains the trolley and feed wires and in street railroad construction would be placed two ieet below the surface of the street, the conduit being 18 inches deep. After the wires are in place, this box is filled with insulating material. Every few hundred feet are manholes and every 20 feet there is a switchbox, a half-section of which is shown in Fig. 1. This consists of an iron casting with a hole through the middle. Through this hole passes the main plunger B, attached to which are the two spring plungers C, one being directly opposite the other. These three plungers consist of one brass casting. Inside the main plunger and insulated from it is the brass conductor E, at one end of which is the switch contact F, and on the other the contact wheel A. When in the normal position, the coil springs J, working against the

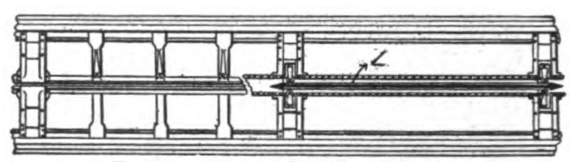

Fig. 2.—Munson Conduit Railway.

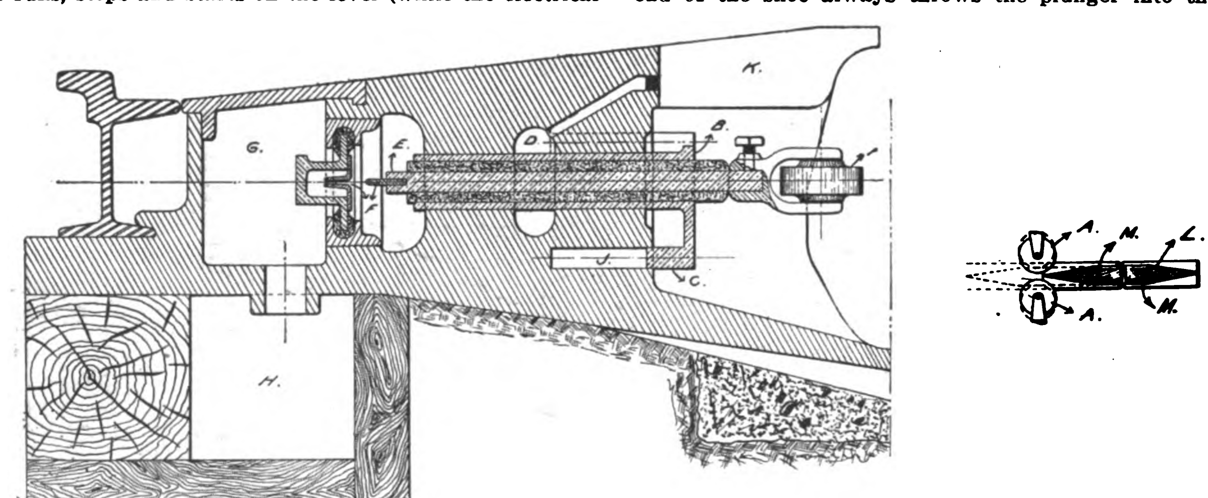
spring plungers, keep the contact points apart. When the contact wheel is pressed back, the contact points are brought together, so closing the switch. The second contact point forms a part of a small brass plug which is screwed into the body of the switchbox. This contact is insulated from the body of the switchbox and has an electrical connection with the trolley wire. After all connections are made the space marked G is run full of insulating material, so as to prevent loss of current by water collecting in the back of the switchbox. D is a recess in the body of the casting to be filled with grease for the double purpose of lubricating the plunger, and preventing water from working past the plunger into the space occupied by the contact points. I is a web on the base of the main casting and is filled around, as shown, with concrete, to assist in holding the box in place. A manhole with cover plate at K permits the contact wheel and plunger to be removed if it should be necessary.

A plan of the track is shown in Fig. 2, a portion being in section to show the shoe L, in the guide slot. The shoe is shown more in detail in Fig. 3. The contact wheels are pressed back by the brass sides of the shoe, their movement being one inch. Three inches of each end of the shoe are made of insulating material and are wedge-shaped. The contact wheels being 20 feet between centers and the shoe 21 feet long, the insulated end of the shoe always throws the plunger into the switch before contact is made between the brass side strips of the shoe and the contact wheels, so that sparking in the switchbox is prevented, and there is always an electrical connection either at one end of the shoe or the other.

It is claimed that the cost of installation will not exceed from $2,000 to $5,000 per mile more than the overhead trolley system. On elevated railroads it is said to be as cheap as the



Figs. 1 and 3.—Munson Conduit Railway.

third-rail system and on steam railroads as cheap as an overhead trolley. Existing cable conduits, it is claimed, may be changed at slight cost per mile.

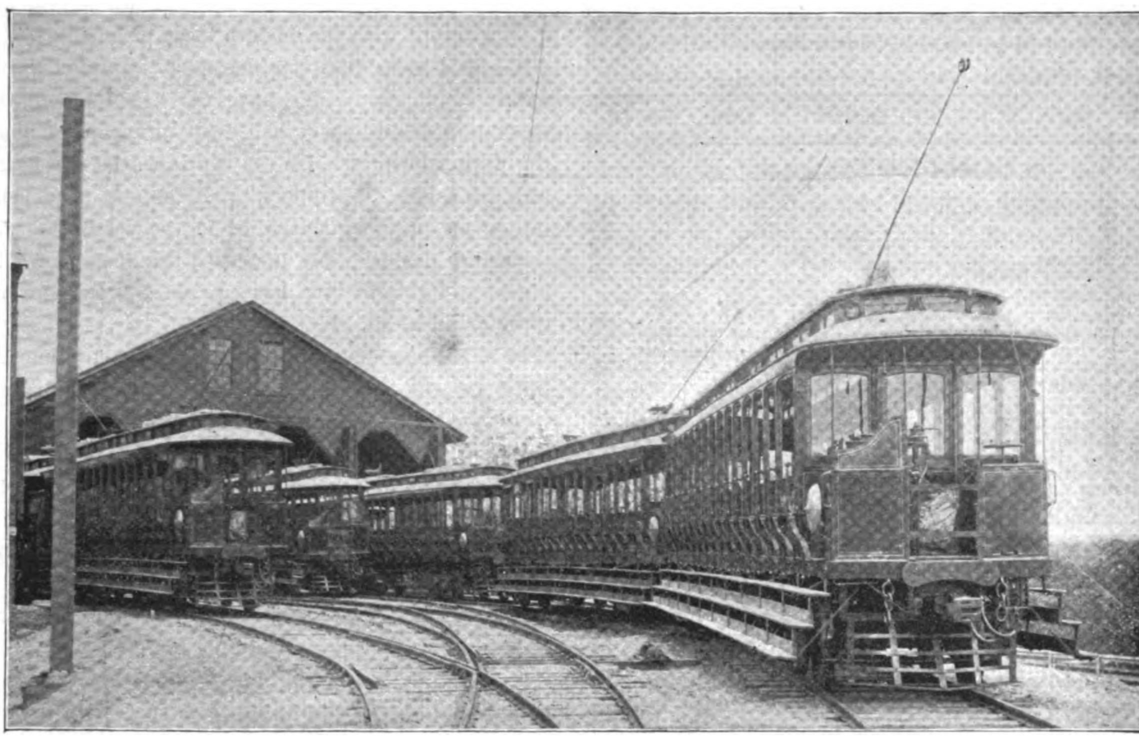
Wooden ties are used to support the rails and slot conduit for side streets and suburban work, but heavy teaming requires a different construction; hence in the streets having goods traffic iron yokes are used, in place of wooden ties, which are modeled after the best cable road practice.

OPERATION OF THE NANTASKET BEACH ROAD.

THE favor with which the electric operation of the Nantasket Beach branch of the New York, New Haven and Hartford Railroad has met from the visitors to Boston's pleasure resort at Nantasket Beach is phenomenal. It has served to confirm the predictions of the engineers of the railroad as well as of the General Electric Company, whose system was adopted. Given a comfortably seated car, open to all the cooling breezes on a hot day, unafflicted by the plague of dust from the dry track or cinders and smoke from the steam locomotive, and the prophecy that the public would avail itself largely of the privilege of riding was not difficult of realization. The traffic on the Nantasket Beach line to-day exceeds the expectations to which that of last year gave rise.

Electric operation of the Nantasket Beach branch was in June last extended as far as East Weymouth in the direction of Boston on the main line of the Old Colony Dominion. On the new line, however, the overhead conductor is not used. A third rail laid between the rails of the surface track takes the place of the trolley wire. This is the first instance of a third rail electrical conductor being laid between the tracks of a steam road, and some measure of failure might consequently be looked for. The cars have been regularly operated over it between the regular steam trains without hitch or difficulty. In the operation of the cars the change from the overhead trolley to the third rail source of power is made imperceptibly. When the car approaches the end of the trolley wire a knife switch under the hood of the car is closed, connecting the shoe beneath the car with the motor circuit. The trolley slides off the overhead wire and is hooked down, the car meanwhile continuing on its journey. On the day of the inauguration of the third rail section, several high-speed spurts were made, and these have frequently been exceeded in the actual service.

The illustration shows the car house of the first electrical division of the New York, New Haven and Hartford Railroad, adjoining power house No. 1, a corner of which is shown to the left. The car house has four pits over which the cars may be run for examination of the motors and is fully equipped with all the necessary appliances.



CAR HOUSE, NANTASKET BEACH DIVISION, N. Y., N. H. & H. RAILROAD.

LETTERS TO THE EDITOR.

PROTECTION OF LARGE ELECTRIC CIRCUITS.

In your issue of August 12 is an article, entitled "Proper Use of Safety Fuses and Magnetic Circuit Breakers," by Mr. Baxter. Some of the statements made are certainly to the point and show an appreciation of the requirements entering into the correct methods of protecting electric circuits.

Mr. Baxter's theory as to the use of generators of greater capacity than that of the engines to run them, thus overcoming troubles incident to overloading, is interesting but not practical. It is not a business proposition to put in more apparatus than is needed. Granting Mr. Baxter's point, the fluctuation of voltage in event of trouble would be about as bad in its effect upon customers as opening the circuit. Further, troubles certainly must be remedied and the juggling with relative sizes of engines and generators will not remove or correct outside troubles. The best engineering practice of to-day demands, without exception, the use of magnetic circuit breakers in lieu of the unreliable dangerous fuse metal.

WALTER E. HARRINGTON,

Camden and Suburban Ry. Co.,
Camden, N. J., August 26.

PERSONAL.

MR. W. E. DAVIS, electrical engineer and purchasing agent of the Detroit Railway, has gone to Saginaw to manage the Bearinger Electric road between that city and Bay City.

MR. RICHARD A. SMITH, electrician, has been appointed to the new position of superintendent of the City Fire Alarm and Police Telephone Systems, at Norfolk, Va., at $75 per month.

PRESIDENT S. L. PHILLIPS, of the Metropolitan Street Railroad Company, of Washington, has resigned, to take effect October 15. His management has been very successful, and in keeping with his record as a highly efficient street railway manager.

CONTENTS.

THE EFFECT OF CHANGING CONDITIONS.

IN discussing, a few days ago, the reasons for the failure of certain concerns in different lines of trade, Mr. W. J. Coombs, ex-Congressman, and an experienced man of affairs, said: "The fight against modern conditions is a hopeless one. For instance, the introduction of electricity for lighting purposes having done away with the necessity for large and expensive chandeliers, has dealt a blow to the gas-fixture business, by taking away the most profitable part of the trade. So we hear of the failure of a gas-fixture house. The combination of various classes into one large retail house has doubtless struck a blow at a great number of small retail dealers in specialties. Where one large house, with an enormous capital, deals not only in dry goods, but in hardware, crockery, shoes, books, and a thousand other articles which in old times were handled by separate establishments, it stands to reason that the day for such separate establishments is past. While this, in some respects, seems hard, no fault can be found with it, for it is in accord with the modern ideas of business."

It seems to us that this statement contains more than one wrong implication. We have not heard before that the introduction of electricity had dealt any kind of a blow to the gas fixture business. On the contrary, the gas fixture makers have all made "electroliers," and there is no evidence of any falling off in the quantity or in the costliness. The use of electricity has certainly increased the demand for light of all kinds, and this in turn has created a better demand for fixtures of all kinds.

As to the combination of several trades into one being a bad thing for the smaller producer or seller, we have yet to be convinced that anything of that nature is true or an established permanent fact. It is quite natural that where a number of small articles of one kind are made and sold, their handling should gradually settle into the care of a relatively few houses of superior capacity; but when it comes to trades very wide apart, it by no means follows that success is sure to attend their combination. Mr. Coombs would not instance Hilton & Hughes as a brilliant example in retail trade; and we ourselves will refrain from quoting the General Electric Company as an overwhelming proof of success in manufacture.

The man who is making or selling specifically the articles of a definite class, and who is giving to his business the best of his time, energy and ability, is under no real or permanent disadvantages when in competition with the man who has spread himself thin over a variety of goods. In many of the industries, patents come in to complicate the problem, but even then it has been found that genius is not a monopoly and that the very success of a new idea is the best possible invitation to hit upon something still more ingenious. The main thing for a business man or a professional man, or for a whole people, is to keep an eye on changing conditions and to live abreast of them.

ARCTIC LIGHTING.

WHEN we recall the fact that the civilized world at one time depended largely for its means of lighting upon the supplies of whale oil, obtained from Arctic waters, it is interesting to note that in these modern days, the electric light is one of the resources most prized by those who traverse the same waters in order to reach the North Pole. It would have seemed easy to capture a whale and get its oil, but the explorer finds it is better to have an electric light plant for purposes of illumination. One of the very first incandescent lighting plants was put on board the unfortunate Jeannette, and now lies on the ever silent floor of some far icy sea; but we are glad to know that Dr. Nansen in his recent voyage to the Pole found his electric plant a great comfort. This intrepid and ingenious man got within less than 250 miles of the Pole, or 200 miles further north than anybody else, and he attributes his success in no small measure to that little dynamo. To his way of thinking, heat and light were the best preventives of disease, and he determined to have plenty of them. He carried a windmill to run the dynamo, and proposed if the wind failed to operate it by human power. It has not been made known whether this became necessary, but a few storage batteries would have avoided even that necessity. At any rate, it is a great pleasure to know that his electric lighting more than fulfilled Nansen's expectations, and it is equally interesting to know that Andree counted a good deal upon the use of the telephone in connection with his balloon trip to the Pole.

MUNICIPAL WIRES.

THE increasing importance of the electrical services in the great cities is adding materially to the responsibilities of those in charge of the wires, and is also, for that matter, providing occupation for many of the younger men graduating in electricity from the colleges. Of late the tendency has been to place all the electrical departments under one common head or control, and this has been done in such cities as Chicago and Pittsburg. Whether it is altogether advisable in large cities is a question not yet settled, but it is the only policy for lesser communities, where one official can easily supervise the work directly.

With regard to Pittsburg, Mr. Morris W. Mead, the superintendent of the electrical bureau, is of opinion that the comprehensive scheme has worked well. It is interesting to note that not only are the police and fire alarm services, as well as others, concentrated in his hands, but that his bureau has of late been regularly engaged in the inspection of all new wiring in buildings and of all exterior wires operated by lighting, railway and other companies. In the last eleven months, he has had 1,339 inspections of interior work made, each requiring from two to twenty visits; and it cannot but be that such work must result in the greater security of life and property.

As an evidence of what electricity can do in the policing of a large city, it is interesting to note Mr. Mead's statement that the 185 police telephone boxes obviate the employment of about 800 men. The city could not, however, afford to hire any such number, in addition to its present force, and therefore derives from the use of the telephone that large amount of extra protection. The old-fashioned detachment of the policeman from headquarters, without means of communication, is in sharp contrast with the electrical methods which can bunch the whole police force of such a city as Pittsburg at any given point within an hour in an emergency.

THE X-RAY FURORE.

SELDOM, indeed, is an excitement seen equal to that which seized upon the world at the announcement of the discovery of the Röntgen ray. Not only were scientific circles stirred to their depths, but the public was delighted and dazed, while the newspapers found no story too wild or improbable. Wonders were rapidly piled on wonders and still the end of the sensation came not. If one daring investigator alleged that he could see through one man, next day another investigator would declare that he could see through two at once; while, not to be outdone, a third would rush into print and asseverate that he could see through three or six. Then came the killing of germs, the curing of disease and the opening up of a new heaven and a new earth.

Scientific discussion of the really great discovery of Prof. Röntgen is still going on, and work of importance is recorded from time to time, but the fantastic revelry of the imagination over the subject has come to an end, and the public wants something new to titillate its curiosity. When we come down to hard, stern fact and look at the net results up to the present time, it is seen that the X-ray has been of use to man in only one direction, namely, in surgery. It has put a new instrument of research into the hands of the doctors and has distinctly lessened the necessity for the probe and the knife, or the application of anesthetics. This is the line, then, along which to look for serious work, and it is not asking too much to expect every hospital and every physician to be equipped with X-ray apparatus or ready to avail themselves of its valuable aid.

THE STREET RAILWAY INDUSTRY.

ACCORDING to advance sheets of "Poor's Manual," just issued, the total of street railway investment in this country is $1,354,497,213 which approximates very closely to the figure of $1,375,410,172 given by the "Street Railway Journal" in August. The "Manual" gives the total length of line as 15,956 miles, against 13,176 in 1895, and the number of cars, all told, as 48,931. A few roads aggregating about 530 miles failed to report, but the remaining 15,425 miles showed a liability of $828,547,285 stock and $525,949,928 in bonds, making a total of $87,809 per mile. The "Street Railway Journal" reaches a corresponding total liability of $95,000 per mile, but the difference does not strike us as serious, or as involving inaccuracy in figures which have evidently been compiled on both sides with great care.

The broad conclusion may be reached that the liability per mile of street railway is about $90,000, as compared with the $60,000 which is the average per mile of steam railroad. We know of no statistics up to date showing how the street railways as a whole stand as to earning capacity and the payment of interest on their bonds, but it may be doubted whether the adverse times, pernicious speculation and harsh legislation have affected them as badly as the steam roads. According to the Interstate Commerce Commission report, no less than 70 per cent. of the stock of the steam roads is paying no dividends, and 17 per cent of the funded debt has not met its interest. From such a depression any industry may well pray to be delivered.

SOCIETY AND CLUB NOTES.

SOCIETY FOR PROMOTION OF ENGINEERING EDUCATION.

At the meeting of the Society for the Promotion of Engineering Education, held in Buffalo, officers for the year were elected as follows: President, Prof. Eddy, of the University of Minnesota; vice-president, Prof. John Galbraith, of Toronto; secretary, Prof. C. F. Allen, of the Massachusetts Institute of Technology; treasurer, Prof. J. J. Flather, of Purdue University.

MEETING OF THE A. A. A. S. AT BUFFALO.

THE annual meeting of the American Association for the Advancement of Science took place under favorable conditions at Buffalo last week. The attendance was fairly good and a number of papers were presented in the various sections.

Among the papers offered in Section D, Mechanical Science and Engineering, were: "The most economical point of cut-off for steam," by H. T. Eddy; "On a continuous indicator for engine tests," by T. Gray; "An arrangement for using storage batteries for the automatic regulation of engine loads in power plants of variable output," by W. S. Franklin; "The better distribution of forecasts," by J. A. Miller.

In Section A, Mathematics and Astronomy, a paper was read by L. A. Bauer, on "The component fields of the earth's magnetism."

In Section B, Physics, Vice-President C. L. Mees gave an address on "Electrolysis and some associated problems in molecular dynamics." The list of papers is as follows:

"Note on the effect of odd harmonics upon the virtual values of periodically varying quantities," by Frederick Bedell.

"Electrical waves in long parallel wires," by A. D. Cole.

"Graphical treatment of alternating currents in branching circuits," by Henry T. Eddy.

"On the counter electromotive force of the electric arc," by W. S. Franklin.

"Some points in the mechanical conception of the electromagnetic field," by W. S. Franklin.

"A theory of galvanic polarization," by W. S. Franklin and L. B. Spinney.

"On the rule for the dynamo and motor," by Alexander Macfarlane.

"On the distribution of high frequency alternating currents throughout the cross-section of a wire," by Ernest Merritt.

"An experimental study of the charging and discharging of condensers," by F. E. Miller.

"The influence of a static charge of electricity on the surface tension of water," by Edward L. Nichols and John Anson Clark.

"A new alternating-current curve-tracer," by Edward B. Rosa.

"Preliminary note on a proposed new standard of light," by Clayton H. Sharp.

"Note on the duration of the X-ray discharge in Crookes tubes," by Benjamin F. Thomas.

During the week a lecture was delivered by Dr. J. W. Spencer, of Washington, on "Niagara as a timepiece," and a large party of members and friends visited and inspected the Falls and the power works.

The following officers were elected for 1895-6: President, Prof. Wolcott Gibbs, Newport, R. I.; vice-presidents, who form the chairmen of the various sections, mathematics and astronomy, W. W. Beman, Ann Arbor, Mich.; physics, Carl Barus, Providence, R. I.; chemistry, W. P. Mason, Troy, N. Y.; mechanical science and engineering, John Galbraith, Toronto, Canada; social and economic science, Richard T. Colburn, Elizabeth, N. J.; permanent secretary, F. W. Putnam, Cambridge, Mass.; general secretary, Asaph Hall, Jr., Ann Arbor, Mich.; secretary of council, D. S. Kellicott, Columbus, Ohio; treasurer, R. S. Woodward, New York. The next place of meeting was left in the hands of the council for final action.

Secretaries of various sections were elected as follows: Mathematics and astronomy, J. McMahon; physics, F. Bedell; chemistry, P. C. Freer; mechanical science and engineering, J. J. Flather; social and economic science, A. Blue.

Secretary Barnes read a resolution sent in by the nominating committee and the sub-committee appointed to select a place of meeting for the association in 1897 which acted like a bombshell exploding in the midst of the camp. The committee reported in favor of holding a formal meeting in Toronto one day next year, August 17, 1897, and recommended that at the close of the formal meeting the association meet in Toronto with the British Association for the Advancement of Science and identify itself with the sessions of that body.

After lively discussion this plan was turned down, and the matter referred back to the council.

LITERATURE.

SUBMARINE CABLE LAYING AND REPAIRING. By H. D. Wilkinson. New York: D. Van Nostrand Co. London: The Electrician Co. 406 pages. 221 illus. Cloth, 8vo. Price, $5.

It is strange, that outside books on testing, there should have been so small a literature on the subject of submarine cable work. This field of industry is one of the oldest; it has been fertile in great inventions; it has required fine engineering; it has been developed by great investments, and it has become one of the most profitable fields of enterprise. Yet it would puzzle any man to name half-a-dozen or even three first-class books, in the English language, on the submarine cable art. It is evident, therefore, that Mr. Wilkinson has had a good opportunity to "fill a gap"—not one of those imaginary voids, fictitious creations of the author's own ignorance, immaturity and inexperience, but a real necessity on the part of those who wish to learn. Careful perusal of the work shows that Mr. Wilkinson has done a real service and has, in a masterly manner, put together nearly all that is valuable, and much that before was not public property, in regard to this important subject.

The book is divided into four sections, which, rather oddly, are called chapters. As the whole book consists of but 406 pages, and as two of the chapters are each over 120 pages in length, it would seem that a finer subdivision might well have been attempted. As a general thing, the reader is helped by the division into frequent chapters. The objection we would raise, is, however, offset by the resort to numerous sections, nearly sixty in all; as well as by a very careful and complete list of illustrations and an excellent index. One other general criticism that suggests itself is the somewhat Hibernian fashion in which the book begins with the repairing cable ship and winds up with the laying of cables, an arrangement that strikes one as being wrong-end-to. It is possible, however, that this is due to what may be termed the evolution of the book, namely, that it began as a series of articles on one branch of the subject and grew into a manual of the whole art.

There is little that is historical or reminiscent in the book, although we are very glad to see preserved in it some early pictures of submarine work when it had a fuller spice of novelty and danger than it knows to-day. Mr. Wilkinson devotes himself almost entirely to the practical side of the subject, and discusses every topic with a clearness and an exhaustiveness that leave nothing to be desired. Especially worthy of commendation are the clear drawings and diagrams scattered profusely throughout the text. The book is based essentially on English practice, and has nothing to say of American methods, there being only one or two branches in which work done on this side demands consideration, and those hardly within the scope of the author's plan.

We have spoken of this book as covering the ground, but do not intend the remark to imply that it includes methods of operation. This is, indeed, a subject by itself, and worthy another volume, quite as large, from the same hand. Nevertheless, many interesting points do come under treatment, of that nature, in connection with testing, and Mr. Wilkinson has presented an admirable chapter on the localization of faults. To a great many, that chapter will be the most useful part of a book every page of which is interesting and instructive.

THE CHICAGO MAIN DRAINAGE CHANNEL.—By C. S. Hill, C. E. Asso. Ed., New York. Engineering News Publishing Co., 1896. Cloth. Quarto. 129 pages. 105 illus. Price, $1.50.

One of the greatest engineering enterprises to be carried out recently in the United States is the excavation of the 28-mile drainage canal from Chicago to Lockport, Ill., with the object of carrying the dilute sewage water of the Chicago River westward into the Mississippi and away from the city's water supply in Lake Michigan. This work has been in hand for about four years and is now, we understand, practically complete. About 40,000,000 cubic yards of earth and rock have been dug out and moved by methods and appliances often strikingly original. All the branches of the work were very ably dealt with by Mr. Hill in a series of articles for his journal, and these have now been republished, constituting a most interesting and valuable monograph. The subject is one having many points worthy the notice of electrical engineers. It will be remembered that it has been said that 80,000 horse-power can be reclaimed electrically by the fall of the water between Joliet and Lockport, while, on the other hand, there has been the discussion as to whether the level of the lakes and the outflow at Niagara might not be reduced by this wholesale diversion.

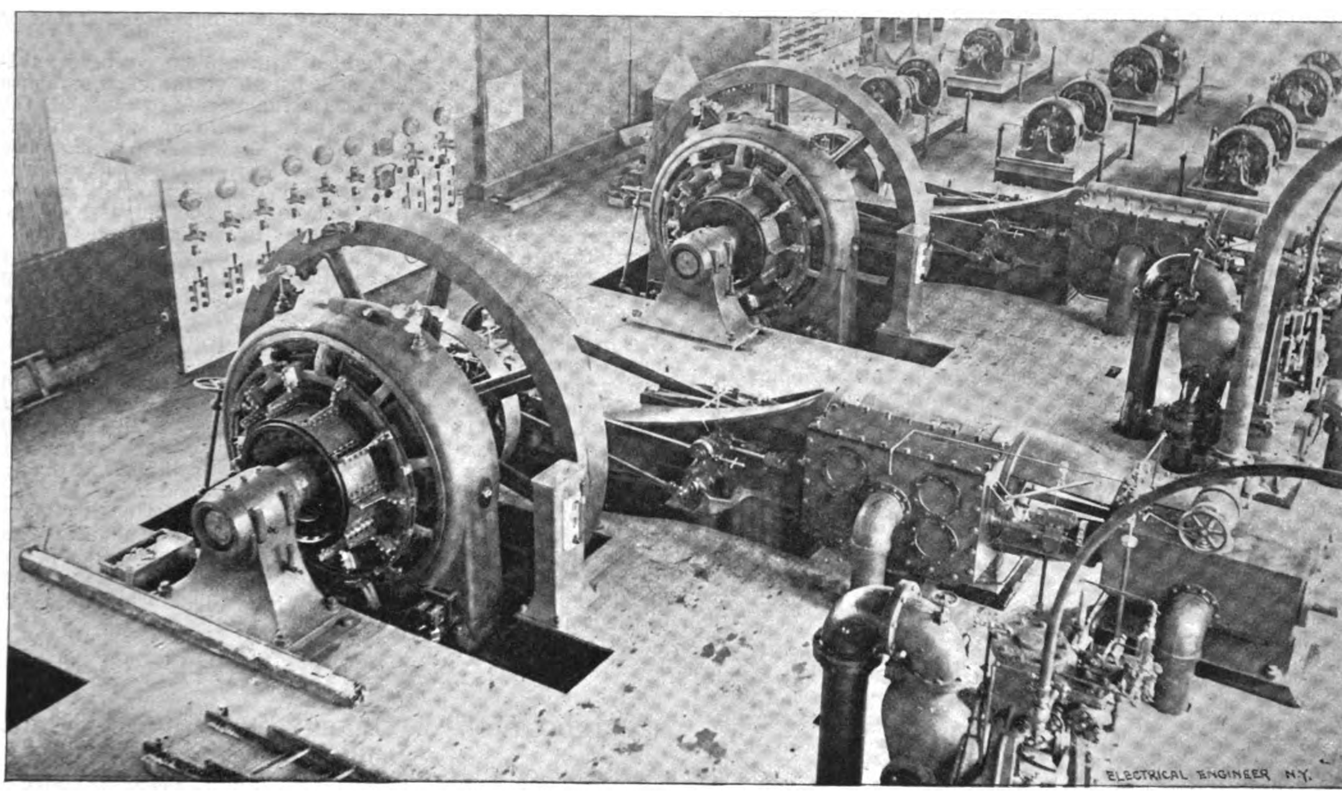
ELECTRIC LIGHTING.

ELECTRICAL PLANT OF THE DUQUESNE STEEL WORKS AND BLAST FURNACES.

THE Carnegie Steel Company, Limited, have recently put into operation at Cochran, Pa., about 12 miles from Pittsburg, an extensive new blast furnace plant on property adjacent to their well-known Duquesne Steel Mills. Several excellent features are noticeable in connection with the electrical plant, the function of which is to supply light and power to the steel mills, six furnaces, and the various buildings and yards appertaining thereto; an area of over 100 acres.

THE ELECTRIC POWER HOUSE.

This plant is situated in a separate brick building, 200 x 50 feet, having a steel shell. The building is divided into three parts; the central 120 feet, contains the electrical machinery and switchboards, which will be described in detail below. The 40 feet at the northern end contains the office of the superintendent of the electrical department and a storeroom for wire, spare parts, etc. The 40 feet at the southern end comprises the machine or repair shop, which is equipped with lathes, drill presses, milling and slotting machines, etc., all operated from a shaft driven by means of a 10 horse-power multipolar shunt wound motor. A 10-ton electric traveling crane runs the entire length of the building. The great advantages of such a crane and repair shop are obvious.



DYNAMO ROOM, DUQUESNE FURNACE AND STEEL WORKS.

GENERATORS.

The photograph illustrated above is a view of the central portion of the power house. In the foreground are two 500 horse-power, 250 volt, direct current, 10-pole generators, each direct connected to a Buckeye tandem compound condensing engine, 18 inches and 32½ x 33 inches, operating at 130 revolutions per minute, and exhausting into a standard Blake condenser. These generators were built by the Westinghouse Electric and Manufacturing Company, and represent their latest development in dynamo design and construction. The field poles are built up of laminated steel and they are cast into the yoke, which is divided vertically as shown. The armature core, which is pressed and keyed upon the engine shaft, consists of laminated steel discs slotted around the periphery. When the discs are superimposed upon each other, they form grooves into which the conductors are placed. These conductors are composed of rectangular copper bars, shaped upon molds and thoroughly insulated before being placed upon the core. The brush holder mechanism is supported by brackets projecting from a cast-iron ring secured to and supported by the field yoke, as shown. Each machine has 10 brush arms, each carrying 5 carbon brushes. These generators are operated in parallel and supply power to a large number of direct current 220-volt motors used for various purposes throughout the plant.

In the background of the same photograph are shown six direct constant current, 60-light arc dynamos, which supply current to arc lamps in the various buildings and yards. These machines are direct connected by flexible insulated couplings, to six 50 horse-power shunt motors, which are also operated by power from the generators described above. The exciting current for the arc machines is also taken from the same generators.

The illustration also gives a view of these arc machines and their driving motors. The arc machines are symmetrically located on each side of an aisle, which is directly opposite the arc switchboard, this arrangement being very convenient for the attendant.

Each of these units (arc machine and motor) is mounted upon a separate foundation, as shown. On a similar foundation is a 45 kilowatt, 7,200 alternation, single-phase generator (not shown in the illustration) which is also direct connected to a motor and excited by current from the large generator. This machine is used for supplying current to about 900 incandescent lamps distributed in the various buildings.

SWITCHBOARDS.

A white marble switchboard, supported by an iron frame work stands back of and between the two large direct current generators. This is the power board and upon it are mounted the necessary switches, circuit-breakers, ammeters, voltmeters, and rheostats, for controlling the two generators; it consists of two generator panels, one main panel and six feeder panels. All the connections are made on the back of the board. A large single-pole switch, mounted on an iron pedestal, near each of the direct current generators, is for the equalizing circuit, which is carried directly from one generator to the other, under the floor.

The arc switchboard consists of six marble panels, the three on the right containing the circuit-breakers and switches for controlling the six direct current motors, while upon the other three are mounted the ammeters, circuit-breakers, plugs and plug receptacles for controlling the arc machine and arc cir-

cuits. By means of the plugs any one of the machines may be connected to any of the feeder circuits. All wires from the arc machines and their driving motors are carried through hollow posts to a pine switchboard situated under the marble one in a light, dry cellar, the floors of which are concreted. No so-called "temporary work" can be found in the plant, the entire installation having a substantial and permanent appearance.

No wires are visible on the ceiling or walls of the building, except at the northern end, where they are brought from the cellar in two groups, positive and negative, pass up the wall and through a circular gable window to a line of steel poles, 50 feet in height, upon which they are carried through the yards and to the buildings. The arc machines, alternating current generators, marble switchboard and all the motors installed in the power house were also manufactured by the Westinghouse Electric and Manufacturing Company.

GENERAL DESCRIPTION OF PLANT.

It was originally intended to confine this article strictly to the electrical features of the plant, but a very brief description of the operation of the entire plant will be given here, as it may be interesting to readers who are unacquainted with the work carried on in such an establishment, and will also be of assistance in understanding the nature of the work to be performed by the electrical apparatus.

The Duquesne Steel Mills have been in operation for several years, but until this summer there have been no blast furnaces in connection therewith, and the iron used in the process of making steel billets was obtained in the form of pig iron. The blast furnace plant, when complete, will consist of six furnaces; the first two of these were placed in operation, or "blown in," in June of this year. The other four are rapidly nearing completion.

At the foot of the furnaces is an immense "stock-pit," 30 feet deep and 230 feet wide, where the ores, coke and the other materials used in charging the furnaces are stored.

A new and improved method of carrying the materials to the top of the furnaces has been employed. A track supported by iron structural work extends from the stock-pit to the top of each furnace and the cars containing the materials are hauled up and when just over the bell, the load is dumped. When the bell is sufficiently charged it is lowered, and the charge falls to a second bell, the first is then brought back into position and the second bell is lowered, thus dropping the charge into the furnace. This prevents the escape of hot air and gas when the furnace is being charged.

There are eight large heating "stoves" for each two furnaces; these stoves are supplied with hot gas from the furnaces and their function is to heat the air which is pumped by 1,800 horse-power blowing engines built by the E. P. Allis Company. There are five of these engines installed in one building, two are used for each furnace and one held in reserve. These engines compress the air to from 15 to 25 lbs. per square inch, it then passes through the "stoves" and is heated to a very high temperature after which it is forced into the furnaces. The gas from the furnaces is also used to operate the boilers, the capacity of which, when completed, will be about 18,000 horse-power; 6,000 horse-power for each pair of furnaces. The boilers are of Babcock & Wilcox manufacture.

Ordinarily the metal is drawn off the furnaces and run into large ladles (mounted upon cars) and taken directly to the Duquesne Mills, where it is mixed and then run into converters and used in making steel billets. On Saturdays and Sundays, when the converters are not in operation, the iron is drawn from the furnaces into the casting house, where it is run into "sows" 26 feet in length. These "sows" are taken to a metal breaker and broken up and later sent to be remelted in the converters.

PUMP HOUSE.

In a separate building near the electric power house, are installed the engines for pumping the immense quantity of water required in the plant from the Monongahela River into a huge stand-pipe 158 feet in height. There are five of these engines built by Wilson & Snyder, of Pittsburg, and the pumping capacity of each is 5,000,000 gallons per day.

ELECTRIC CRANES.

There will be over 40 Morgan electric cranes in the plant; all of these are driven by 220 volt direct-current motors manufactured by the Westinghouse Electric and Manufacturing Company.

Each of the six casting houses is equipped with two 10-ton three movement electric traveling cranes. A 10 horse-power multipolar motor, enclosed type, is used for the hoist, 10 horse-power for bridge travel and 3½ horse-power for carriage. The hoist and carriage motors are equipped with automatic electric brakes, the bridge motor with powerful foot brakes; an arrangement which permits a very accurate movement in each direction. These cranes carry the pig iron to the metal breaker previously mentioned. Each blowing engine house is provided with a 25-ton three movement crane of 61 feet span; a 20 horse-power motor being used for hoist, 5 horse-power for carriage and 30 horse-power railway type motor for bridge travel. Automatic electric brakes and foot brakes are supplied as on the cranes in the casting houses.

A 50-ton electric crane of a special type built by the Morgan Engineering Company, is erected over the metal mixer. It is a four movement crane; two hoists, one carriage and one bridge movement. The motors are: 100 horse-power for main hoist, 20 horse-power for auxiliary, 10 horse-power for carriage and 30 horse-power railway type for bridge.

By means of this crane the molten metal is poured from the ladles into the metal mixer. In this way metal from several different furnaces is mixed together before being run into the converters. There is a 10-ton electric crane of 50 feet span installed in the pump house. The motors thereon are 10 horse-power for hoist, 10 horse-power for bridge and 3½ horse-power for carriage.

OTHER USES OF ELECTRIC MOTORS.

The metal breaker is direct connected to a 60 horse-power multipolar shunt wound motor. The breaker, which is provided with a flywheel four feet in diameter, is fed from a long table driven, through suitable gears, by a 30 horse-power railway type Westinghouse motor. Cranes are used to lift the metal to the table. This apparatus can handle over 100 tons of pig iron per hour.

Each casting house is provided with a 5-ton conveyer; this is a carriage running the whole length of the casting house and thence to the stock yards. Its function is to carry all the scrap iron to the foot of the furnace hoist, from where it will be taken to the top of the furnace again. A Westinghouse railway type motor moves this conveyer, and, although working day and night in an extremely warm and dusty atmosphere, it has proven entirely successful. The operator on the conveyer is protected from the heat by an iron cage.

Over the ore stock yard are three electric traveling bridges of 260 feet span. These were constructed by the Brown Hoisting and Conveying Company, of Cleveland, Ohio, and are the largest ever built for the purpose. The carriages are driven by steel ropes, all the machinery, such as drums, clutches, etc., being mounted on the bridge. Two 100 horse-power Elwell-Parker shunt motors are direct connected to the drums and enable the operator to move the bridge, carriage and hoist at the same time. The purpose of these bridges is to unload all the ores needed for the furnaces. A 20 horse-power shunt motor drives the crushing machines in the ore sampling department, and a 2 horse-power motor is used in the laboratory. In fact, electric motors are in use in almost every part of the plant for a large variety of purposes. The electrical apparatus is giving complete satisfaction and the superintendent of the electrical department is to be congratulated in having under his charge one of the largest and most complete isolated plants in the country.

NEWS AND NOTES.

ELECTROCUTION MACHINERY WANTED AT COLUMBUS, O.

Warden Coffin and R. P. Green, superintendent of electricity, have issued circulars asking for bids from the various electrical manufacturers for the necessary machinery for lighting the prison and at the same time to be used for electrocutions. The bids will be opened on September 4. The specifications call for one compound wound alternating dynamo with exciter, with a capacity of from 30 to 50 kilowatts at 2,000 volts. Alternations not to exceed 16,000 per minute, nor less than 7,200. The dynamo to be mounted on a cast-iron sliding base frame and provided with belt tightener. The armature of said machine to be iron-clad type. Both the alternator and exciter to be provided with self-oiling bearings with oil rings.

In addition to the above one alternating current station armature, one alternating current voltmeter, blocks, arresters, switchboard, converters, etc., are required. Contractors are required to guarantee the machinery for two years, and the committee reserves the right to reject any or all bids.

AMERICAN ELECTRICAL PLANTS FOR THE FAR EAST.

A large quantity of American electrical goods and apparatus has found its way to the Far East, and the market is one that appears to have a capacity for rapid growth and development. The firm of Bagnall & Hilles, of Singapore, Straits Settlements, and Yokohama, Japan, has been giving its special attention to this field, and the results are already of a very hopeful and promising nature. One of its recent contracts of

more than usual interest is that made with the Sultan of Koetei, one of the Straits potentates, who has built a new palace and who wants the best electrical plant to be had. Messrs. Bagnall & Hilles are doing what they can to gratify this laudable ambition. The palace will be fitted throughout with Habirshaw wires and cables, and the other parts of the equipment are to be of equally high standard.

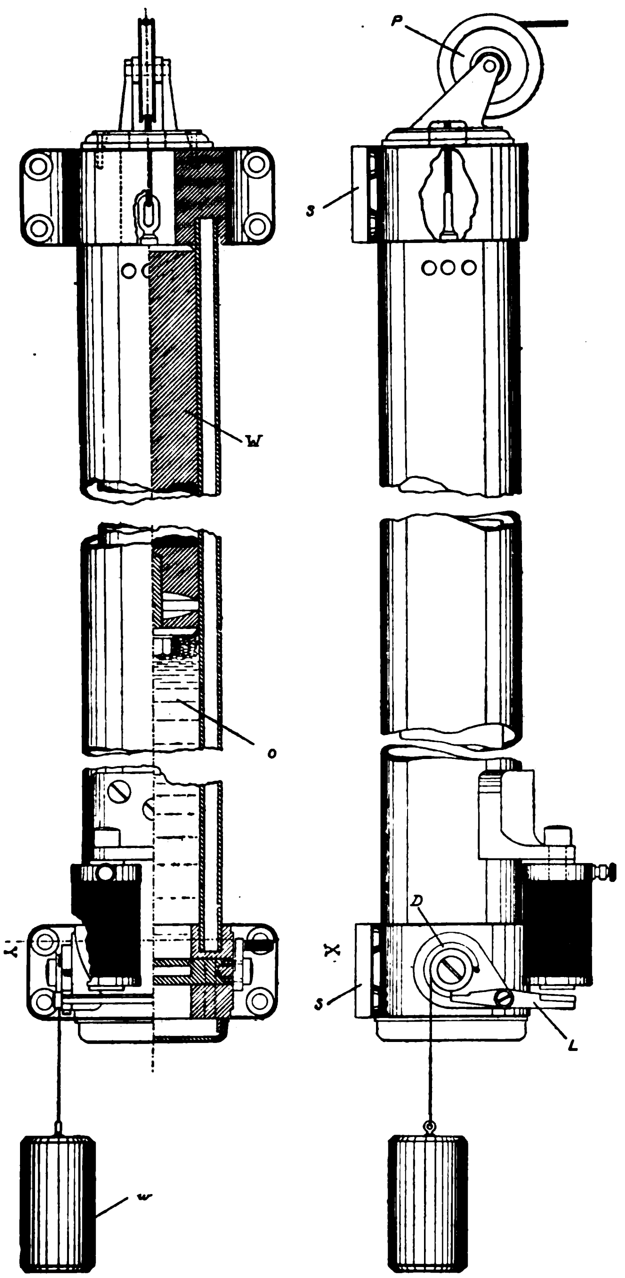
MISCELLANEOUS.

AN ELECTRICALLY CONTROLLED WEIGHT.

BY

Ernest K. Adams.

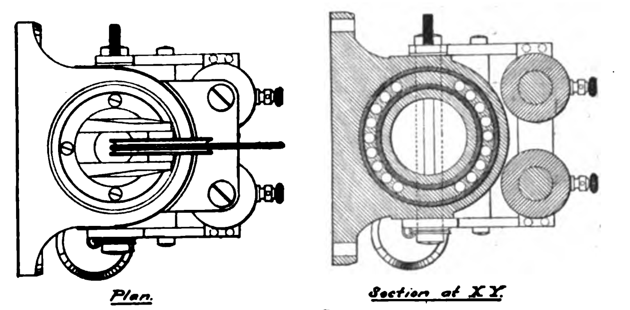
As its name implies, this device is designed to store up a small amount of energy by means of a weight which can be electrically set free. It can be applied to a variety of uses, among which are, the starting or stopping of machinery, operating those apparatus which are used in connection with fire departments, opening or closing doors, windows or registers, in fact, in any place where a small amount of work is to be done on the closing of a circuit.



METHOD OF ELECTRICALLY CONTROLLING A WEIGHT.

It consists of two tubes, supported at either end by a brass casting, having holes drilled in it for fastening the arrangement to the wall. In the interior of the inner tube a weight of a size suitable for the work in hand slides smoothly and at the same time fits tightly enough to prevent the oil, which is in the lower portion of the tube, from passing up around its sides. When the device is set, this oil cannot flow through the holes drilled in the lower support, into the jacket between the tubes, on account of a valve being closed. A small weight, sufficient for turning this valve, is fastened by a cord to a pulley on the valve rod. When a current is sent through the electromagnet the armature lever moves and, becoming disengaged from the slotted disc back of the pulley, allows the small weight to pull the valve open.

The oil has easy access now to the jacket outside, and the working weight descends, performing whatever work that may be desired. A pulley at the top, may be turned around at any angle, permitting the cord to run smoothly. When it is desired to set the apparatus, this weight is drawn to the top by pulling the cord. This causes the oil to resume its former position, air coming in from outside through several groups of holes at the top of the outer tube. As soon as the weight is in the desired position, the valve is turned by the small handle on the right, until the armature lever drops into the slot in the disc. The device is now set. By using a valve, a minimum current may be employed to set free a comparatively large weight.



PLAN AND SECTION.

THE METRIC SYSTEM IN ENGLAND.

It is stated on good authority that according to a strict interpretation of the law in England it is at present actually illegal to possess a weight or measure on the metric system. A contemporary in discussing this says that in the piecemeal way in which legislation is effected in that country it is quite possible that this may have been brought about without anybody knowing it. If so, it is appalling to think of the august institutions that have been encouraging this illegality. Most people, including the writers of some text-books, thought the metric system was legalized years ago.

NOVEL ELECTRICAL EXPERIMENTS.

The London "Electrician" states that at a special meeting of the South African Philosophical Society, held on the 2d ult., a lecture on the above subject was delivered by Mr. A. P. Trotter, Government Electrician and Inspector. Towards the end of the lecture the lecturer rang up the Capetown Telephone Exchange, and asked if any of the longer post office telegraph lines were clear. The Port Elizabeth line was then connected up, and by means of a Wheatstone bridge on the lecture table, the resistance of the line was measured. The lecturer then observed that, with the extremely sensitive instrument used in the Government Electrical Laboratory, it was not necessary to use ordinary electric batteries for signalling to such a distance as to Port Elizabeth. He disconnected the battery, and, plunging a steel knife and silver fork into an orange, sent signals by means of the feeble current thus generated. He then asked the front row of the audience to join hands, and, putting them in the circuit, sent signals through their bodies to Port Elizabeth and back by means of the orange cell. As a concluding experiment an omelette was made "under some disadvantages," and the cost of the electrical energy was stated to be only 1d.

WATER JETS AS CONDUCTORS.

Reports have been heard from time to time concerning firemen who have received electric shocks which were supposed to be communicated from a fire engine hose. Considering what a particularly good earth a fire engine must have in its suction pipe it seemed unlikely, but it appears that so far as alternating currents are concerned the matter has been already determined experimentally by Professor Slaby, of Berlin. The

overhead conductors of a 10,000-volt power transmission line were used for the experiment. A voltmeter was connected between the metal mouthpiece of the water hose and the earth. On turning the water on to the live conductors no flow of current to earth was noticeable.

GUTMANN'S METHOD OF CHANGING FREQUENCY.

A METHOD of changing the frequency of periodic currents has been designed by Mr. Ludwig Gutmann by means of which periodic currents may be transmitted to the place of consumption and there be changed in frequency to suit the requirements of any particular case; that is, an alternating current may be transformed into one having a greater or less time period than the original current.

The apparatus by means of which this is accomplished is ex-

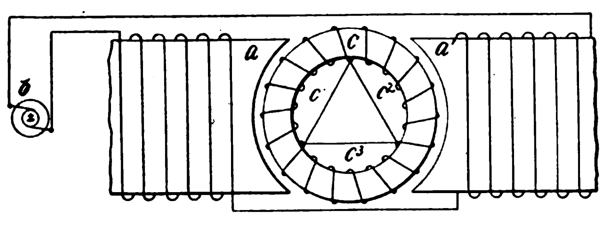


FIG. 1.

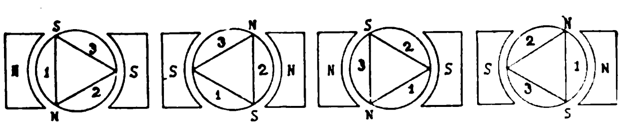
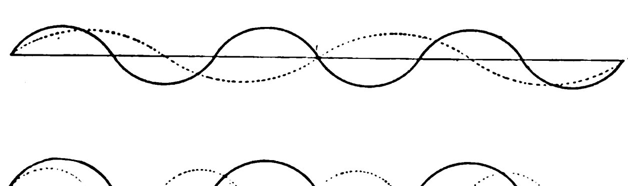
plained by reference to the following illustrations: Fig. 1 shows a diagrammatic view of the motor and Figs. 2-5 show the armature in four positions during a revolution. In Fig. 1 the field magnets a, a' are excited by a current from an alternating current generator b, thus producing an alternating magnetic field. An armature c rotates within this field, having three coils c'c²c³ cross-connected so as to form three subcircuits. If the armature be started the alternating current generated in any one of the three coils will have a frequency different from that of the current exciting the field. In Fig. 2 the coil 1 stands opposite a north pole, and at the end of one-sixth of a revolution it has advanced to the position shown in Fig. 3, the pole to the right now being of north polarity, the field strength having changed through half of a complete period, or 180 degrees. At the end of one-third of a revolution coil 1 has advanced to the



FIGS. 2, 3, 4 AND 5.

position shown in Fig. 4 the pole to the left now being north, the field strength having changed through a complete period, or 360 degrees. At the end of three-sixths of a revolution of the armature-coil 1 stands again in front of a north pole, as shown in Fig. 5. The current induced in 1 has therefore passed through one complete cycle, while the field strength inducing the current has passed through one and one-half cycles. The ratio therefore of the frequency of the current induced in coil 1 to the frequency of the field, or, what is the same thing, the frequency of the current exciting the field, will be as one and a half to one, or as three to two, so that if the frequency of the original current be sixty per second, the frequency of the induced current will be forty per second. If, instead of inter-

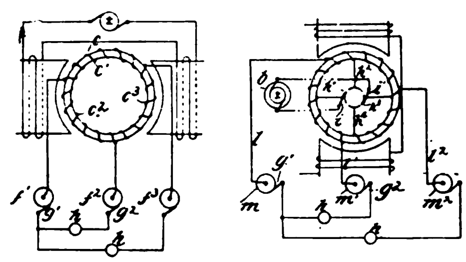


FIGS. 6 AND 7.

connecting the winding, as shown in Fig. 1, the ends of the coils c' c² c³ be connected with collecting rings f' f² f³ and brushes be placed upon any two of the collecting rings, an alternating current possessing the altered frequency may be collected, and a motor h, connected in circuit between the brushes, as g' g², will be traversed by the current of altered frequency.

In Fig. 9 is illustrated another form of apparatus for producing the same result comprising an armature the coils of which are connected with the commutator-segments h' h² h³ h⁴, upon which bear brushes i i', connected in circuit with an alternating current generator b. Three equidistant points in the winding are connected by the conductors l l' l² with collecting rings m m' m². If brushes be provided in connection with any two of the collecting rings, an alternating current of altered frequency will be collected. Thus the motor h, connected between the brushes g' g², will be traversed by the alternating current of altered frequency.

In Fig. 6 the curve of the alternating current the phase of



FIGS. 8 AND 9.

which is to be altered is shown in full lines, while the resultant current of two-thirds the frequency, as shown in connection with Figs. 2 to 5, is plotted in dotted lines.

In Fig. 7 is shown a similar curve, and a curve of greater frequency produced therefrom, the method being equally applicable to increasing or decreasing the frequency. As here shown, the frequency is increased in the ratio of three to four. It is evident that the resultant current may have a period equally divisible into the period of the current to be altered, that is, a period of one-half or one-third, or it may have a period forming a multiple of the period of the current to be altered, as twice or three times, or the periods may bear a harmonic relation, as three to two or four to three.

ALTERNATE CURRENT TRANSFORMERS[1]—III.

BY DR. J. A. FLEMING, F. R. S.

We shall consider in a later lecture the disadvantages of a small-power factor. Meanwhile, it may be said that a small-power factor in a transformer, when taken at no secondary load, is always an indication of large magnetic reluctance in the magnetic circuit, and hence open iron circuit transformers have always small-power factors. The primary and secondary coils, having been placed upon the core and insulated from one another, the transformer is put into an iron case, which is constructed to be water-tight. Many manufacturers include in the same case porcelain plates or terminals, to which they attach the extremities of the primary and secondary coils. This, however, is not so good a plan as connecting by a highly insulated joint the extremities of the primary and secondary coils to highly insulated cables, which are brought out through watertight glands in the iron case, any necessary connections to fuses or switches being then made outside. In the design of large transformers, one important consideration is getting rid of the heat. A transformer ought never to rise above 100° Centigrade under any conditions of use, and for every watt which is lost in hysteresis and by copper resistance at least 3 to 4 square inches of cooling surfaces must be provided. In the case of very large sub-station transformers, it has even been found advantageous not only to leave ventilating spaces in the core, but to force a draught of air through the transformer to keep it cool. In some cases a highly insulating oil is put into the case, but the insulation of the transformer must be good enough to work without it. The use of the oil is merely to keep out damp air, and even then it is not always successful in preventing break down. The notion that oil could be used as an insulation for transformers, which would heal up again after the passage of a spark or arc, was not confirmed by experience. As regards the general design of transformers, the battle of open versus closed iron circuit transformers was fought out and decided long ago. Open circuit transformers—such as the Hedgehog transformer—have no advantage over the closed iron circuit transformer in respect of core loss per kilowatt output and they have a decided disadvantage in a smaller power factor. Moreover, in a closed iron circuit transformer, as the transformer is loaded up, the power factor very soon reaches unity; the curves in Fig. 30 show the manner in which the power factor of several different types of transformer varies as the transformer is loaded up. In a good closed iron circuit transformer, with small magnetic re-

[1] Society of Arts Cantor Lectures.

luctance,' a very little loading of the secondary circuit brings the power factor up to unity. In the case of a 6 kilowatt Mordey transformer I found that, loading up to 1-60th of full load, brings the power factor up to unity. The advantage of large power factor means we have a small root-mean-square value in the magnetizing current at no load, and, therefore, a small heating loss in the main supplying the current of that transformer. When the transformer is at work we not only have energy losses going on in the iron, but, at the same time, we have energy losses in the copper, called the copper losses, which are due to the resistance of the copper circuit. It can be

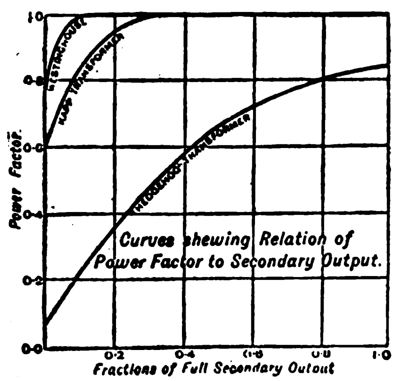


FIG. 30.

shown the most advantageous ratio between the copper losses and the iron losses is to so construct the transformer that at full load the total copper losses are equal to the total iron losses. In very large transformers, where the secondary circuit consists of very thick copper bands or wire, if magnetic leakage exists to any sensible extent, we may have eddy current losses set up in the copper circuits, and this, in addition, may be a source of energy waste. The copper resistance operates not only to cause a large energy loss, but partly to account for what is called the secondary drop of the transformer. If a transformer is connected to a constant potential primary circuit, and if the secondary circuit is gradually loaded up, the potential difference between the secondary terminals is less when the transformer is fully loaded than it is when the transformer is on open secondary circuit. This difference is called the secondary drop. This drop is due to three causes—firstly, the resistance of the primary circuit; secondly, the resistance of the secondary circuit, and, thirdly, to magnetic leakage. As far as regards the copper resistance, we can calculate the secondary drop by the following formula:

$$\text{Secondary drop} = \frac{100 \times (C_1 - \textit{mag. cur.}\ R_1)}{E_1} + \frac{100\, C_2 R_2}{E_2}.$$

Where C_1 is the R.M.S. of the primary current.
C_2 is the same value for the secondary current.
R_1 is the resistance of the primary circuit.
R_2 is the resistance of the secondary circuit.
E_1 is the difference of potential between the primary terminals.
E_2 is the difference of potential between the secondary terminals.

taken when the transformer is on open secondary circuit, and the symbol mag. cur. stands for the magnetizing current of the

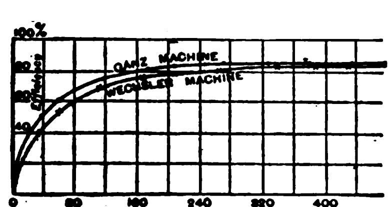

FIG. 31.—EFFICIENCY CURVES OF TWO TRANSFORMERS OFF TWO ALTERNATORS.

transformer—that is, the primary current when the transformer is on open secondary circuit.

This formula, however, only gives us that part of the drop which is due to the copper resistances; the actual observed drop would be greater than this by an amount due to magnetic leakage.

In dealing with the testing of transformers in our next lecture, we shall discuss the method by which this drop may be measured. In considering the action of transformers, it is important to notice that the iron core loss of the transformer at no load, are all greatly affected by the form of the curve of primary electromotive force. It is the custom sometimes to speak of the core loss of a transformer as if it were a quantity inherent in the transformer itself, and which could be exactly specified for any particular instrument. As a matter of fact, this is not the case. Experiments carried out with different transformers worked on different alternators by Dr. Roessler in Germany, and by myself in England, have abundantly demonstrated that the form of the curve of primary electromotive force has an immense influence on all the above-mentioned quantities. Dr. Roessler employed two machines—one a Wech-

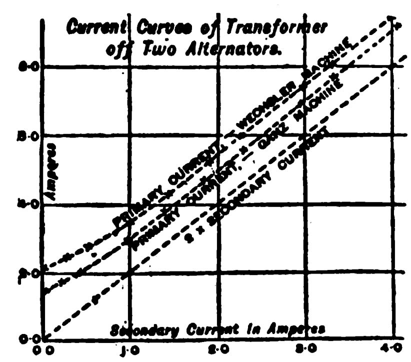

FIG. 32.

sler and the other a Ganz alternator. When these machines were running on open circuit, the Wechsler alternator gives a curve of electromotive force which has a well-rounded form; whereas the Ganz machine has a curve of electromotive force which has a very sharp or peaked form. The machines I chiefly employed in my own experiments were the Mordey alternator, the Thomson-Houston alternator and a Ferranti machine. The form of the curves of electromotive force of the first two named machines, under various conditions, have been shown in Lecture I. The general effect of all these experiments has been to demonstrate that when a transformer is worked off an alternator giving an electromotive force curve with a very sharp or peaked form, the effect of this is to make the iron core loss less, and the secondary drop greater than it is if the same transformer is worked off an alternator having a curve of electromotive force with a rounded or square-shouldered form. If, therefore, we draw an efficiency curve for a transformer, that efficiency curve giving the efficiency—that is to say, the ratio between the watts delivered from the second-

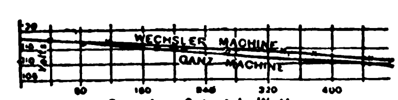

FIG. 33.

ary to the watts taken in on the transformer circuit—and express this efficiency in terms of the fractions of the secondary load of the transformer, the form of that efficiency curve will be affected by the nature of the machine which is supplying the primary current. In Figs. 31, 32, 33, are shown curves illustrating the effect of the employment of different alternators on the same transformer in affecting the efficiency, primary current values and secondary drop of any given transformer, when taken on open secondary circuit.

For fuller information on this point the reader is referred to the treatise on the "Alternate Current Transformer"[1] (Vol. I., Chap. vi., new edition) by the present writer, which will supply more details on this question than we have space to consider here.

ELECTRIC LIGHT POLE CAUSES TROUBLE.

The method of placing arc lamps in the center of a wide street gives a good distribution of light and at the same time a pleasing effect. This necessitates a refuge round the base of the lamp, which is also a great convenience for foot passengers. A new aspect of the case is reported in England, where, to save expense, the lamp on one of these refuges has been switched out at a certain hour each night. No less than three hansom cabs have collided with the obstruction. The first case was tried, and the judge held that the Vestry had a perfect right to extinguish the lamp. The jury, taking, perhaps, the common-sense view of the matter, gave a verdict for the

* "The Alternate Current Transformer in Theory and Practice." 2 vols. The Electrician Printing and Publishing Company, 1 Salisbury Court, Fleet street.

cabby, which the judge did not allow. The case is under appeal. From the recommendation of the electric lighting committee to the Vestry, we see that the Vestry is advised to stick to its guns. It has been suggested that a few incandescent lamps grouped round the lamp column would be the best way to check the series of accidents.

ROENTGEN RAYS.

WAVE LENGTHS OF ROENTGEN RAYS.

A SUMMARY of the researches on Röntgen rays published in "Nature" gives the following information in regard to the experiments to determine their wave length:

An important point in connection with the debated nature of Röntgen rays is the determination of their wave length, which has been successfully effected by Dr. L. Fomm, of Munich (Sitzb. der Bayerischen Akademie, xxvi. ii.). As these rays show no measurable reflection or refraction, the only way available was by diffraction. The Röntgen rays emanating from a large Hittorf tube were made to pass through a brass slit 0.5 mm. in breadth, and, after being diffracted by a second slit, were received on the photographic plate. The width of the second slit could be varied from 0.1 mm. up to 2 mm., and with the former width an exposure of fifty minutes was required. As long ago as March last Dr. Fomm obtained photographs showing interference bands, thus affording proof of the undulatory nature of Röntgen rays. By starting with a very narrow slit and gradually increasing its width, the interference lines approach closer together, until a dark line—the first minimum—appears in the center. As the opening becomes still wider, this minimum gives place to a maximum with two minima, one at each side, and so on, and by means of Lommel's formula, the wave length can be determined from this phenomenon. Dr. Fomm obtains $\lambda = 0.000014$ mm., so that the wave length is about fifteen times smaller than the smallest wave length hitherto observed in the ultra-violet. Owing to the difficulty of determination, Dr. Fomm regards this number as giving the upper limit rather than the exact measure of the wave length of the observed rays. Meanwhile MM. G. Sagnac, L. Calmette, and G. T. Lhuillier have published investigations in the same direction (Comptes rendus, cxxii. 13 and 16). M. Sagnac uses a wire grating, and from a scarcely measurable diffusion of the image of the slit he obtains 0.00004 as an upper limit to the wave length. MM. Calmette and Lhuillier have made diffraction experiments with two slits, and have obtained bright and dark lines without expressing an opinion as to the wave length of the rays.

Another closely allied question is whether Röntgen rays consist, like ordinary light, of radiations whose wave lengths vary over a considerable range. Such differences of wave length give rise in the case of light to the phenomenon of color, and the corresponding phenomenon for Röntgen rays has been studied by Dr. F.-V. Dwelshauvers-Dery (Bulletin de l'Académie Royale de Belgique, No. 6) under the name of actinochroism. Observing that differences in the degree of exhaustion of a Crookes tube might be expected to give rise to differences of wave length in the emitted rays, and that the higher the vacuum the shorter would the wave-lengths probably be, Dr. Dwelshauvers-Dery has examined whether certain substances are more transparent for certain Röntgen rays than for others. For this purpose, their transparencies were compared by placing the substances in front of a fluorescent screen and observing their shadows side by side with that of a test-object consisting of laminæ of tinfoil, whose total thickness could be varied at pleasure. To obtain the necessary variation in the nature of the Röntgen rays, it was found sufficient to compare the radiations from a new tube, which had not been previously used, with those emanating after the tube had been in action for some time. The observations were repeated on the new tube after a quarter of an hour, half an hour, an hour, an hour and a half, and two hours, respectively, and transparency curves obtained by plotting the results on paper. These curves show that (1) the transparency of every specimen, with the exception of obsidian, increases during the first few minutes; (2) agate and alum, after increasing in transparency for some time, become more and more opaque; (3) obsidian continually diminishes in transparency. It is, of course, here a question of relative transparency with respect to tin. Although we have no measure of the variations of the absolute transparency of the tin itself, the experiments suffice to prove that the absolute transparencies of different substances vary according to the state of the tube, and it is therefore, not considered hazardous to explain these variations by the actinochroism of Röntgen rays.

The same phenomenon has been observed by MM. Benoist and Hurmuzescu, and, perhaps, by other physicists. In some of Mr. A. A. C. Swinton's experiments it will be remembered that the properties of Röntgen rays, and particularly their power of penetrating through organic tissues, varied with the degree of exhaustion of the vacuum.

TELEPHONY AND TELEGRAPHY.

TELEPHONE LINE CONSTRUCTION IN THE ROCKIES.

Telephone construction in the Rocky Mountains is attended with a great deal of hardship. The line built from Leadville to Aspen several years ago is a case in point. It took two months, says the Denver "Field and Farm," to cover the entire length, forty-eight miles. In ordinary construction the poles would be set forty-two to the mile, but at certain points where sharp turns are necessary, the number sometimes increased to seventy-five to the mile. The members of the construction gang had to be expert as axmen as well as linemen, for when timber was encountered a path of 200 feet on each side of the line had to be cleared in order that wires might not be broken when trees were blown over by the terrific blasts which at times prevail in that region.

A great deal of the comparative slowness of the installation was owing to the inability of the workmen to labor in such a rarified atmosphere. At one point the wires were strung at an elevation of 12,000 feet above the level of the sea. In such an altitude the linemen soon became completely tired; after he has climbed two or three poles he has to take a rest to recuperate his energies. The preparation of the holes for poles, which would have been tedious in similar ground even in an ordinary atmosphere, was an especially slow and fatiguing operation. It was often necessary to blast a hole for the pole by the use of giant powder, and an ex-miner who had had an extensive experience with explosives, was assigned to the job.

The digging of one pole hole would sometimes occupy him a whole day, working honestly. Over 300 pounds of powder was used on the line for this purpose. When the continental divide was reached the poles had to be abandoned, and the wires placed in a cable, which was buried in a two-foot trench for a distance of 7,000 feet. The advisability of abandoning aerial construction at this point was demonstrated by the experience of the company that maintains the Leadville and Denver line. At one point on that line, Mosquito Pass, the poles were originally set seventy feet apart. As soon as the wires were covered with sleet they snapped and the line was useless. Double the number of poles were then used, with the same result. The space between the poles was then reduced to twenty-five feet, but when the sleet came the line was swept down flat. Eventually an underground cable was laid for two and a half miles, and there has been no trouble since.

DO TELEPHONE SUBSCRIBERS SWEAR?

The following statement of the influence of the telephone on the average subscriber is from the New York "Press." We venture to regard it as grossly exaggerated and untrue:

"The telephone system, as manipulated by the American Bell Telephone Company, is not only an insolent monopoly, but is the greatest uncivilizer of the age. The average man who goes to the transmitter to call up a friend, or for business, becomes a savage. The service in this city is so poor that he is in danger of becoming a devil. If bad language felt as hot as it sounds our telephone subscribers would have a sure revenge against the company, inasmuch as a few well chosen words would suffice to fuse the wires and wreck the plant. But, unfortunately, profanity hurts only the air, which, we have heard, it makes blue.

"Aside from the usual ordinary inducements to swear, which every man encounters in the course of the day—and the women swear a little, too, with their 'plague-take-its,' 'confound-its,' 'oh, bothers,' 'darn-its,' and similar fearful oaths—he is positively encouraged by the managers of the insolent telephone monopoly to let loose the vials of imprecation no less than ten times every twelve hours. A really good man dislikes to swear, and when he catches himself at it he is ashamed. His self-respect is lowered. A brave man who swears feels that the act has weakened his courage. But there is no escape from swearing at the "phone' as operated in this city. It is heathenizing us all.

"We find that there is an infinitesimal amount of swearing at the telegraph, the express, the theatres, the electric lights, the steam railroads, the ocean steamships, the ice trusts, the match trusts, the soda fountains, the bicycles and the type-

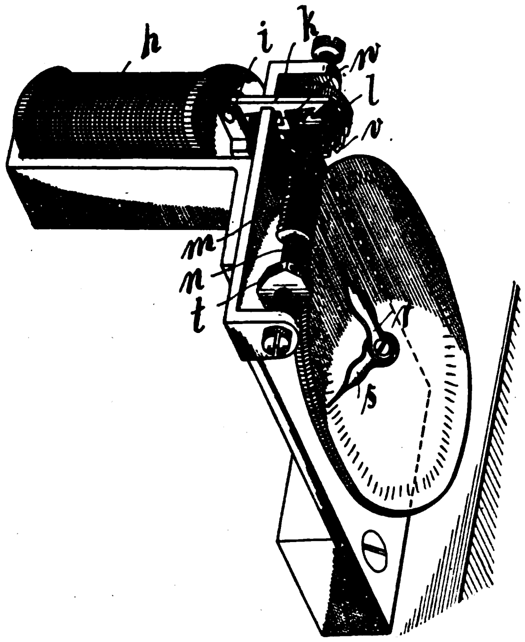
writers, but that nearly all of our profanity is expended upon the telephone, the cable cars and the gas monopoly. And of these three, telephone, cable car and gas, the worst of all is the telephone!"

MUNCH'S TELEPHONIC REGISTER.

A DEVICE for registering the number of times telephonic apparatus is used for conversation, and, if desired, the duration of such conversations, has been invented by August Münch, of Charlottenburg, Germany. For the registration of both the number and duration of telephone conversations, it is essential in any apparatus to be satisfactory that it should be easily and cheaply applicable to the arrangements already in use.

The operation of the registering mechanism is effected by means of single-current impulses which excite an electromagnet which serves to move the registering mechanism. This electromagnet is so connected with the switch mechanism of the central exchange that when the plug is used for the purpose of connecting or separating two subscribers' instruments, circuit closing devices are automatically brought together or separated by the action of the plug upon a spring. In this way the circuit of the electromagnet is either closed or opened so that it acts upon the registering mechanism.

This arrangement is applicable to single or to multiple



THE MUNCH TELEPHONE REGISTER.

switchboards of any system whatever, and possesses the advantage that the registering device may be set up at the central exchange and allows the usual switches to remain unaltered as far as the main details of their arrangements are concerned. It also has the advantage of not requiring a special manipulation of the attendants to operate the device.

When the switchboard plug is inserted or withdrawn, its head moves a projection by means of which an electric circuit from the local battery is closed through the electromagnet h (Fig. 1), of the registering device. The armature i of the magnet is thereby attracted and, by means of a pawl k, caused to operate a ratchet-wheel l, carried by an axle n, furnished with a worm m. This worm engages with two numbered discs p and q, which are able to rotate independently of each other on a stud o and one of which has, as in an ordinary Krafft's revolution-counter, one hundred teeth and the other one hundred and one teeth. In connection with these discs are two pointers, shown in the illustration, one of which, r, stands constantly at zero, while the other, s, turns with the disc, q, the extent to which the latter has turned, as compared with the disc, p, being thereby indicated. The ratchet-wheel l has twenty teeth, so that the armature must be operated twenty times to effect one complete rotation of the ratchet-wheel Two closures of the circuit are required for the registration of a conversation in correspondence with the working of the switchboard. A small numbered disc t on the axle n allows of numbering the units of conversations made. With the construction described this has ten numerals, one for every two teeth of the ratchet-wheel.

The mode of action of the apparatus is as follows: When a call is received from a subscriber, the attendant at the central station draws the corresponding plug out of the earth connection to see whether the desired circuit be free. As the plug is withdrawn two plates are pressed into contact with each other, so that the armature i of the electromagnet is attracted and the ratchet-wheel l is turned to the extent of one tooth and the worm-axle n through one-twentieth of a revolution. The small numbered disc will thus be moved half the distance it is to be moved for a conversation. If the attendant finds the desired circuit free, he will put the plug e in the corresponding aperture of the switchboard, and when the conversation is concluded he will replace the plug in the earth connection, whereupon the armature i will be again attracted and move the worm axle n another twentieth of a revolution, the two partial revolutions moving the registering-disc sufficiently to make the desired record. If the attendant finds the desired circuit engaged as will frequently happen in practice, he then places the plug not in the earth connection again, but in an independent aperture which may be either a dummy or provided with a contact-plate. The condition of the circuit may then be investigated by the attendant from time to time, and when it is finally found to be disengaged the connection is made. When the conversation is concluded, the plug is replaced in the earth connection and the registration by the counting mechanism is completed.

The attraction of the armature is more or less forcible according to the strength of the current in the local circuit, so that it is necessary to provide an arrangement by means of which the worm-axle n is prevented from turning through more than one-twentieth of a revolution for a single movement of the armature. For this purpose a crown-wheel v, with, say, twenty teeth, is placed upon the worm-axle n, and in the intervals between these teeth a catch w on the pawl engages at the moment when the ratchet-wheel l has turned to the extent of exactly one tooth, and thus locks the apparatus against movement until the magnet has been deënergized.

In order to effect the disengagement of the worm m from the indicating-discs, when it is desired to bring these to the zero-point, these discs are carried by a bent arm which rotates upon a pin, this arm being capable of being clamped in position by means of a screw.

If it is desired to record the duration of the conversations a train of clock work is inserted in the local circuit by which it is operated.

THE OPPOSITION TELEPHONE SYSTEM IN DETROIT.

THE Detroit Telephone Company's plant is rapidly approaching completion. Of the 60 miles of conduit that are to be laid 40 miles have already been laid, and the remaining 20 miles will be completed within a short time. Details of its work are given by the Detroit "Tribune." The company has contracted with the Standard Underground Cable Co. for the laying of cable, and shipments of cable to Detroit will begin in two weeks. The cable will all be laid within six weeks. The poles for telephone wire within the half mile circle have been purchased and are in the city and will all be set within three weeks.

The company has secured a 10 years' lease of the Jones building, corner of Griswold and Clifford streets, and will establish its exchange on the upper floor of that building, and begin the construction of the exchange switchboard as soon as the building is ready for occupancy, September 1. Then the work of putting in the 2,000 telephones within the two-mile circle will begin. It will be proceeded with very rapidly, and the company confidently expects to have 2,000 business telephones in operation by the middle of November. The company has nearly 5,000 telephone subscribers, of which number 3,500 have signed three-year contracts.

Of the 5,000 subscribers it is claimed the company has secured practically 80 per cent. of the Bell Telephone Company's subscribers, including almost every wholesale and retail grocer and druggist in the city, three-fourths of the physicians, and almost every business man on Woodward avenue, from the river to the Woodward avenue railroad crossing.

Up to date the company does not owe a cent, but has paid for all labor and material so far used in the construction of the plant. The company is authorized to issue $1,000,000 of stock. The original estimate for the completion of the plant is $600,000. So far in the work the actual cost has run a little below the estimates, and it is confidently stated that this will prove true throughout the entire work of constructing the plant. Of

the $1,000,000 capital stock authorized, $355,100 has actually been subscribed for, of which amount $300,000 has been issued, the remaining $50,000 having been sold to local subscribers on the installment plan, six months' time being allowed in which to pay for it.

Of the total amount of stock subscribed all but $25,000 is held by Detroit parties. There are very few stockholders who own more than $1,000 of stock, and the sum total of the stock held by these persons falls far short of representing a controlling interest in the company. The company can issue $1,000,000 of bonds, but at no time have the directors considered it necessary to issue more than $400,000 of bonds. It was originally proposed that these bonds be sold to stockholders, no individual stockholder being allowed to own more than $500 worth of bonds, but this idea has been abandoned. The company is using its bonds to some extent in paying for its work. The bonds are taken at par value rapidly, and are now being printed.

Stock enough has been sold to complete the plant within the two-mile circle, where the company has 2,000 subscribers. The conduit system of 60 miles will cost less than $225,000, and as soon as it is completed the company will extend it by running a conduit up the alley between Second and Cass avenues to Warren avenue. This is not required by the company's ordinance, but it is considered to be a stroke of economy in the long run on account of the great multiplicity of poles and wires already in the alley.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED AUGUST 25, 1896.

Alarms and Signals:—

SIGNAL APPARATUS. J. P. Coleman, Edgewood Park, Pa., 566,499. Filed May 21, 1896.

A fluid pressure cylinder for controlling the movements of a mechanically actuated signal.

AUTOMATIC SIGNALING. J. P. Culgan, Swissvale, Pa., 566,503. Filed March 18, 1896.

The arrangement of two banners in a case in such a manner as to be shiftable into and out of line with a common aperture and an arrangement of circuits operating magnets, whereby the banners are shifted into line with the aperture in the case or shell. It further provides for the successive control of a signal by two successive track-circuits.

ELECTRIC SWITCH AND SIGNAL APPARATUS. J. G. Schreuder, Wilkinsburg, Pa., 566,541. Filed March 31, 1893.

Method of operation and control of several parts of appliances of a railway switch and signal apparatus and the illumination of the signals by electric currents from a dynamo electric machine located at some central point or station.

ALARM FOR BOILERS. J. O'Connor and C. A. Turner, New York, 566,612. Filed March 20, 1896.

A float having connections at its highest and lowest positions with an electric alarm circuit.

Secondary Batteries:—

METHOD OF MAKING SECONDARY OR STORAGE BATTERY PLATES. W. Petschel, Berlin, Germany, 566,531. Filed Jan. 18, 1896.

Process consists in mixing or stirring together oxide of lead with sulphate of zinc in solution, so as to form a paste, then molding the paste, drying and then submitting to the action of dilute acid.

Conductors, Conduits and Insulators;—

INSULATOR SUPPORT. J. B. Oliver, Shields Station, Pa., 566,468. Filed Dec. 30, 1895.

Details of construction.

CONDUIT OUTLET INSULATOR. F. W. Erickson, Revere, Mass., 566,507. Filed June 8, 1896.

A hollow metallic pipe of the conduit, and an insulating member enveloping the outer and inner surfaces and the end or edge of the metallic member opposite to the end which is attached to the conduit pipe.

ELECTRIC CABLE CONDUCTOR AND SHEAVE WHEEL. J. F. Place, Montclair, N. J., 566,697. Filed April 12, 1894.

The combination of copper with other metal and insulating material, so arranged that the copper forms the outside and the other metal the core or inside of said conductor, with the insulating material as an annular ring between said copper and other metal.

Dynamos and Motors:—

RING ARMATURE. F. B. Badt and O. S. Lyford, Jr., Chicago, Ill., 566,288. Filed Jan. 15, 1896.

An armature provided with ventilating channels through its core.

BRUSH HOLDER FOR DYNAMO ELECTRIC MACHINES. C. E. Woods, Chicago, Ill., 566,366. Filed Jan. 15, 1896.

A frame having a series of brush-holding devices provided with a movable part adapted to engage the brush and a series of elastic connecting devices.

Lamps and Appurtenances:—

ARC LAMP HANGER. W. S. Bosley, Chicago, Ill., 566,652. Filed Feb. 13, 1896.

The lamp is suspended from a drum or roller, means being provided for rotating the drum to wind thereon or unwind therefrom the cords or cables from which the lamp is suspended. To the suspending cords is attached the cross-piece, which, when the lamp is raised, actuates a switch which throws the lamp into circuit.

Miscellaneous:—

SELF-WINDING ELECTRIC CLOCK. E. G. Hammer, Brooklyn, N. Y., 566,313. Filed Jan. 12, 1891.

The spring is wound at intervals by means of an electromagnet.

ELECTRIC HEATER.—H. O. Rockwell, St. Louis, Mo., 566,341. Filed Feb. 8, 1896.

A special frame within which the resistance wire is wound.

ELECTRIC DISPATCH SYSTEM. C. F. Pike, Philadelphia, Pa., 566,532. Filed May 31, 1895.

A tube having exhaust mechanism, a transmitter and receiver having end gates, one of which is controlled by a carrier exhausting mechanism and air supply for the receiver, electromotor for a carrier and a line conductor in the tube for the electromotor carriers.

ELECTRICAL HAMMERING MACHINE. T. C. Robinson, Boston, Mass., 566,537. Filed March 6, 1895.

A tack driving machine comprising a holder, a tack delivering throat, a driver movable in said throat, an electric motor within the casing to project and retract the driver and a motor controlling switch.

ELECTRIC HEATING APPARATUS. R. A. L. Snyder and A. F. Tinnerholm, Pittsburg, Pa., 566,545. Filed July 23, 1895.

An open magnetic core, a short-circuited secondary entirely surrounding the said core, a primary coil wound on the outside of the said short-circuited secondary.

ELECTRIC HEATING APPARATUS. M. W. Dewey, Syracuse, N. Y., 566,564. Filed July 24, 1891.

An electric heater covered with illuminated artificial fuel.

STEAM GAUGE. J. O'Connor and C. A. Turner, New York, 566,613. Filed March 20, 1896.

A steam gauge having a scale and an index arranged in the path of the index, an electric circuit, including said contact, and an electrically operated device controlled by the electric circuit when closed.

ELECTROLYTIC APPARATUS. O. W. Fielding, London, England, and L. B. Walker, Elizabeth, N. J., 566,673. Filed May 11, 1896.

The combination with anode and cathode plates, of separating and supporting blocks of insulating material having cords or flexible connections as a support.

ELECTRIC RHEOSTAT. H. W. Leonard, New York, 566,693. Filed May 10, 1895.

A method of preventing undue heating in an electric conductor, by placing the conductor in close proximity to a large mass of material having a high specific capacity for heating.

Railway Appliances:—

TROLLEY SUPPORT FOR ELECTRIC RAILWAYS. S. H. Short, Cleveland, O., 566,345. Filed April 20, 1896.

A laminated flat spring rigidly attached to the roof of the car, and which bends in the direction of the length of the car.

TROLLEY WIRE HANGER. W. Cooper, Schenectady, N. Y., 566,-376. Filed Sept. 28, 1895.

A wooden bar arranged above and substantially parallel with the trolley wire and supporting the trolley hanger proper and arranged to slide back and forth in a collar that is rigidly secured to a cross-arm above.

ELECTRIC RAILWAY CONDUIT. W. S. Hull, Dallas, Tex., 566,-397. Filed Feb. 28, 1896.

Contains a continuous metallic conductor, and a sectional metallic segmental conductor laid upon the upper interior walls of conduit and an inner, insulating tube held between the sections of the conduit and a hollow metallic spherical switch to travel bodily through the conduit in contact with segmental conductor.

ELECTRIC RAILWAY. C. Skinner, Chicago, Ill., 566,542. Filed March 7, 1895.

A sealed conduit placed alongside of and parallel to the track and circuit-closing devices for conducting the current from current wire to the car, the circuit-closing devices being operated by mechanical means that are actuated by the car.

BOND-CONNECTOR FOR RAILS. J. Bryan, Pittsburg, Pa., 566,-709. Filed May 21, 1896.

A connector which can be employed for attaching a continuous wire to the rail independent of the bond-wires at points intermediate of the rail ends or at the points at which the bond-wires are attached.

SWITCH FOR CONDUIT SYSTEMS OF ELECTRIC RAILWAYS. J. L. Hornig, St. Louis, Mo., 566,714. Filed Aug. 26, 1895.

Details of construction.

Regulations:—

SYSTEM OF CONTROL FOR ELECTRIC MOTORS. E. A. Sperry, Cleveland, O., 566,426. Filed Feb. 16, 1895.

Contacts for regulating the supply of energy to the motors and the brake magnets, contacts for weakening the field of one of the motors when they are used for braking the car, and the contacts for weakening the field of both motors when it is desirable to increase the speed of the car.

Switches, Cut-Out, etc:—

ELECTRICAL INDICATING AND CUT-OUT APPARATUS FOR PORTABLE OR OTHER ELECTRIC LAMPS. B. Hacking and G. Brand, Nottingham, England, 566,573. Filed Jan. 13, 1896.

A clockwork having a stop mechanism (which may be similar to that of an ordinary stop-watch) so connected with the switch of the electric lamp that the manipulation of the switch to light the lamp sets the clockwork in operation.

Telegraphy:—

FAC-SIMILE TELEGRAPHY. H. W. C. Cox and R. J. Crowley, London, England, 566,298. Filed June 19, 1895.

An ink which will permeate paper on which a message is written and which will by its permeation render the paper a conducting medium.

Telephones:—

APPARATUS FOR REGISTERING THE NUMBER OF TELEPHONIC CONVERSATIONS. A. Munch, Charlottenburg, Germany, 566,334. Filed Oct. 25, 1894.

For description see page 235.

TELEPHONIC APPARATUS. C. J. Schwarze, Adrian, Mich., 566,-416. Filed Feb. 11, 1896.

An instrument adapted to be used in connection with different telephone exchanges and which is made capable of being quickly changed from a magneto to a microphonic telephone, as required.

TELEPHONE EXCHANGE SYSTEM AND SWITCHING APPARATUS. A. R. Bennett, London; G. J. Somerville, Heaton Chapel, and R. McLean, Nottingham, England, 566,648. Filed March 20, 1896.

Enables the subscriber to a telephone exchange worked with metallic circuits to speak to the operator at will without any preliminary calling signal or the use of a special service or calling wire.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Miscellaneous:

CONDITION OF ELECTRICAL INDUSTRY IN BERLIN. —Reports of the firms Siemens & Halske, Allgem. Electr. Ges., Berl. Maschinenbau A. G., furnished to the Board of Trade. All report progress and a healthy condition of the trade.—"Elektrotechn. Zeitschr.," Aug. 13, '96.

Electro-Physics:

POLARIZATION PHENOMENA IN AN ELECTROSTATIC FIELD.—By Dr. L. Lombardi. From the annual report of the physical society, Zurich. Repeating former experiments by Grätz and Fromm, author investigated under Prof. H. F. Weber various dielectric constants; he found for petroleum 2.03, for olive oil 3.11, for water at 15° C. 80.4.—"Elektrot. Zeitschr.," July 30, '96.

Measurements:

DETERMINATION OF DIELECTRIC CONSTANT.—By Dr. C. Henike. A description of the handling of a rotating double commutator (secohmmeter) to determine the dielectric constant and temperature coefficient of liquid insulators.—"Elektrotechn. Zeitschr.," July 30, '96.

Dynamos and Motors:

ROTARY CURRENT MOTORS WITH REDUCED SPEED.—By Hans Görges. Delivered before the Verband Deutscher Elektrotechn. Author explains that three-phase motors can run or be made to run at two different speeds; that at times a motor may be made to run ahead of synchronous speed and will then act as a generator, which action may be utilized as brakes in hoists or possibly in railway service.—"Elektrotechn. Zeitschr.," Aug. 13, '96.

ON THE MULTIPLICITY OF BRUSHES IN LARGE GENERATORS.—By Wm. Baxter, Jr. Author advocates the use of a single pair of brushes.—"Elec. World," Aug. 29, '96.

Mechanical:

ROPE DRIVING.—By Abram Combe. In "Notes on the introduction and development of rope driving," the author advocates low velocity. The following minimum diameters of pulleys for the various sizes of ropes are quoted:

1¼ inches diameter rope,	3 feet diameter pulley;	ratio 1 to	28.8
1½ " " "	4 " " "	" 1 "	32.
1¾ " " "	5 " " "	" 1 "	34.3
2 " " "	6 " " "	" 1 "	36.

Power transmitted by each of the foregoing sizes with 100 rev. per minute, made by the pulley:

Rope 1¼ inches diameter	on a 3 foot pulley,	5 I. H. P.
" 1½ " "	" " 4 " "	8 "
" 1¾ " "	" " 5 " "	11 "
" 2 " "	" " 6 " "	15 "

Lond. "Elec.," Aug. 14, '96.

Mining:

THOMMEN COLLIERY IN VASAS.—Careful estimates gave the following expenditure for installing a steam plant:

Engine with piping, pumps and installation	fl 8,150
Machinery for coal separation	1,080
Illumination of colliery with 35 lamps (separate engine and dynamo)	1,600
	fl 11,200
	$4,032

For electric plant:—

Two dynamos with triple pump, including wiring and piping	fl 4,800
Electrically driven coal separator and lighting	2,400
Steam engine	1,300
	fl 8,500
	$3,060

The later was installed and is described in detail with illustrations in "Elektrotechn. Echo.," Aug. 8, '96.

Electro-Chemistry:

FLUORESCENT SUBSTANCES.—By A. Schertel. A short prescription for preparing platino cyanides.—"Journ. of Franklin Inst.," Aug., '96.

DESCRIPTION OF THE ALUMINA FACTORY AT LARNE HARBOUR.—By James Sutherland. Read before the Instit. of Mech. Eng'rs. After stating the sources of Al. author explains the K. H. Bayer process of manufacture from bauxite.—Lond. "Elec. Engr.," Aug. 14, '96.

Isolated Plants:

THE SYNDICATE BUILDING.—Light and elevator service are on the same 110-volt circuit. Three 200 horse-power engines and 100 kilowatt internal pole dynamos. Building is wired for 1,750 lights, taking 35,800 feet of wire. Details in "Elec. World," Aug. 29, '96.

Railways:

HOW TO SAVE MONEY ON FEEDERS.—By J. E. Woodbridge. An arrangement of rotary transformers is illustrated diagrammatically and described.—"Elec. World," Aug. 29, '96.

ELECTRIC RAILWAY UP MONT SALEVE, GENEVA.—Well illustrated description of this mountain road.—"Elec. Engr.," Aug. 26, '96.

PRINGLE AND KENT'S SURFACE ROAD.—A line with insulated studs with a distributor which supplies twenty-four surface contacts in succession, thus doing away with a great many electromagnetic switches. Summary of cost adapting this system to an existing tram line.

Cost per mile of single track, with distributors arranged to supply cars running in either direction; distributors and brick boxes	£ 301.	11.	0
Main conductor, 1 square inch section	755.	...	..
Iron conduit, excavating, concreting, etc.	1,228.	19.	..
Total per mile	£2,292.	10.	0
Cost per mile of double track	£4,130	0.	0

Lond. "Lightning," Aug. 13, '96.

Roentgen Rays:

AN X-RAY LABORATORY IN CHICAGO FOR MEDICAL DIAGNOSIS.—Dr. O. L. Schmidt and Dr. F. C. Harnisch have just opened this laboratory, the installation of which is illustrated and described in "Western Elec.," Aug. 29, '96.

Central Stations:

LIGHTING AND TRACTION FOR PLYMOUTH.—Mr. John H. Rider, M. I. E. E., handed in his report upon this plant, advocating the combination of light and railway service. The initial installation is to include three Lancashire boilers, with mechanical stokers and coal-conveying plant; two direct coupled steam alternators of 200 kilowatt each; two 100 kilowatt sets, each consisting of a vertical high-speed engine, with an alternator and a dynamo; rectifiers, or rotatory transformers, for the arc lighting; a battery of accumulators; and the requisite switchboards, condensers, pumps, etc. Electric motors will take the place of small engines for driving all the subsidiary machinery in the works. The estimates of total cost of installation is £46,000.—Lond. "Lightning," Aug. 13, '96.

Power Transmission:

ELECTRICITY AND MOTOR POWER.—By Mark A. Replogle. With an article on the "Greatest of electric water power propositions, Niagara Falls," this series of articles is brought to a close.—"Elec. Rev.," Aug. 26, '96.

Alternating Currents:

NOTES ON POLYPHASE CURRENTS.—By E. Gerard and G. Henrard. Data on European practice, from "L'Eclairage Electrique," in "Elec. Rev.," Aug. 26, '96.

NEW YORK NOTES.

THE ELECTRICAL MAINTENANCE COMPANY, 50 Broadway, is now almost two years in business and can count on its books about 300 electric plants in New York City and Brooklyn, comprising 952 machines of about 49 different makes. They have also 100 plants in Philadelphia, 25 in Baltimore and 33 in New York State. This company is similar to an insurance company, employing expert electricians to test the electrical machinery and appliances in plants, keeping them in order, assuming necessary expenditures to remedy defects, etc., etc., and making a reasonable charge for its services rendered.

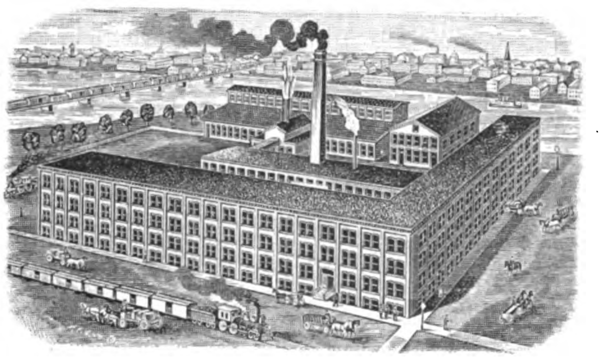
THE ELECTRIC APPLIANCE COMPANY report that their success with Armorite iron armored interior conduit is away ahead of their expectations, and their sales have already been very large.

Trade Notes and Novelties

AND MECHANICAL DEPARTMENT.

BARNES' METAL WORKING MACHINERY.

WE illustrate herewith the factory of the W. F. and John Barnes Company, located at 281 Ruby street, Rockford, Ill. This company, who manufacture a variety of high-grade machinery for metal working, both for foot and steam power, call special attention to their No. 4½ lathe which is the smallest back-geared and screw cutting lathe they make. This machine feeds right or left and cuts screws right or left with-



W. F. & JOHN BARNES FACTORY.

out change of gearing. The carriage is thoroughly gibbed for taking up wear. A general view of the machine is given in Fig. 2. These lathes are not made with an automatic cross feed. Twenty-five years' experience as lathe users and builders has convinced the company that on a small lathe, say, less than 15 or 16 inches swing, automatic cross feed is of no particular advantage. The tool carriage on these lathes swivels so that the tool can be set to work at any desired angle, and it also adapts the lathe for taper boring. These features, they believe, are of greater value than automatic cross feed.

The tail stock has side movement to adjust the centers for turning tapers. The head stock has hollow spindle for rods up

BARNES' NO. 4½ LATHE.

to ⅝ inch. All the gearing is cut from solid metal and all parts are made of steel where this best serves the purpose.

It will cut all ordinary threads from 5 to 48, and miscellaneous threads up to 154. It swings 9 inches, and takes 25 inches between centers. It swings 4¾ inches over tool carriage.

The company publish a catalogue which they will be pleased to forward to all interested users of high-grade metal working machinery.

CLEVELAND, O.—The Bradley Electric Light, Heat and Power Company, of Cleveland, has been formed by G. Lillis, J. C. Burgess, S. H. Holding, M. W. Neal and F .S. Mather with a capital stock of $100,000.

HUEBEL & MANGER'S NEW CATALOGUE OF ELECTRICAL GOODS.

THE enterprising and progressive firm of Huebel & Manger, 278-282 Graham street, Brooklyn, have just issued a neat and complete new catalogue of their electrical and brass goods. They give special attention, as is well known, to bells and push buttons, and this, their third catalogue, displays a very handsome and comprehensive assortment of such wares. Their bells have pure platinum in the contacts, riveted and not soldered, in the spring and screw, and are distinguished also by having their improved lock nut and immovable binding and contact posts. The gongs are nickel plated brass, of clear, sharp tone. These goods in all the classes of iron box, wooden box, and iron frame are excellent, and the prices are fair and moderate. A page is devoted to showing the different styles of gongs that are usually fitted on their bells, and the fact is mentioned that they also furnish a 2½ inch wooden gong.

The push button goods are also shown in a great variety of styles, all being made with hard rubber centers and German silver springs, and with washers under the contact screws. They also have hard fiber backs. The sizes are like the shapes, numerous and suited to all standard work in the house, office, etc. The specialty in improved water-tight push buttons brought out in 1895 is admirably adapted to use in cold storage warehouses and other damp places. It is made with a protecting inner cap, while the connecting wires also run in through insulating tubes.

Among other goods made by the firm and illustrated or mentioned in their catalogue are gas key pushes, watchman's key switch, table pushes and connections, midget pushes, rubbing contacts, bronze letters, wood and rubber switches, window attachments, mouthpieces, letter boxes, binding posts, etc. There is also a very ingenious line of brass novelties in the shape of cigar rests and ash receivers, combination pincushion and spool holders, etc., to be clamped readily on chair or table, and for which a large market must exist everywhere. The firm will be glad to send a copy of this catalogue to any address.

CLAY AND PORCELAIN GOODS.

The Akron Smoking Pipe Company, of Mogadore, O., are extensively engaged in the manufacture of all kinds of white and brown clay and porcelain insulators, being a new department which this company have added to their business. They make insulators in a variety of sizes running from one to twenty-four inches, with diameter from 5-16 to 1¾ inches. They also manufacture in the three materials two styles of cleats which are designed to hold two wires, a complete line of knobs suitable for all wiring purposes, such as telephone, telegraph, street railway purposes, etc., and a line of specialties. They solicit any specialty that is used in quantities that can be manufactured either of porcelain or clay material, such as fuse boxes, switchboard plates, etc.

RACINE ENGINES.

The Racine Hardware Company, of Racine, Wis., are building a general purpose engine, but it is specially adapted for electric lighting or other purposes requiring uniform power, close regulation and extreme economy.

They build high grade automatic cut-off engines in the small sizes, the vertical from 1 to 55 horse-power and horizontal from 30 to 55 horse-power inclusive. These engines have been on the market for the past ten years, and have gained a reputation for service, durability, economy and general efficiency. They embody the highest quality of mechanical construction throughout, and contain the best material.

All "Racine" engines are furnished with a broad outer bearing, giving three bearings to the shaft for belt connection and four bearings for direct dynamo connection. They are furnished with a sub-base and do not require an expensive foundation. All wearing parts are made adjustable to wear. Seventy per cent. of the company's engine sales are for electrical purposes.

CENTRAL ELECTRIC 100-HOUR ARC.

The Central Electric Company, 173-175 Adams street, are introducing a new 100-hour arc lamp for use on 110-volt direct current circuits. The lamp is used singly instead of the usual "two-in-series" fashion and gives a brilliant yet soft and steady light without hissing or noise of any kind. The Central Electric Company also reports a very encouraging prospect for fall business. Even during the dull season orders for such standard goods as Wagner transformers, okonite wire, and interior conduit, have continued without apparent diminution. Large orders have been recently placed for brass and iron armored conduit. The season for fan motors just

closing has been a very successful one. The Lundell seems to gain popularity as the seasons go by. The Central Electric Co. have sold several hundred more this year than last.

J. H. BUNNELL & CO.

The old and ever enterprising firm of J. H. Bunnell & Co., 76 Cortlandt street, New York City, have stolen a march on Father Time by issuing in August their catalogue, No. 15, dated October, thus eclipsing the magazines which usually appear half a month before they are due. It is an unusual thing, indeed, to see a catalogue ahead of time; in fact we have known of catalogues that were belated a whole year; but in the present case the promptitude shown is but another evidence of the intention of the firm of J. H. Bunnell & Co. to be up and doing, no matter how hot the summer or how unsettled the political aspect. In fact, there are many lines of electrical goods that are just as necessary, in the dullest times, as bread, beef and whisky, and such electrical goods, the firm propose to supply, once they can get within touch of a prospective customer.

The catalogue runs a length of 224 profusely illustrated pages (800 cuts, many of them new), and the cover bears a neat reproduction of one of the diplomas awarded the house at the World's Fair. The goods brought under notice range through all the branches of the art, from telegraphy to X-ray apparatus, and embrace whatever is standard and up to date. The selection of tools and implements is also complete and excellent in every way.

Accompanying the catalogue, the firm have sent out, and will supply to any address on application, a copy of S. M. Wells' "Electropathic Guide," a book intended to go with the J. H. Bunnell & Co.'s No. 4 D. D. Medical Battery. This little book contains a great amount of well digested data on the subject of diseases to which electrical treatment is applied.

CHLORIDE CELLS FOR "ELLERSLIE."

The Electric Storage Battery Company has closed a contract through W. T. Hiscox & Co., for a storage battery installation for "Ellerslie," the residence of Governor Morton, at Rhinecliff, N. Y.

The battery, which will be located in the power house, 1,400 feet away from the mansion, will consist of 67 chloride accumulator elements, type G-11, in lead-lined wooden tanks. The generator will be run but a few hours per day, and the battery will carry the lighting load during the time that the dynamo is shut down and over Sunday, thus giving a 24-hour lighting service per day with but a comparatively very few hours' run of the generator.

BIG BUSINESS OF THE WALKER CO.

AMONG recent orders received by the Walker Company may be mentioned incandescent lighting machines, as follows: One 100 kilowatt and one 30 kilowatt direct connected, multipolar generators for Murray Hill Hotel, New York City, and switchboard complete; Two 75 kilowatt, direct-connected, multipolar generators for Windsor Hotel, New York City; one 50 kilowatt, direct-connected multipolar generator and switchboard for Cochin, China.

Railway generators as follows: Six 600 kilowatt, special rope driven multipolar generators and switchboard for Chicago City Railway Company; four 200 kilowatt, direct-connected multipolar generators for Englewood and Chicago Railroad (storage battery road); one 400 kilowatt, direct-connected multipolar generator for London, Ont., Street Railway Company; one 300 kilowatt, direct-connected multipolar generator for Pacific Power Company, of San Francisco, Cal.; two 150 kilowatt, direct-connected multipolar generators and switchboard for Albion Construction Company, Chicago, Ill.; one 1,200 kilowatt, direct-connected multipolar generator for Metropolitan Street Railway Company, of Kansas City, Mo.; two 400 kilowatt, direct-connected multipolar generators and switchboard for Brooklyn Bridge; one 600 kilowatt, direct-connected multipolar generator and switchboard for Albany Railway, Albany, N. Y.; two 600 kilowatt, direct-connected multipolar generators and switchboard for Syracuse Street Railway Company, Syracuse, N. Y.; two 100 kilowatt belted generators for Hamburg, Germany; two 250 kilowatt, direct-connected multipolar generators and switchboard for Newcastle Electric Company, Newcastle, Pa.

Among recent orders for equipments may be mentioned: Twelve double No. 3 narrow gauge motor equipments for Hamburg, Germany; forty No. 3 double motor equipments for Brooklyn Heights Railway Company, Brooklyn, N. Y.; twenty-three No. 10 special storage battery equipments for Englewood and Chicago Electric Railway, of Chicago, Ill.; four double No. 10 motor equipments to Union Railway Company, of New York City; five double No. 10 motor equipments for Albany Construction Company, of Chicago, Ill.; one double No. 3 motor equipment for Meridian Street Railway Company, of Meridian, Miss.; one double No. 3 motor equipment for Market Street Line, San Francisco, Cal.; eleven double No. 15 motor equipments for Rapid Railway Company, Detroit, Mich.; eight 50 horse-power equipments for Union Railway, New York City.

Among recent shipments may be mentioned: one 100 kilowatt, direct-connected multipolar generator to Rapid Railway Company, Detroit, Mich.; two 750 kilowatt, direct-connected multipolar generators to Detroit Railway, of Detroit, Mich.; one 600 kilowatt, direct-connected multipolar generator for Los Angeles Street Railway Company, of Los Angeles, Cal.; one 25 kilowatt, direct-connected, 220 volt, multipolar generator for Abner-Doble Company, of San Francisco, Cal.; one 50 kilowatt, direct-connected incandescent lighting machine for Jordan Marsh & Co., of Boston, Mass.; three 25 kilowatt, direct-connected incandescent lighting machines for Mohawk building, Cleveland, O.; five double No. 3 motor equipments to Hamburg, Germany; five double No. 3 narrow gauge equipments to Paris, France; five double No. 4 motor equipments to Rahway, N. J., and numerous other orders for equipments.

NEW ELECTRIC CARRIAGE OF THE AMERICAN ELECTRIC VEHICLE CO.

ON Tuesday, August 25, several representatives of the trade and technical press had a very enjoyable ride in the new electric brake which has just been constructed by the American Electric Vehicle Company, of Chicago, for the well-known firm of Montgomery Ward & Co. This concern have an immense business all through the country, which is entirely transacted through the mails, as they don't employ any traveling salesmen. It is their intention that the brake shall be sent all over the States. Stops will be made in the principal towns, and the carriage driven through the streets. A Pullman car has been purchased by the company, which they have had elegantly fitted with sleeping and living accommodations for the use of those who will have charge of the brake. In the middle of the car a place has been constructed which will be occupied by the brake during the journeys between the different points.

The brake, which is an elegant specimen of the carriage builders' art, is equipped with two 2 horse-power single reduction motors which can be worked up to about double their nominal capacity when necessary. Instead of the sprocket and chain gear which has been so generally used on horseless carriages, the two motors are geared direct to the rear wheels of the vehicle by two small rawhide pinions on the motor shafts, meshing into large brass pinions attached to the axle inside the wheels.

Attached to each of the motors are also two geared wheels for the purpose of changing the speed of the motor shaft when necessary, this unique piece of mechanism being regulated from the driver's seat. The carriage is also equipped with controller, brake and steering apparatus, and for night runs two incandescent lamps are used which are enclosed in handsome lamp holders of the regular type used in carriages. The carriage is very light in appearance, contains two seats capable of holding six persons, and will be able to run up to a speed of 14 miles an hour. The motors and controllers are of a special pattern made by the American Electric Vehicle Company, the storage batteries being of the well-known make of the Syracuse Electric Battery Company, Syracuse, N. Y.

CLAIMS IN FAVOR OF ENCLOSED ARCS.

The "Pioneer" enclosed arc lamp, manufactured by the Electric Arc Light Company, 687 and 689 Broadway, demonstrates that it is possible to obtain an absolutely steady arc without casting any shadows on the globe. Before the advent of the enclosed arc, it was common to see arc lamps sputtering and burning irregularly, and globes being cloudy with shadows. Even with the best open arc lamps of the present time the presence of shadows is noted on the globes. When the method of operation of these lamps is taken into consideration the explanation of this disagreeable feature is simple. In the open lamp the arc is very short, being generally less than an eighth of an inch in length. When the lamp is in operation the light from the arc is largely obscured by the carbon points, the latter casting shadows on the globe.

With the enclosed arc operated by the Marks method the distance between the carbon points is about four times as great as in the case of the open arc, and the light is not obscured. Besides this the carbons are very small in diameter, thus increasing the efficiency of the arc and giving the largest percentage of available light. Moreover the small enclosing bulb

which is used in the "Pioneer" lamp acts as a diffusing medium and distributes the light perfectly. It is safe to say that over 25 per cent. of the light which is lost in the open arc is made use of in the "Pioneer" enclosed arc.

CHANGES IN THE CUTTER CO.'S BUSINESS.

The Cutter Electrical and Manufacturing Company, of Philadelphia, report that they have closed out their entire construction and repair business to Messrs. Francis Bros. & Jellett, of that city. This step has been taken by reason of the large increase in their manufacturing business. In future the Cutter Electrical and Manufacturing Company, will devote their entire attention to the manufacture of their two specialties, the C-S flush switch and the I-T-E circuit breaker. Notwithstanding the dull season the Cutter Electrical and Manufacturing Company report that their sales during the previous two months have far exceeded the business done in any other two months. This is largely due to the success which has attended their efforts to introduce their I-T-E circuit breaker.

The Electrical Exhibition held in May last in this city gave them an unusually good opportunity to bring their needed device before the public, which was just about ripe for such an improvement. Making an attractive display, and having a thoroughly reliable article, the need for which was daily growing stronger, it was natural to expect largely increased business, but the actual business done has far exceeded their expectations.

They have closed contracts for their circuit breakers well known by the name "I-T-E," with some of the most exacting electrical concerns in the United States. These orders were not placed until the circuit breakers were subjected to every known test, and it was clearly demonstrated that their device would do all and more than was claimed for it. The edition of their I-T-E circuit breaker catalogue which was published last spring, has been almost exhausted, and they are about to go to press with another edition, containing all their improvements to date.

NEW PLANT FOR THE EMERSON MFG. CO.

The Emerson Electric Manufacturing Company, of St. Louis, after five years in their present location, have found that they need increased facilities and quarters better adapted to their growing business, and have secured a new location at Eighth and St. Charles streets, in the very center of the wholesale and manufacturing district, where their several departments of manufacturing will be on one floor, and in exceptionally large, roomy and well lighted quarters. They have arranged to keep their business moving with little delay, and assure their customers that orders will have as prompt attention while the change is being made, as heretofore. In spite of dull times, this enterprising firm have secured a large increase of business for 1896, over the year of 1895, and with increased facilities in their new location, are prepared to make a new record for the future.

THE DALE COMPANY.

Our readers will be interested to learn that the former Dale Manufacturing Company has ceased to exist and that it has been succeeded by the Dale Company, a corporation formed under the laws of the State of New York. Mr. John H. Dale is the president of the new company, and will have personal charge of the manufacture and sale of its product. As heretofore, the company will devote its energies to electric light specialties, combination fixtures, etc., but new facilities are being added, and the delivery of goods will be expedited. All orders will be filled according to the numbers in the existing Dale catalogues, copies of which will be sent to any address upon request; and the old rates of discount still apply.

The company's agents are: Kennedy & Du Perow, Washington; Pettingell-Andrews Co., Boston; Standard Electrical Works, Cincinnati; Michigan Electric Company, Detroit; Robbins Electric Company, Pittsburg; Commercial Electric Company, St. Louis; Western Electric Company, Chicago and New York. All mail matter should be addressed to the Dale Company, 108 Greenwich street, New York, and not to the Dale Manufacturing Company, which, as stated, is now out of existence.

NEW ENGLAND NOTES.

MR. GEORGE C. EWING, of Boston, agent for the Western Electric Company's electric railway apparatus, is also doing a successful business in second-hand apparatus of all kinds. He has at present a lot of railway apparatus, including cars, motors, controllers, etc., which he is offering at surprisingly low figures.

MR. CHAS. N. WOOD, of Boston, is enjoying a well-earned reputation as a reliable dealer in second-hand apparatus, and has on hand some bargains in electric railway appliances that are worth inquiring into.

THE WHEELER REFLECTOR COMPANY, of Boston, are calling the attention of the electrical trade to their immense variety of reflectors, of which they always have on hand a large stock for immediate delivery. This company are the pioneer in this line of goods, and as the shortening days and earlier nights approach, they are enjoying a good business, in furnishing progressive users of incandescent light with suitable reflectors, which undoubtedly enhance its value and at the same time produces effects otherwise unattainable. Rather pleasant reflections in these dry days!

BRATTLEBORO, MASS.—A Cushing switchboard for operating the electric lights in the opera house has been placed in the auditorium. The board is equipped with 38 switches, which control the lights in all parts of the stage and audience-room, and four dimmers for varrying the intensity of the light, whereby any combination of colors may be made, producing sunlight and moonlight effects, etc. The board is also equipped with two large switches which control all the lights in the house. The stage is furnished with 120 24-candle-power white lights, 124 red and 124 green lights of the same candle-power.

NEW YORK NOTES.

THE METROPOLITAN TELEPHONE COMPANY has transferred its property and buildings in this city to the New York Telephone Company, which takes its place.

MR. FRANK SUTTON, E. E., a former graduate of Columbia University, has opened an office as electrical engineer at 27 Thames street. He is prepared to do general consulting work.

THE STAR ELECTRIC LAMP COMPANY, of Tarvers, N. Y., has been formed with a capital stock of $50,000. The directors are: J. Silver, of New York City; R. R. Moffatt, of Brooklyn, and G. W. Mills, of Elizabeth, N. J.

THE DALE COMPANY, of New York City, has been formed to make electrical chandeliers and other electrical supplies. The directors are W. E. Hawkins, J. H. Dale and D. Dale, all of New York City. The capital stock is $25,000.

FIRE IN THE "BIG STORE."—A fire broke out last week among some painters' stores in the basement of Siegel, Cooper Co.'s new "Big Store," and an explosion resulted. The only person who was hurt was Mr. Harry Alexander, the electrician, who was burned on the hand by blazing oil. His dynamos were close to the place of danger, but he stuck to his post and gave valuable aid to the firemen by keeping the otherwise dark basement lighted. It will be remembered that Mr. Alexander has installed for the company a large plant, which his staff have lately been getting into full operation.

Electrical Engineer.

Vol. XXII. SEPTEMBER 9, 1896. No. 436.

MISCELLANEOUS.

THE TESTING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY'S WORKS.—I.

BY THEO. STRAUS.

INTRODUCTORY.

THE General Electric Company, realizing the necessity and importance of thoroughly testing all apparatus before shipment, have, at an immense outlay, constructed at their Schenectady works a model building, to be used for testing and experimental purposes. This paper is intended to place before the public in a general manner, the striking degree to which this department has been developed in the last few years, and to give a description of this building, with its different modern appliances, resources and means for testing the various styles, forms and types of machines, now placed by the company on the market.

TESTING BUILDING NO.—XI.

The building, designated at the shops as No. 11, is substantially built mostly of brick, and steel, wood being used only where found to be an absolute necessity. It is two stories in height, having galleries on each side running lengthwise, and tapering at one end, giving an average length of 310 feet.

The sides being parallel, the width is 91 feet throughout its length. Its eastern extremity is connected with the old testing building, No. 12, by an overhead arch, covering the craneway, and at its western end by an annex to building No. 9, one of the large machine shops.

The second floor of this annex is used as a tool room and the first floor for storage material It is 60 feet in width, with an average length of 79 feet. The soil being very sandy, extra care was taken with the foundation. The piers upon which the building rests have a footing of stone 5 feet in depth, being 3 feet six inches square at the top and tapering to 4 feet 6 inches at the bottom. Below this for a depth of 2 feet is a foundation of concrete 7 feet square. Besides this, 36 of the 55 piers have granite caps 12 inches in thickness and 3 feet square, bedded on the top of the stone footing. The retaining walls, built upon these piers, which are 18 feet apart and connected together by an 18-inch foundation,, are of hard, well-burned brick, 16 inches in thickness, and rise to the height of 30 feet. The columns for the craneway and roof supports are of Z bar section, weighing respectively 58 and 39.8 lbs. per lineal foot. These have a riveted base, are set on the granite caps of the piers and are held together and secured to the craneway girder. The craneway girder, running lengthwise of the building is of steel plate 30 inches deep and weighing 152 lbs. per foot. Firmly clamped to the craneway girder is a 5-inch rail of steel weighing 95 lbs. per yard, upon which run the cranes. Twenty-one steel trusses resting upon the columns support the roof over the craneway space. The girders under the galleries and flat roof are imbedded in the wall and fastened to the columns. Extending from end to end of the building they are so constructed that small electric traveling cranes run on the lower flanges. The floor beams of the galleries, bolted at one end to the girders and resting on the retaining walls at the other, are of 12-inch I-beams, weighing 32 lbs. per foot, and are spaced four feet to centers. The rafters of the flat roof are of 9-inch I-beams weighing 21 lbs. per foot, and spaced 9 feet to centers. These project two feet over the retaining wall and are bolted to the longitudinal girders.

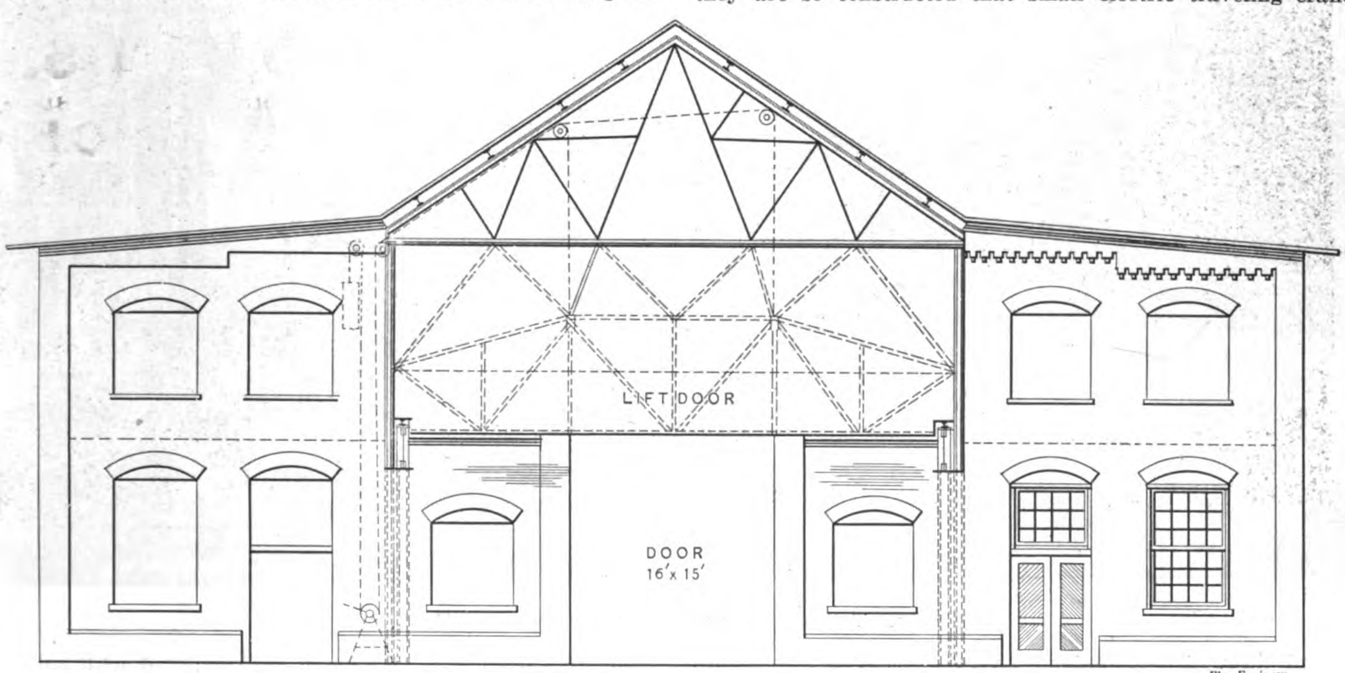

FIG. I.—NEW TESTING DEPARTMENT BUILDING, SCHENECTADY.

The flat roof over the galleries is covered with a preparation of gravel pitch and tar, and the inclined roof, over the craneway area by tin and translucent fabric for skylights. These lights are 16 feet wide on each slope, and run continuously from end to end of the building, being fastened to the purlins, which are bolted to the trusses. The effect of the light through these skylights and side windows upon the white painted interior, gives a clean appearance seldom seen in a factory building. Beneath the skylights is a copper wire screen of No. 14 gauge and of 2-inch mesh. On each side of the galleries are railings 42 inches high and of No. 10 iron. The foundation for the ground floor was prepared by laying a 5-inch layer of concrete, made of screened cinders and coal tar, both being

heated and mixed proportionally. On top of this was laid an under floor of best straight grained hemlock 2⅞ inches thick and 8 inches wide. The upper floor is of best 1⅛-inch square-edged maple, kiln-dried, and 4 inches wide. Throughout the building at different points, imbedded in the floor, are heavy iron bed plates, set in a foundation of grouting upon which the heavy machines are tested. At the western extremity is installed an Otis electric freight elevator run by a G. E. 800 railway motor. This, together with the electrical connections, was supplied by the General Electric Company. At the eastern end are lift doors which are raised and lowered as the cranes pass in going from one building to the other. These doors are of angle iron frames and are sheathed on one side with No. 16 iron. Located at both ends, are stairways connecting the galleries with the ground floor. The building is ventilated by seven 60-inch ventilators placed on the apex of the roof and distributed throughout the building. There are two traveling electric cranes built by the Morgan Engineering Co., one of 20 tons capacity and the other of 40 tons. In the center of the main floor running from end to end, connecting building No. 12 at one end, and No. 9 at the other, is an electric railway operated on the closed conduit system.

In the middle of the track, at equal intervals, are contact strips, which are switched in and out of circuit as the car passes over them, by the automatic operation of electromagnets.

At the northeastern corner of the building are located the consultation room and the office.

The consultation room is used exclusively for the engineers, who are in the building at various times throughout the day, keeping in touch with everything that is going on. The office is used by the manager of the department, his assistants, the office corps and the calculating department.

SYSTEM OF WIRING.

The testing department includes not only the work performed in the main testing building, No. 11, but all testing at the company's works. The department is subdivided, according to the character of the tests, into different sections, each section having a separate head, but under the direction of the manager. The sections located in the new building, No. 11, are:

Tests of small motors and generators below 25 kilowatts.
Tests of large motors and generators above 25 kilowatts.
The marine test.
The induction motor test.
The railway motor test.
The special and experimental testing.

With these different tests in one building it necessarily becomes very difficult to arrange the power, widely varied in character, so that the requirements of the different sections will not interfere with each other. To obviate this, considerable attention has been given to the system of wiring. Stationed throughout the building are switchboards known by letters numbering from A to H. These are connected with one another by cables either stretched overhead beneath the galleries or through terra-cotta tubing laid under the ground floor.

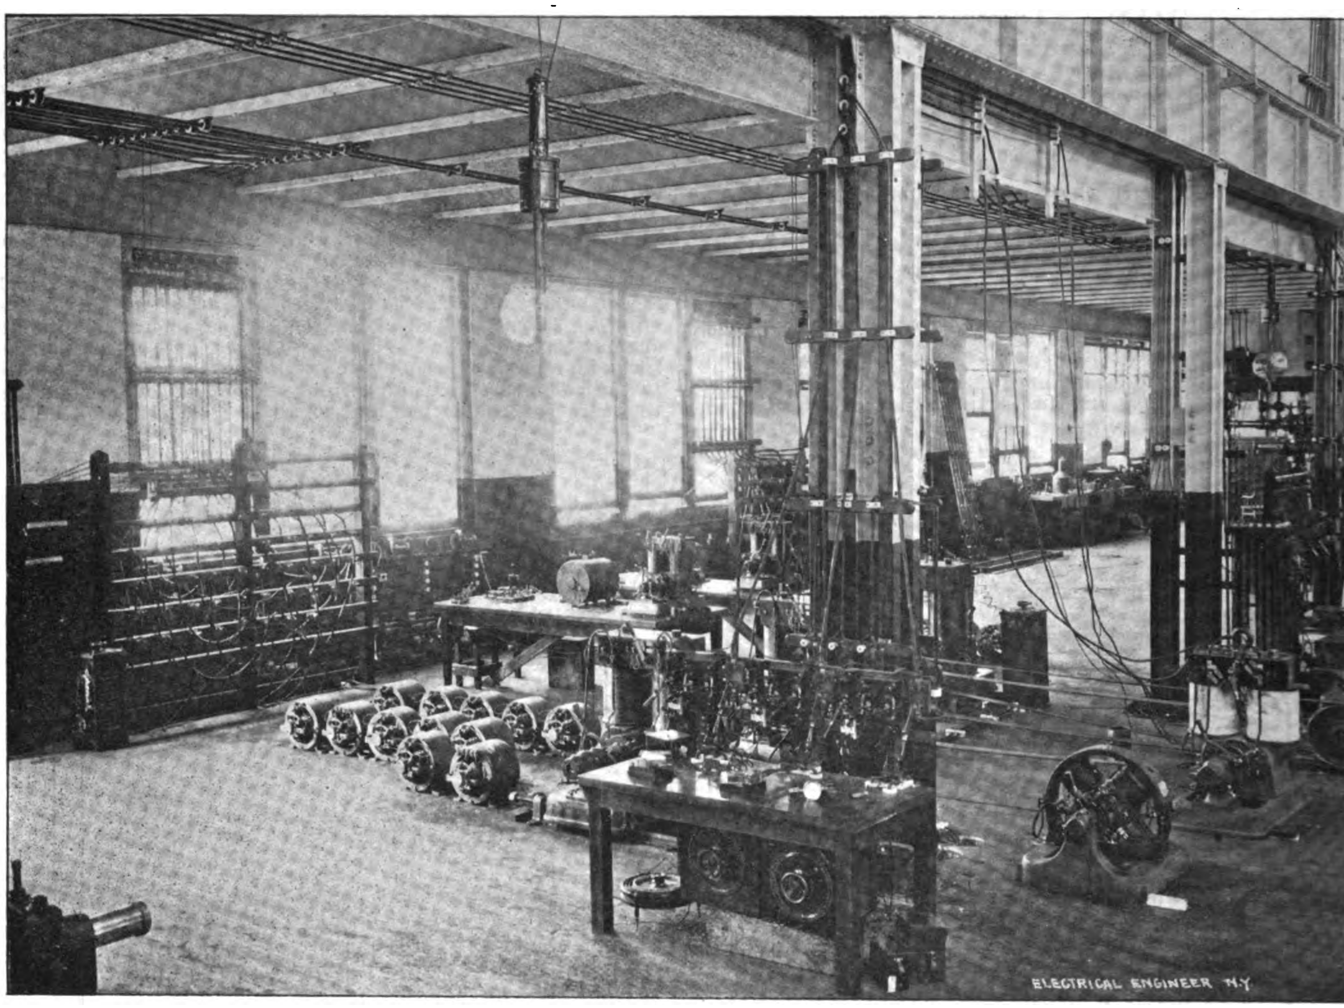

FIG. 2.—TESTING ROOM FOR MACHINES UNDER 25 K. W.

On the various columns are located switches and terminals which are connected to the nearest switchboard. On every switchboard, no matter where it is located, are currents of all voltages, either connected with machines running temporarily on the floor, or from the power plants, located in this building, and in building No. 12, or from the central power station. Therefore, in running a test, it is only necessary to connect short cables, to the nearest switchboard or column to obtain the current suitable for the occasion. This is strikingly noticeable, one rarely seeing any obstruction produced by the stretching of cables along the floor except at close proximity to the machines in test.

As an example of this arrangement, if one has occasion to connect a machine at one part of the building to a generator at another part, he would go to the nearest switchboard (say E) and connect his machine to cable building posts marked, say, 22D. Then going to switchboard D, he would find the terminals of the cables marked 22E. Connecting the generator to these, he would obtain the required power at the machine terminals.

Water rheostats are also connected to the switchboards. They consist mostly of box-shaped iron castings, resting upon porcelain insulators, and having a regulating plate, which can be moved in and out of the water according to the desired load. The others are of wood, with a permanent iron plate at one end, and another sliding plate, movable from end to end.

There is one point alone, above all, which shows the immensity of this department; that is the amount of copper wire and cables permanently placed throughout the building.

Besides using thousands of feet of cables from the old testing building, the following new rubber covered cable and wire was used in building No. 11: 7,000 feet of 500,000 cir. mils cable; 2,000 feet of 250,000 cir. mils cable; 2,000 feet of 200,000 cir. mils cable; 4,000 feet of 100,000 cir. mils cable; 8,000 feet of 26,250 cir. mils No. 6 B. & S. wire; 2,000 feet of 10,380 cir. mils No. 10 B. & S. wire. Approximately, about 10 miles of new and old wire and cables are in use.

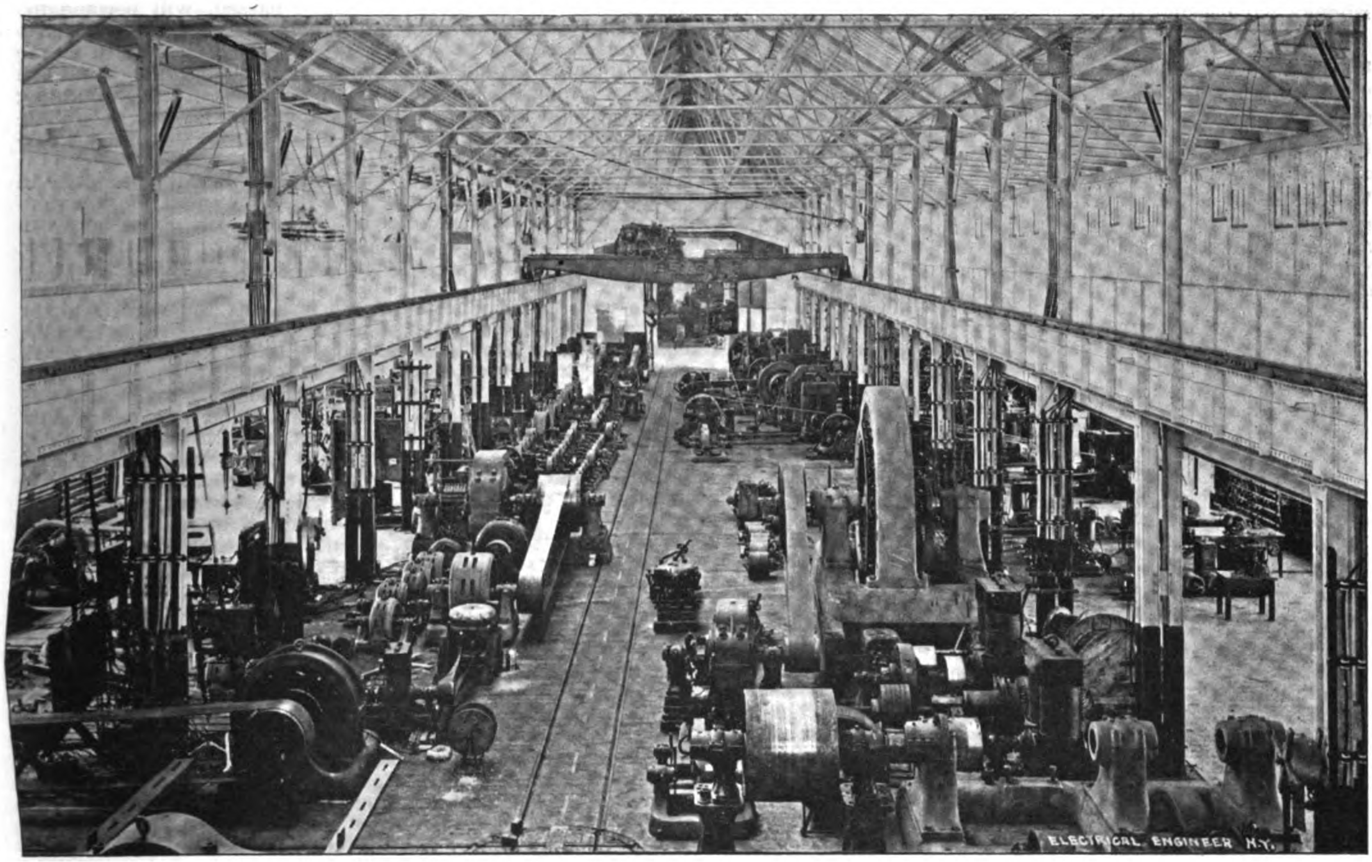

FIG. 3.—INTERIOR OF NEW TESTING BUILDING, SCHENECTADY.

A TIME TO CELEBRATE.

Many facts, recently presented to the public, make, when taken together, a splendid showing for Buffalo's continued growth. One of the most striking of these is the fact that their street railways in the fiscal year just ended carried 4,798,936 more passengers than in the preceding year. The assurance that power will be electrically brought to Buffalo from Niagara Falls by November 1st is being widely commented on by the press of the country.

It won't hurt Buffalo to have this thing talked about. She might talk about it herself to good purpose. And why not hold some sort of an electrical jubilation, as was proposed a year or so ago? It can be easily arranged so as to draw a great crowd, please the visitors and advertise the town.

And if held soon after the 3d of November it can be treated as a celebration over the industrial progress of the Niagara frontier, and a Thanksgiving jubilee over the election of McKinley.—Buffalo "Express."

AN EXAMPLE OF WHAT TO AVOID.

Whenever electric traction is under consideration by town councils or other local authorities the usual practice is to appoint a committee to visit the best existing electric lines in the country and report on them.

The London "Electrician" thinks that, by way of contrast, it would be a good thing to show these deputations how the work ought not to be done. A striking instance of this would be afforded by the electric Vevey-Montreux-Chillon tramway. The overhead construction of this ancient line is simply amazing. The two conductors consist of iron tubes about one inch in diameter, having an underrunning slot in which the collectors slide. These tubes are suspended from a bearer wire, and this again is carried by brackets fastened to houses or wooden posts. All the feeders are carried overhead, too; and in places where the line is double the mass of wires and iron work looks most formidable to the passer-by. But all this is as nothing compared with a ride over the line on a top seat. The line is about six miles long, with single track, which is now on one side and then on the other side of the road. The connecting cables between the sliding contacts and the car hang down anyhow, and when the overhead conductors run from one side of the road to the other, or when the line runs round a sharp curve, an outside passenger is in danger of being strangled. It would be well for peripatetic committees to see for themselves what an electric line may become without proper control.

AN UNLUCKY ELECTRIC MOTOR.

Lawyer Francis H. Van Vechten, of Jamaica, counsel for the Long Island Illuminating Company, will shortly begin an action against Queens County to recover a large sum of money, which, he alleges, is due his client on the contract signed January 17, 1895, under which it was to furnish electric power for operating a motor which was intended to turn the old Vernon avenue bridge over Newtown Creek for five years. A similar action is likely to be instituted against Kings County if the company's bills are not settled.

A motor which cost both counties $2,100 was furnished for the bridge. The first time the power was turned on, the structure was turned too rapidly, and all the cogs of the turntable were torn off. No sooner were the necessary repairs made than the British ship Eurydice ran into the bridge and damaged the motor beyond all hope of repair. That was nearly a year and a half ago, since which time the damaged motor has lain idle, and the two counties are paying about $450 a month to men who are employed to turn the structure by hand.

MR. W. B. SCATTERGOOD has been appointed to succeed Mr. T. A. Closs as manager for the Postal Telegraph Company at Atlanta. Mr. Closs goes to Augusta.

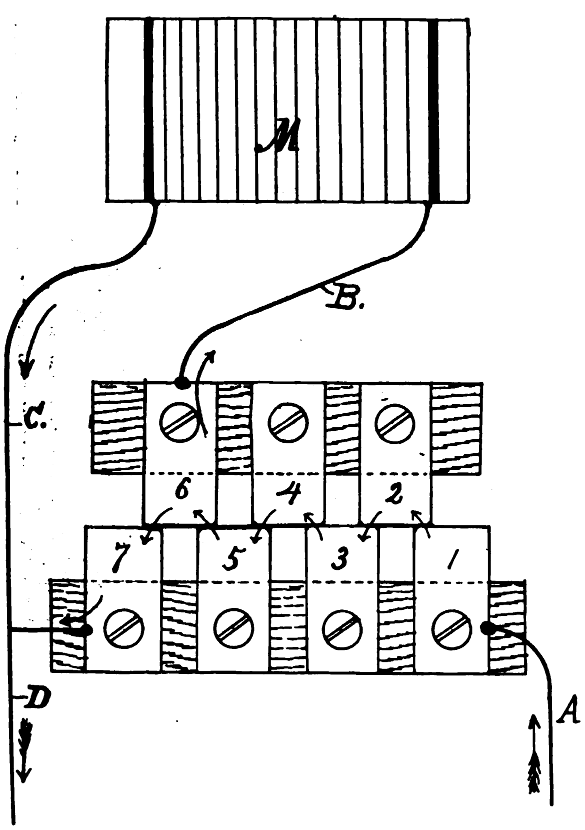
LIGHTNING ARRESTERS.

BY

Wm Baxter Jr

OF all the apparatus used in connection with electrical machinery, none has received more attention than, if as much, as the lightning-arrester; but, notwithstanding all that, the results obtained as yet cannot be said to be wholly satisfactory. A great many varieties of arresters have been tried, but in every case, so far as the writer is aware, the efforts of the designers have been directed entirely to providing means for breaking the ground connection should the line current continue to follow the path across the gap bridged by the lightning discharge. This is an important function of a lightning-arrester, but it is not the principal one; if it were, an ordinary fuse would serve the purpose perfectly well, except in the matter of convenience.

The principal object of a lightning-arrester is to provide a path for the discharge that will be so much easier than that through the insulation, that the latter will not be taken. To accomplish this result it is clearly evident that the circuit through the arrester must be of considerably lower resistance



BAXTER LIGHTNING ARRESTER.

than that through the insulation of the apparatus that is to be protected.

There are many engineers who claim that this is not the case; that lightning has no respect for Ohm's law, and will pick out a path to suit itself without any regard to the resistance. Those who hold such views give the law a narrow interpretation, and fail to see that inductive action is equivalent to ohmic resistance in so far as it impedes the passage of a current. When lightning strikes a line, the inductive action of any portion of the circuit that is wound in a coil, is very great, even though the number of turns be few. This is so simply because there is an instantaneous rise of current to enormous proportions, and therefore the rate of change of magnetic flux is infinitely great. On this account the reaction of even a small magnet coil is so enormous that it stops the current about as effectually as an open circuit. Such being the actual conditions, the available paths are through the ground circuit of the arrester, and through the insulation of the magnet coil, and the discharge will take the one that offers the least resistance. This being the case, it follows that the ground circuit through the arrester should be of as low resistance as is practicable, while every path through the insulation to ground should be obstructed as much as possible. The ground circuit in all properly designed arresters is free from coils, and as nearly non-inductive as it can be made, but this alone will not insure its effectiveness, as the width of the air gap may be enough to make the resistance through that path greater than through the insulation of the apparatus that is to be protected. The air gap ,as ordinarily constructed, cannot be made very narrow on account of the danger of its bridging across if the points should fuse under the action of a strong current. In some cases carbon points have been used to overcome this difficulty, but the objection to these is that if neglected the distance between them, after a few discharges have passed, will become too great to be effective. As the striking distance of the electromotive forces used in practice is very small, the width of the air gap could be reduced to two or three hundredths of an inch without danger of grounding the generator current, providing the gap could be kept at this distance, but this cannot be depended upon with the ordinary construction; therefore a considerably greater separation has to be used.

The writer several years ago designed a lightning-arrester in which the width of gap could be made very small, and the danger of actual contact avoided. The diagram given herewith shows the general principle of construction, but not the design, which it is needless to say can be varied to suit the requirements of any case.

The wire A is connected to the line, and the wire D to the ground. The pieces 1, 2, 3, 4, 5, 6, 7, are rectangular metallic contacts, about one inch long by half an inch wide and an eighth of an inch thick, all insulated from each other. The pieces 1, 3, 5, 7, are held on a block of insulating material which is attached to the base of the apparatus, and 2, 4, 6, are similarly held on a movable frame that carries an armature which is actuated by a magnet of which M is the coil. If the pieces 1, 3, 5, 7, and 2, 4, 6, are filed so that their ends are nearly in line, that is, as near as possible, without resorting to extreme accuracy, the points of contact, indicated by the arrows will be very close to each other, but not more than two will be in actual contact. The separation at the other points will be very small, ranging not over 100th of an inch, down to an invisible amount; but the combined resistance of these gaps will be sufficient to prevent the line current from jumping, while it will afford a lightning discharge a path of exceedingly low resistance, in comparison with that through the insulation of the apparatus that it protects.

The gap between 6 and 7 is filed so as to be wide enough to cause a current to be diverted through the coil M, that will be of sufficient strength to enable the magnet to actuate the armature which is attached to the frame that carries the contacts 2, 4, 6. When a lightning discharge passes the current goes across the gaps from 1 to 7 as indicated by the arrows, and thence to ground. If the line current should follow up the discharge, the resistance of the gap between 6 and 7 will send a current through the magnet coil, and the armature being attracted, the points 2, 4, 6, will be drawn away from the others until the resistance of the gaps becomes great enough to break the current.

When the contact points become rough, through the action of the current, they should be filed down so as to not have too great a separation.

The advantage of this construction is that the width of air gap can be greatly reduced, owing to the fact that the points that do not come in actual contact can be maintained in their position without any danger of grounding the line, as they are held from coming closer together by the points that are in actual contact. In addition to this, if one or more of the gaps should be bridged through any cause, there would still be two breaks in the circuit. When a single gap is used, its width must be very much more than is really necessary, so as to guard against grounding.

Lightning-arresters of the foregoing design have been used on railway cars with good results, and if kept in proper condition should always be effective. The greatest difficulty that had to be contended with in their use was to prevent the electricians of the roads from purposely making the gaps too wide, the general impression appearing to be that there was danger of grounding the line if this precaution were not taken. This fear, however, is groundless; in fact, with six breaks, as shown in the diagram, it is difficult to file the points so true that the current will jump with an e. m. f. of 500 volts.

To obtain the best results the number of breaks should be made in proportion to the electromotive force. As it is more difficult to obtain perfect alignment with a large number of contacts, it follows that the width of the gaps will be greater on an average as the number increases, hence the higher the e. m. f. the fewer in proportion the breaks.

ALTERNATE CURRENT TRANSFORMERS[1]—IV.

BY DR. J. A. FLEMING, F. R. S.

HAVING considered the action and construction of transformers, our next duty is to notice the principal facts connected with the testing of transformers. This is a matter of considerable importance. It is not too much to say that in very few alternating current stations is there any proper system of purchasing transformers to a rigid specification, and enforcing delivery to this specification by efficient methods of electrical testing. Engineers appear to be far too often quite content to accept manufacturers' figures without any confirmation. As

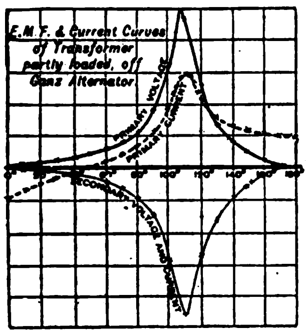


FIG. 34.

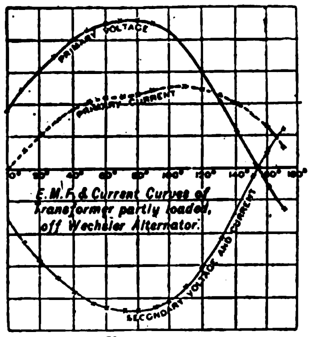

FIG. 35.

an instance of the possible consequences of such a course, I may, mention that not long ago I had occasion to specify for two transformers on behalf of a corporation, the core loss of these transformers was to be not greater than 550 watts when measured at the proper primary pressure, and on open secondary circuit. When the transformers were delivered they were tested. One of them was found to comply with the specification, the other took up 1,090 watts under the same circumstances. As these transformers were 30-kilowatt transformers, intended to be worked in a sub-station, and to be connected with the mains for at least 4,000 hours in the year, it is perfectly clear that if no test had been applied, and if the transformers had both been accepted, one of these transformers would have taken up 500 watts more than the other. This additional core loss, proceeding for 4,000 hours in the year, would have meant an addition to the magnetizing losses of 2,000 Board of Trade units per annum. As this would have involved an expenditure in coal and water of at least one penny per unit, the facts, translated into money, mean that one transformer would have cost something like £8 per annum more than the other to maintain magnetized. If this is capitalized at only 3 per cent. it means £240, whereas the actual cost of the transformers did not exceed £140 each. It is clear, therefore, that the omission of a systematic process of testing transformers and of specifying for them for test may involve a supply company or corporation in an increased annual expenditure for maintenance, which under some circumstances may even amount to a considerable sum. In dealing briefly with the subject of testing transformers I shall not attempt to describe all the many different methods which have been suggested, but confine myself shortly to one which is simple, direct, and can be applied in any sub-station or workshop. It should always be remembered that although an electrical method may theoretically give the required result, yet practically it may be difficult to get good results with it on account of the fact that to obtain the necessary accuracy we must assume an unattainable precision in some of the measurements. The method which, after long experience in this matter, I have found most applicable in all ordinary cases is one depending on the employment of a properly constructed wattmeter, standard power absorbing resistance, and an auxiliary transformer. We will discuss, in the first place, the construction of each of these instruments separately. If an alternating current is sent through a fixed coil of wire, and another current through a movable coil suspended with its magnetic axis at right angles to the first coil, the centers of the coils being co-incident, then in general we find an electrodynamic force tending to turn the movable coil from one position to another. If the initial position of the coils is with their magnetic axes at right angles, then the passage of the current tends to displace the magnetic axes so as to make them co-incident. If a couple or torque is applied to the movable coil to bring it back to its original position, either by means of a spiral spring or a torsion wire, it can be shown that the couple required to hold the coils in their initial position, with magnetic axes at right angles to one another, is proportional to the mean value of the product of the instantaneous values of the two periodic currents passing through the two coils taken at equidistant intervals throughout one complete period. This mean product, is therefore, at once measured in terms of a mechanical couple. Such an arrangement is called an electro-dynamometer. If the current through one of these coils is the current being supplied to an inductive circuit, say a transformer, and if the current through the other circuit, say the movable circuit, can be made to be proportional to the potential difference between the extremities of the inductive circuit, then the dynamometer, now called a wattmeter, will give us, when used as above described, the true mean value of the product of the instantaneous values of the current through the inductive circuit, and its terminal potential difference taken at equidistant intervals throughout the phase; this mean product is a measure of the mean power being taken up at that instant in the inductive circuit, and hence we are able by one measurement to measure this power. In order that good results may be obtained with a wattmeter constructed as above described when employing alternating currents, there are certain precautions which must be observed, but which instrument makers almost habitually disregard. In the first place, the wattmeter must be constructed entirely of non-conducting material. There must be no metal, either iron or brass, in or near the fixed or movable coils. The reason for this is, that if metal is placed in this position, the alternating currents circulating in the fixed or movable coils set up eddy currents in this metal, and these eddy currents react upon the movable coil, and cause a displacement which creates a false reading. In the next place, in order to make the instrument direct reading, it is essential that the fixed coil should be constructed in two parts, which are capable of being moved to or from one another, so as to strengthen or weaken the field in the place where the movable coil hangs. In this manner the wattmeter can be adjusted, so that a certain angular deflection of the torsion head of the instrument, creating a certain definite couple acting on the movable coil, can be made to mean a certain definite amount of mean power passing through the instrument. Thirdly, precautions must be taken to prevent the effect of the currents in the wires bringing the currents to or from the wattmeter affecting the movable coil. For this purpose these leads ought to be constructed of concentric cable, and the wattmeter carefully tested, before employment, to find out if this cause of error exists. In the next place we require a non-inductive resistance to act as a standard power-absorber. This can best be made by employing the cages as described in the first lecture. A series of these inductionless resistances, say, 20 of them, each capable of withstanding a pressure of 100 volts, are joined up in series, and well insulated. Under these circumstances, a pressure of 2,000 volts can be placed on the extremities of this resistance, and a certain current will flow through it. This current can be measured by a sensitive dynamometer, which has previously been calibrated in the usual way. The potential difference between the extremities of the non-inductive resistance when employed on a high-tension circuit is best measured by means of an electrostatic voltmeter. Then, lastly, we require an auxiliary transformer for the following purpose: It has been explained in Lecture I. that when a transformer of the closed iron circuit type is worked on a constant potential primary circuit, the secondary electromotive force set up in the secondary circuit is exactly opposite in phase to the primary electromotive force.

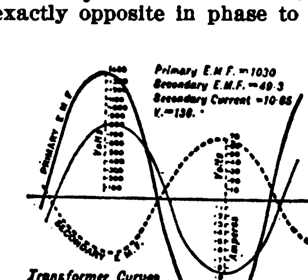

FIG. 36.

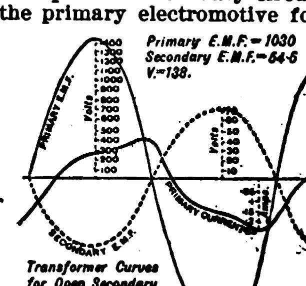

FIG. 37.

This is further illustrated by the curves in Figs. 34, 35, 36 and 37, which show the primary and secondary e. m. f. curves of a Ganz, a Wechsler, and a Westinghouse transformer in various conditions of load, and it will be seen that the primary and secondary e. m. f. curves are in step with one another, but opposite in phase. If, therefore, a transformer has its secondary circuit closed through a non-inductive resistance, the secondary current will always be exactly opposite in phase, but proportional in magnitude to the potential difference between the primary terminals of the transformer. In order, then, to make a measurement of the efficiency of any transformer, this apparatus is arranged as in Fig. 38, the transformer to be tested is denoted by the lines over the words "Transformer under test." The wattmeter has its fixed coils connected in series

[1] Society of Arts Cantor Lectures.

with the primary circuit of the transformer to be tested, and its movable coil is connected in series with the secondary circuit of the transformer, which is called the auxiliary or wattmeter transformer, and by including a few incandescent lamps, L, in the secondary circuit of this auxiliary transformer, the proper current can be given to the movable coil of the wattmeter. The primary circuit of the auxiliary transformer is connected to the same two mains as the primary circuit of the transformer to be tested, and an electrostatic voltmeter, V, is joined across the primary terminals of the transformer to be tested. The standard inductionless resistance just described is also placed across the primary terminals of the transformer to be tested, and a two-way high-tension switch is arranged so as to throw on the resistance, or the primary circuit of the transformer under test at pleasure. A dynamometer is connected in series with this standard resistance, to measure the current passing through it. The process of measuring the power supplied to the transformer under test is then as follows: In the first place we connect to the wattmeter the standard power of absorbing resistance, and observe the current flowing through it, and the potential difference between its extremities. The product of these two numbers in amperes and volts gives us the mean power in watts taken up in the standard resistance. At the same instant a reading of the wattmeter is taken; that is to say, an observation of the amount of torsion required to be given to the wire or spring holding the movable coil to bring it back into its normal position. Let this reading be D_1, and let the power taken up in the standard resistance in watts be represented by W_1. In the next place, the standard resistance is switched off, and the transformer under test is switched on to the wattmeter, and another reading is taken of the wattmeter. Let this reading be D_2. The true power being taken up in this transformer under test is given by the value of the expression $\frac{D_2}{D_1} \times W_1$. In this manner the wattmeter is employed as a kind of electrical steelyard, to weigh or measure the ratio between the known power taken up in the standard resistance and the unknown power taken up in the transformer.

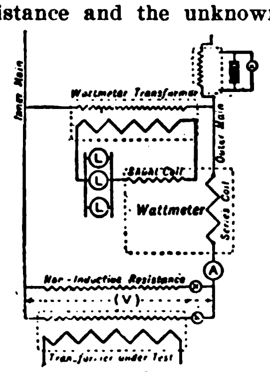

FIG. 38.

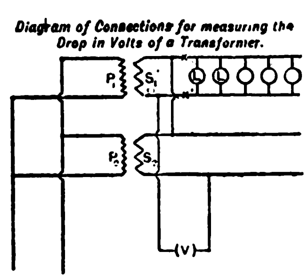

FIG. 39.

A measurement can thus be made with extreme accuracy, either in a central station, a transformer sub-station, or a private house. All that it is necessary to do is to connect the wattmeter, in the manner described, in place of one of the primary fuses; that is, to place the series coil of the wattmeter in series with the transformer under test, and then to connect up the standard resistance and the auxiliary transformer, as shown in the diagram. The iron core loss of a transformer on open secondary circuit can thus be quickly and accurately measured, and, with a properly constructed wattmeter of the kind described, there is not the slightest difficulty in making the measurement of the core loss of any required degree of accuracy.

The wattmeter before you and the standard resistances, have in this way been used for an extensive series of measurements on the efficiency and core losses of the transformers of the City of London Electric Lighting Company. No difficulty was found in making these measurements, even in the small underground sub-stations which are distributed about the city. In addition to the iron core loss of the transformer on open secondary circuit, it is also necessary to make two other measurements; one of these is the copper resistance of the two circuits of the transformer when the transformer is warm. The most easy method of doing this is by means of the fall of potential method. When the resistance of the primary circuit is moderately high, say, anything over 5 ohms, it can be very easily measured on the ordinary post office wheatstone bridge, taking the precaution, however, to short circuit the secondary circuit, but in those cases in which the resistance of either or both circuits is very low, then it is best measured in the following manner: A suitable standard low resistance, either 1-100th or 1-10th of an ohm, or 1 ohm is connected in series with the transformer circuit to be measured, and a small current from a dry cell or secondary battery is sent through this circuit, appropriate resistance being added to increase the total resistance to a proper amount. A movable coil high resistance galvanometer has its terminals then connected first to the extremities of the standard low resistance, and second to the terminals of the copper circuit of the transformer which is under test. The ratio of these two deflections gives us at once the ratio of the transformer circuit to that of the standard low resistance, and in this manner the copper resistance of each circuit of the transformer can be measured. This copper resistance, of these two deflections gives us at once the ratio of resistance however, if measured at the ordinary temperature of the air has to be corrected to determine what it is when the transformer has reached its constant temperature. When a transformer is put to work, whether on open circuit or closed secondary circuit, it soon reaches a final temperature which ought never, under any circumstances, to be more than 100° C. In order to determine what this temperature is, one of the easiest methods is to connect the transformer on open secondary circuit for five or six hours to the high pressure circuits, and when the transformer has reached its final and constant temperature to suddenly switch it off, and quickly make a measurement of the copper resistance of the secondary circuit, as above described. Then, when the transformer is quite cold, another measurement of the copper resistance may be taken, which will be found to be much less, since the high conductivity copper employed in transformer manufacture has a temperature coefficient of about 0.4 per cent. per degree Centigrade, it is very easy to calculate from these two measurements what is the final and constant temperature of the transformer. Having then measured the copper resistances, and calculated what it will be at the final temperature of the transformer, we have next to measure the secondary drop between full and no load. For this purpose an electrostatic voltmeter is connected across the secondary circuits, and its reading taken when the primary terminal potential difference is also known. The transformer is then loaded up to its full load on its secondary side, and the primary potential difference being kept at the same amount, the secondary potential difference will be found to have fallen, and the amount of difference between its value when the transformer is fully loaded and its value when the transformer is on open circuit is called the secondary drop. It is sometimes difficult to make this measurement with great accuracy, especially when the transformers are working off commercial circuits, but it can always be done in the way shown in the diagram in Fig. 39, if we possess two identical transformers, and a low reading electrostatic voltmeter. The two transformers are connected up with their primary circuits in parallel, and with their secondary circuits opposed to one another through the voltmeter. The voltmeter then reads, not secondary volts to either transformer, but the difference between the two differences. If one transformer is loaded up to full load, the voltmeter will read directly the secondary drop, and since both transformers are affected equally by any variation of the primary pressure, it does not affect their difference, and, therefore, there is no difficulty in getting the measurement with any required degree of accuracy. Having in this manner measured the iron core loss at no load, or on open secondary circuit, the copper resistances when the transformer is warm, and the secondary drop, we have all the information necessary to enable us to make a complete report on the transformer. It has been abundantly shown by experiments which were carried out by me in the year 1892,* that when a transformer is gradually loaded up, the iron core loss is constant at all loads, and that it is only the copper losses that vary. Hence, if we know the iron core loss—that is to say, the loss due to eddy currents and hysteresis in the core when the transformer is on open secondary circuit, we have only to add to this loss the copper losses in the transformer, that is, the energy losses due to the resistance of the copper circuits, in order to obtain the total power absorption in the transformer at any load. Let P_1 be the total power in watts given in a transformer on the primary circuit, and let P_2 be the total power in watts given out on the secondary circuit to some external resistances, such as lamps. Let I be the total iron losses in the transformer, and C the total copper losses, $P_1 = I + C + P_2$. Hence the difference between P_1 and P_2 is a quantity which can be calculated when we know I and know C; and the efficiency of the transformer is given by the ratio of P_2 to P_1, expressed as a percentage. The copper losses can be calculated with sufficient accuracy in the following manner: Let us suppose that the transformer under test is a 10 kilowatt transformer, that is to say, is constructed to permit 10,000 watts being taken out from the secondary circuit, and that the secondary watts are intended to be 100. Then the transformer at full load will give

* See "Experimental Researches on Alternate Current Transformers," by J. A. Fleming. "Proceedings of the Institution of Electrical Engineers," November, 1892.

out a current of 100 amperes. If we imagine the full load of the transformer to be divided into 10 parts, then when the secondary circuit is delivering 10 amperes at 100 volts the transformer is on 1-10th load, when it is delivering 20 amperes at 100 volts the transformer is on 2-10ths of full load, and so on. If the transformation ratio of the transformer is known, that is, the ratio between the secondary volts and the primary volts, or secondary terminal potential difference and primary terminal potential difference, when the transformer is on open secondary circuit, then the primary current can always be calculated with approximate accuracy from the secondary current by simply multiplying the secondary current by the number expressing the transformation ratio. Hence we can calculate the primary and secondary currents corresponding to each decimal fraction of full secondary load. Knowing the resistances of the two circuits of the transformer when warm, we can, therefore, calculate the copper losses in each circuit, because if R is the resistance of a circuit, and C the R.M.S. value of the current flowing through it, then C^2 R is equal to the mean power wasted in that circuit. Calculating in this way the total copper losses for the two circuits corresponding to each decimal fraction of the full secondary load, we can add these values to the constant iron core loss experimentally determined, and obtain the total power lost in the transformer, corresponding to each decimal fraction of the full secondary load, we can add these values to the constant iron core loss experimentally determined, and obtain the total power lost in the transformer, corresponding to each decimal fraction of full load. We have, therefore, the difference between P_1 and P_2, corresponding to known values of P_2. Hence we can calculate the ratio of P_1 to P_2 for each decimal fraction of the full secondary load, and, therefore, we have the efficiency of the transformer and the total loss in the transformer given to us at each fraction of the full secondary load. This is by far the best method of determining the efficiency of very large trans-

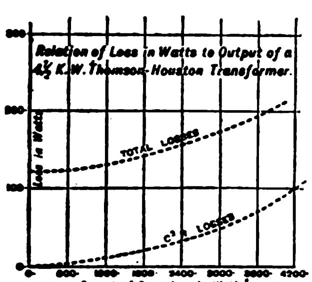

FIG. 40.

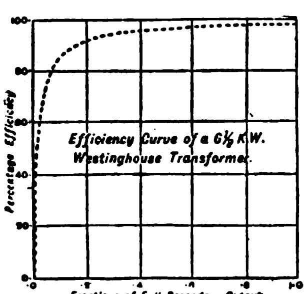

FIG. 41.

formers, because it does not necessitate loading up the transformer to its full load on an actual resistance; and even if this can be done, the measurement which we actually require is the difference between two large observed quantities, and is, therefore, very liable to be affected by an error in either of them. Having obtained in this manner the total losses in the transformer for the various decimal fractions of the full secondary load, the most convenient graphic method of representing the results is by a total loss diagram. A horizontal line is taken, and is divided into 10 equal parts representing the decimal fractions of the full secondary load. At each part a vertical line is set up, representing the total losses in the transformer, both the copper and the iron losses, and two curves are drawn, as in Fig. 40, one representing the variation of the total copper losses in the transformer with the secondary load, and the other representing the constant iron loss at all loads. From this curve another curve, called the efficiency curve, can be drawn in the following manner (see Fig. 41). A horizontal line is taken, representing the secondary output, and divided into ten equal parts representing the decimal fractions of the full secondary load. At each point a vertical line is set up, representing the ratio between the power given out by the transformer to the power taken in by the transformer, expressed as a percentage, and the curve delineated by these points gives us the efficiency curve of the transformer. In a well-designed transformer this efficiency curve is a square-shouldered curve, rising very rapidly up to 90 per cent. at one-tenth of full load, and to 96 or 97 per cent. at full load. A fairly good estimate of the value of a transformer, from an efficiency point of view, can be obtained by taking its efficiency at one-tenth of full secondary load. Even quite small transformers are now made which have an efficiency of 80 per cent. at one-tenth of full load. Large transformers of 30 to 50 wilowatts and upwards can be made to have an efficiency of 90 per cent. at one-tenth of full load. Ten years ago it was difficult to get any transformer having more than 40 to 50 per cent. of efficiency at one-tenth of full load.

It should be noted, however, that the form of this efficiency curve, as well as that of the current curve, depends upon the nature of the curve of primary e. m. f. The diagram in Fig. 30, chapter III., shows the difference which may exist in the efficiency curves in the case of the same transformer tested in two different alternators, a Ganz and a Wechsler.

In considering the performance of transformers, we are not only concerned with the instantaneous efficiency—that is, the efficiency under any particular load—but with what is called the all-day or all-year efficiency. This can be calculated when we know the efficiency of the transformer at various loads, and when we know the nature of the load diagram, as it is called, on which the transformer is supplied. Thus, for instance, let us make the assumption that the load diagram of a transformer is a 10 per cent. load diagram—that is to say, let us assume that out of the 24 hours, for 11 hours the transformer is giving no current from the secondary circuit, for five hours is supplying at one-tenth of its full secondary output, for four hours one-eighth, for three hours one-quarter, and for one hour three-quarters. It will be found, on adding up these outputs, that they amount to one-tenth of that which the transformer would be supplying if working at its full secondary output for the whole 24 hours. Let us take, then, the case of a 24-hour kilowatt transformer, having 1.35 per cent. loss on open secondary circuit, and 1.35 per cent. — 1.60 per cent. loss at full load. This gives an open circuit loss of 324 watts at no load; that is to say, 324 watts is the core loss in the transformer at no secondary load; the efficiency at one-tenth full load is 86 per cent. and at full load 96 per cent. From the total loss diagram it can then be shown that the transformer takes up in its primary circuit 324 watts on open secondary, 2,762 watts at one-tenth of full load, 3,372 watts at one-eighth of full load, 6,420 watts at one-fourth full load, and 18,162 at three-fourths of full load. We can then construct an energy balance-sheet for the transformer as follows, putting on one side the energy in watt-hours given by the primary circuit, and on the other side the energy in watt-hours taken from the secondary circuit, and these figures will be as follows:

Energy in Watt-Hours Given to Primary Circuit.

11	×	324	=	3,564
5	×	2,762	=	13,810
4	×	3,372	=	13,488
3	×	6,420	=	19,260
1	×	18,612	=	18,612

Total = 68,734 Board of Trade units.

Energy in Watt-Hours Taken from Secondary Circuit.

11	×	0	=	0
5	×	2,400	=	12,000
4	×	3,000	=	12,000
3	×	6,000	=	18,000
1	×	18,000	=	18,000

Total = 60,000 Board of Trade units.

CONTEMPORARY ELECTRICAL SCIENCE.

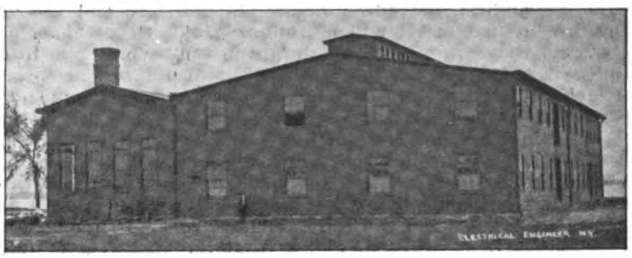
"Il Nuovo Cimento" for July contains some very interesting contributions. A. Garbasso writes about the discharge of a cathode by flame gases. The products of combustion of a candle give rise to exactly the same phenomena in the spark-gap as those produced by Röntgen rays and by ultra-violet light. They promote the discharge when impinging upon the cathode, but produce no effect upon the anode. If a glass plate is brought between the knobs so that the discharge can only just pass round the edge, a candle placed below the cathode on one side of the plate produces a shower of sparks, while when placed under the anode it stops the discharge altogether, if anything. This action is not due to the heat of the flame. The gases can be led up to the knob through a tube 40 cm. long, and the tube can be immersed in cold water, without altering the effect. Besides, a current of hot air does not produce the effect described, whereas it may be brought about by the smoke from a cigarette. Signor Garbasso suspects that the discharge produced by ultra-violet and X-rays may be a secondary effect, and may be due, as in the case of a flame, to the action of electrified particles in the shape of dissociated molecules. Dr. Maiorana gives the results of his studies of the effect of light upon the resistance of selenium. He finds that the effect is anything but "instantaneous." The resistance of a piece of selenium, with a normal resistance of 258,100 ohms, was lowered in the first second of illumination to 224,000, in the second to 212,-000, and after that it gradually approached a limit of about 200,000 ohms. The recovery proceeded equally gradually. We also find a description of the new system of electrical distribution patented by Profs. Ferraris and Arnò. The system is to provide for the case when the same current has to be used for lighting and power to nearly the same extent. The ordinary alternate current is sent through the lamps, and the power portion is transformed so as to suit the requirements of polyphase motors. This is done by the "phase-difference transformers" designed by the inventors.—London "Electrician."

Power Transmission.

THE MANUFACTURE OF CHEMICALS BY NIAGARA POWER.

BY ORRIN E. DUNLAP.

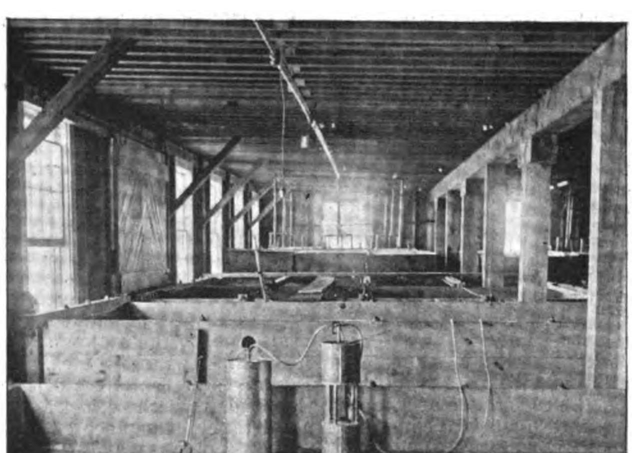
THE new plant of the Chemical Construction Company, of Niagara Falls is now in operation. This factory is located further east than any other plant on the Niagara Falls Power Company's lands and is therefore more distant from the power house than are the other factories built there. This company will make chlorate of potash, chlorate of soda, chlorate of barium, etc., while later on they expect also to make chloroform



Chemical Construction Co.'s Factory, Niagara Falls.

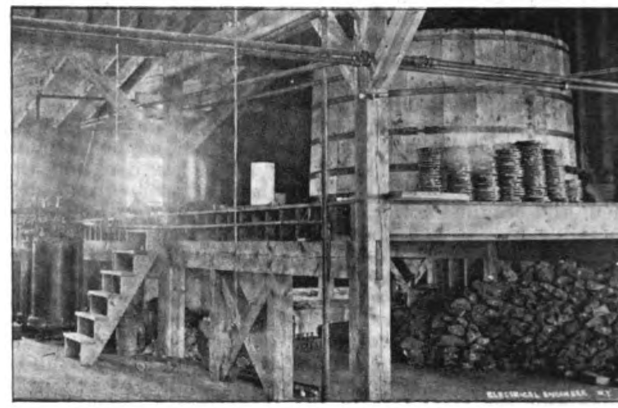
and iodoform. Eight acres of land have been leased from the Niagara Falls Power Company, and the power lease makes available 4,000 horse-power. At present only 500 horse-power is in use, and the factory covers but a small proportion of the land leased. It will thus be seen from these facts that the company have made ample provision in the matter of power and space for the enlargement of their plant in accordance with the dictates of their judgment and the demand for their goods. As it stands to-day the plant is composed of three frame buildings, the main structure being two stories high, 125 feet long by 65 feet wide, and the transformer house 60 feet long by 40 feet wide. This building is also two stories in height. The third building is used as a storage building and is located in the rear of the main building.

The process is started in dissolving the muriate of potash in five large tanks, each 10 feet in diameter and 6 feet deep, each having a capacity of 3,000 gallons. These tanks are located in the rear of the main building, two of them being in the storage room. From these tanks the solution is pumped by steam to the upper floor of the main building, where it passes through filters made by the Continental Filter Company of New York, and then into a storage tank of 4,000 gallons capacity. From this tank the solution is tapped off for use in the pot room, 90 x 65 feet in size and which is also on the second floor, as



Tank Room on First Floor.

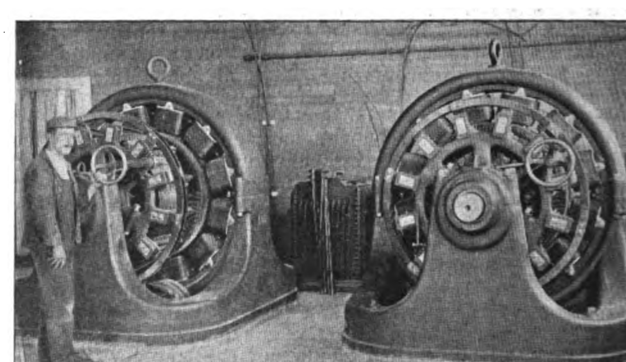
needed. This pot room is an interesting place. The switchboard is on the east side of the building and above the transformer room. In addition to this main switch each pot has a switch by which it can be thrown in or out of circuit. The iron pots are sixty in number and porcelain lined. They are said to be the largest porcelain lined tanks ever made in the United States and the largest ever used for this purpose. In length they are about 8 feet, the width being 4 or 5 feet, which makes a large casting. They were made by Messrs. Dawes & Myler, of New Brighton, Pa., and it is said the shrinkage between the iron and the porcelain lining was so much as to cause considerable trouble in their manufacture, but as they stand to-day they are fine samples of good work. The pots being all insulated one from the other and also from the floor, there is no danger of shock of any kind. It is in these pots or tanks that the muriate solution is decomposed, forming the chlorate which is allowed to run down to the first floor into porcelain lined crystallizing tanks or pans, then into lead lined pans and finally into a wooden pan, after which it is shovelled



Storage Tank and Filtration Plant.

up and thrown into a centrifugal dryer, where the moisture is driven by centrifugal force. It is then placed in the dry room where the remaining moisture is removed, after which it goes into the packing room where it is put up in 100-pound kegs and sealed for shipment. The operation from the time the muriate solution enters the pot room to the time the chlorate is ready for shipment consumes about twenty-four hours, the process being continuous night and day, the factory being operated in shifts of twelve hours each. The present capacity of the plant is about one ton of chlorate of potash per day.

The electrical equipment of this factory was manufactured by the Westinghouse Electric & Manufacturing Company, of Pittsburg, Pa. It consists of two rotary transformers of 250 horse-power each, and four static transformers, which give 3,000 amperes at 60 volts. The current is supplied by the Niagara Falls Power Company and flows to the factory over cables laid along the ground, the subway not yet being extended to this point. As it is received at the plant the current is of the two-phase alternating variety at 2,200 volts, which is converted into direct current by the rotaries shown. No other factory in Niagara Falls uses quite so much copper for conductor purposes as is found in the plant of the Chemical Construction Company.



Transformer Room.

From the transformer building twelve copper bars, each 5 inches wide by ⅝ inch thick, carry the current to the main building where it is distributed to the sixty pots on copper bars 4 inches wide by ½ inch in thickness.

Those who have watched electrical progress in America know that this is the first factory of its kind in this country and that its erection is the birth of a new industry on this continent, for not one ounce of chlorate of potash is made by chemical or other process in the United States outside of Niagara Falls.

In England and other European countries chlorate of potash is made by chemical process, but this Niagara Falls factory is expected to revolutionize several fields of manufacture in the chemical industry. To-day chlorate of potash is worth from nine to ten cents per pound, wholesale, in net ton lots, the supply for the United States coming mainly from Germany, England, France and Switzerland. The consumption averages five million pounds per year in the United States alone. Since the passage of the McKinley bill no duty has been imposed on it, but before that time the duty was three cents per pound. The uses of chlorate of potash are very numerous. It goes into parlor matches, blasting compounds, and smokeless powders. It enters into alizarine dyeing and all the various colored lights and also torpedoes. It is used in making cough mixtures and other medicines, oxygen gas, and as an oxydizer generally.

The electrical process established at the Falls offers, it is said, many advantages over the old chemical process, one being that there are no by-products, each and every atom of salt used being converted into chlorate. By the chemical process chlorate of potash is made in a roundabout way, by which there are two or three by-products, all unsaleable. More than this, five out of six equivalents of salt are lost, while in the electrical process there is no waste whatever. So thorough is this economy that the floors of the pot and crystallizing rooms are asphalted and have a pitch of one inch in four from both sides toward the center to catch all drippings from the pots, which are carried to two tanks outside of the main building to be filtered and used again.

The salt to be used in chlorate of potash is imported from Stassfurt, Germany. It comes in bags of 224 pounds each and is known to the trade as muriate of potash, the correct name being chloride of potash. Stassfurt, strange to say, is the only place in the world where this salt is found, and there is mile after mile of it, the supply being practically unlimited. It is likely that the other salt to be used in this factory will be brought from Syracuse, N. Y.

Further advantages of the Blumenberg electrical process are the extremely low voltage used, the peculiar construction of the cell which gives a very high efficiency and the use of carbon anodes in place of platinum. In addition to all of which, the cost of production will be much less than by the chemical process.

Statistics on the manufacture of chlorates in various countries are very meagre. England, France, Germany, Switzerland and Austria are all interested, and for England some data exists showing that up to 1879 in that country the production of chlorate of potash was about 1,400 pounds per year by chemical process. Since then progress has been made in the amount produced, but there has been no special change of the method. To-day, chlorate of potash is made by three electrical processes. These are the process employed by Gall & & Montlauer, of France; Franchot & Gibbs, of Buckingham, Canada; and that of the Chemical Construction Company, of Niagara Falls. Both of the first named firms, it is understood, use platinum, which is more costly than the carbon of the latter. M. Kolbe, of Germany, was the first to demonstrate the possibility of producing chlorates by electroysis, but the fact was also noticed about the same time by John T. Sprague, of Birmingham, England, who refers to it in his well known book. The establishment of this and other plants of like nature at Niagara Falls well supports the statement of M. Lunge, Professor in the Ecole Polytechnique at Zurich, Switzerland, who has expressed faith in the future of countries of great hydraulic power, and who has said these countries would be the center of all new electrical methods.

The capital stock of the Chemical Construction Company is $75,000. The president of the company is Mr. W. Ferguson, of New York. The vice-president of the company is Mr. W. T. Wilson, and the secretary is Mr. B. Hoes, both of New York. The general manager of the company is Mr. Frederick Overbury, a pleasant, affable young gentleman, who, with Mr. Henry Blumenberg, Jr., the patentee of the process, has had full charge of the important duty of equipping the Niagara Falls plant. For all Mr. Blumenberg is a young man, he is very brilliant, and his name and field of research and invention are well known in the patent office at Washington, D. C. He has been granted four patents on electroysis since April 2, 1895, the last bearing date of Aug. 4, 1896.

NEWS AND NOTES.

THE ST. LAWRENCE RIVER SEARCHLIGHT TRIP.

IT is a generally admitted fact that the attractions offered by the scenery and waters of the St. Lawrence River are equalled by few other resorts. The neighborhood is the summer home of thousands of cottagers, and as many more, as tourists, make this their stopping place for shorter periods while in quest of recreation and pleasure.

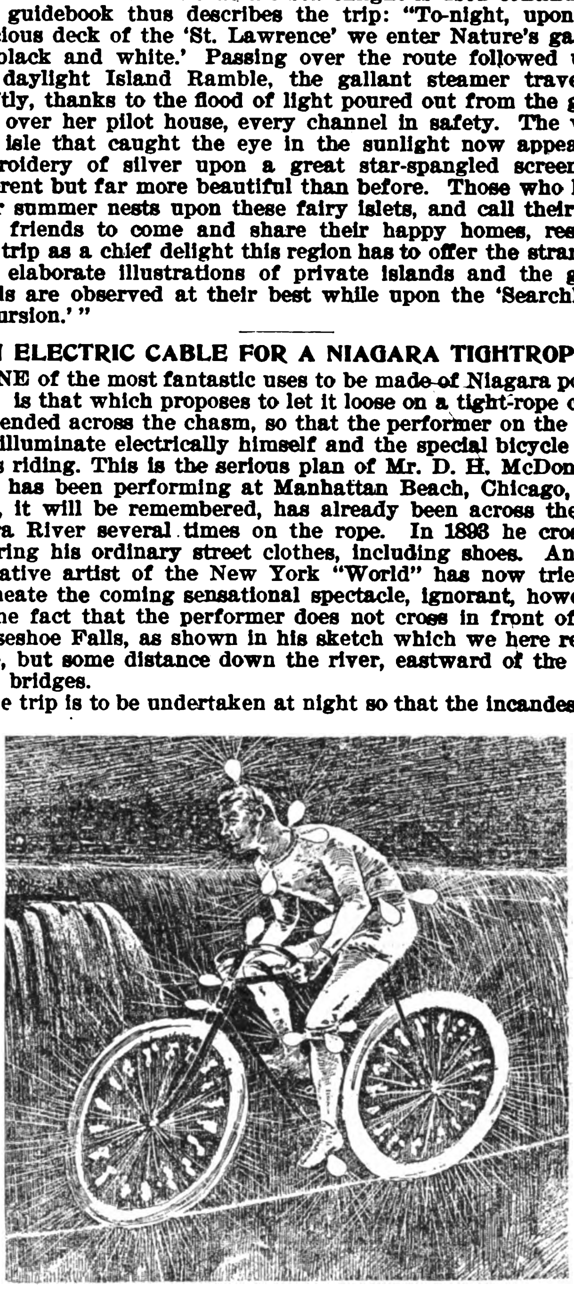
One of the prominent features of the river is the "White Squadron," the fleet of the Thousand Island and St. Lawrence River Steamboat Companies, consisting of the "St. Lawrence," "Empire State," "America," and "Islander," all side-wheel boats of goodly proportions. Besides these, the propeller, "New Island Wanderer," the swiftest boat on the river, makes regular trips. All of these boats are equipped with electrical plants, consisting of Westinghouse engines, belted to high speed dynamos of various makes, neat and compact switchboards, with ammeters and voltmeters, and on the pilot house of each boat is erected a large searchlight, those on the "St. Lawrence" and "America" said to be of 1,000,000 candle power each. The boats are lighted by 250 incandescent lights, making the interior as bright as day.

The "New Island Wanderer" and "St. Lawrence" make regular trips during the season from 8 to 11 p. m. among the islands between Clayton and Alexandria Bay. The novelty of the trip is due to the fact that the searchlight is used continually. The guidebook thus describes the trip: "To-night, upon the spacious deck of the 'St. Lawrence' we enter Nature's gallery of 'black and white.' Passing over the route followed upon the daylight Island Ramble, the gallant steamer traverses swiftly, thanks to the flood of light poured out from the great lens over her pilot house, every channel in safety. The vista and isle that caught the eye in the sunlight now appear in embroidery of silver upon a great star-spangled screen, so different but far more beautiful than before. Those who have their summer nests upon these fairy islets, and call their distant friends to come and share their happy homes, reserve this trip as a chief delight this region has to offer the stranger. The elaborate illustrations of private islands and the great hotels are observed at their best while upon the 'Searchlight Excursion.'"

AN ELECTRIC CABLE FOR A NIAGARA TIGHTROPE.

ONE of the most fantastic uses to be made of Niagara power is that which proposes to let it loose on a tight-rope cable suspended across the chasm, so that the performer on the rope can illuminate electrically himself and the special bicycle that he is riding. This is the serious plan of Mr. D. H. McDonnell, who has been performing at Manhattan Beach, Chicago, and who, it will be remembered, has already been across the Niagara River several times on the rope. In 1893 he crossed, wearing his ordinary street clothes, including shoes. An imaginative artist of the New York "World" has now tried to delineate the coming sensational spectacle, ignorant, however, of the fact that the performer does not cross in front of the Horseshoe Falls, as shown in his sketch which we here reproduce, but some distance down the river, eastward of the railroad bridges.

The trip is to be undertaken at night so that the incandescent



CROSSING NIAGARA ON A LIGHTING TIGHT ROPE CIRCUIT.

lamps on the rider and wheel will show up brilliantly. The rubber tire is removed, and the metal rope will fit the groove of the tire, thus making contact and delivering 500 volt current. At Manhattan Beach, Chicago, McDonnell's belt got short-circuited, when he was badly burned about the breast and back. Should anything of the kind happen while he is swaying out over the rushing torrent, two hundred feet in midair, the consequences might be disastrous. The current is to be supplied from one of the plants in the vicinity run by Niagara.

STEAM TURBINE ECONOMY.

THERE never was a time when the economies of central station working were looked after more sharply than they are at present, and still, if we may judge from the statistics available, the coal consumption in American central stations on the average is frightfully high. We believe it may be fairly assumed that in the majority of cases the blame of the avoidable loss may be attributed to the engine rather than to the boiler. But even assuming it to be evenly divided between them, enough would be left to put the engine in the position of an habitual offender. The rapid introduction of compound and triple expansion engines of late years, more particularly in the larger stations, has brought the engine economy in many cases within limits closely approaching the best marine practice, but the rank and file of American stations still worry along under conditions which tend to make the earning of dividends harder and harder every year, and not a few have already undertaken to remodel their plant thoroughly and substitute more efficient apparatus, entailing, in many instances an expense equal to the original outlay. Whether it is a case of remodeling or of entirely new construction the engine must always command its due share of attention. American engine builders have not been slow to recognize this, and engine users have appreciated their efforts by a liberal and ready adoption of the new types of engines which the electric light and railway enterprises have called into life. Yet it would seem that so far as one particular type of engine is concerned, it has been entirely ignored in spite of the fact that for ten years past its use in England and on the Continent of Europe has been steadily extending. We refer, of course, to the steam turbine. Two principal types of these engines have been brought out, the Parsons, which is in quite extended use in England, and the De Laval, which has more recently been gaining ground on the Continent. We had long been waiting for the first step towards a trial of these machines in America, and this has at last been undertaken by the New York Edison Company, to whom the electrical industries of the entire country are already much in debt for their pioneer work. The results of the tests of the De Laval steam turbine in the New York Edison station—all things considered—must be taken as eminently satisfactory. It is quite true that 19.25 pounds of steam per horse-power hour has been considerably exceeded by triple-expansion electric lighting engines, but these, as a rule, have been of very much larger power than the De Laval turbine under discussion. More significant than the figure of maximum economy shown, is the high, sustained duty at light load. It is this feature which will commend itself, it seems to us, more particularly for isolated plant work, in which, as a general thing, light load is the rule. But besides its unquestioned economy in steam consumption, the steam turbine also lays claim to economy of space occupied for a given power. In this respect it stands unrivalled, owing, of course, to the high speeds at which it is operated; this consideration may be a dominating one in many instances. The steam turbine has already made a sufficiently good record to establish its claim to recognition, and we are glad to know that an American firm has undertaken to build this type of engine.

ERRONEOUS IDEAS ABOUT STREET RAILROADS.

THE recent passing of the Kings County Elevated Railroad of Brooklyn into the hands of a receiver has led the "New York World" to arrive at the conclusion that the elevated fares in New York ought to be reduced to three cents. This is based on the statement of the road's treasurer that the first year after the trolley system was introduced in Brooklyn the company lost $120,000, owing to the new competition; and though some of this was regained during the famous trolley strike, the reflux of travel was only temporary. It seems to us that this is puerile and grotesque reasoning, if it can be dignified by being regarded as serious argument. It is hard to

see what the condition of affairs in Brooklyn has to do with that in New York. As a matter of fact the New York elevated has felt the competition of the surface cable cars to such an extent that any reduction in its rate of fare would probably stop the payment of dividends and might even throw it into bankruptcy.

Meantime, as the "World" was such an abusive foe of the trolley, it is interesting to note its concession that "People are using the electric cars, not because they love their management, but because electricity undoubtedly stands for progress and increasing concessions to public convenience."

Another point in regard to which the "World" needs fuller information is the cost of street railway construction. It speaks of the average capitalization of the street lines at $95,-600 a mile as "an extreme case of inflation," because the rate for the steam roads is only $62,951 per mile, and because "the cost of constructing the average mile of steam railroad track is, of course, much greater than that of laying the average mile of street railway track on a roadbed already prepared and not ballasted." All this, again, has nothing to do with the case, the figures being the capitalization per mile and not the mere cost of track construction, which is but one item and leaves out of account rolling stock, power plant, real estate, and lots of other things. This the "World" either does not know or prefers to ignore. But even on the individual point of track construction, the "World" and its readers should know that it is grossly in error, as the average cost per mile of a street railway is very high, in almost any city that can be named, above 10,000 inhabitants. In cities like New York it runs into enormous figures, and in many places has to include the reconstruction and paving of the whole street between the curbs. Hence, on this point again, the "World" is wrong in trying to base an argument for three-cent fares. No doubt there has, in some instances, been over capitalization by street railroads. So there has been by farmers, and hence we have the silver craze. It is a common mistake to overestimate earning capacity and capitalize it and go into debt on it. But in the case of the railroads three-cent fares are no cure, for most of them could not operate at that rate, and the public would thus lose heavily both as to its investment and as to its facilities for locomotion.

TELEPHONE SWEARING.

IT seems to us that a question of fact is broadly involved in the accusations recently made in one of the New York newspapers and quoted by us last week, to the effect that owing to the badness of the local telephone service, those who used the instruments were more grossly profane than any other people in the city. There are two definite charges or indictments here. One is that the service is very bad. The other is that New Yorkers have so little self-control that they lose their temper and good manners whenever they handle the telephone.

Taking up the latter accusation, we venture to say that it is wholly untrue. Our inquiries of the telephone managers do not go to show that anyone has been cut off, as the rules provide, for use of foul language; in short, there are no statistics on the subject because the alleged practice of indecent profanity does not exist. But admitting that the telephone management would wink at such conduct because provoked by its own incompetent service, we must appeal to the experience of our readers and ask them whether among the ten or twelve thousand local subscribers they have heard a single one of them swear, and that profusely, at the telephone or through it, because the service was bad. We have made inquiries and investigation on this point ourselves, and cannot carry home the proof of a single "cuss word." It is, moreover, one of the well known facts that New Yorkers are mild mannered men of soft speech. They do not swear horribly like the English troops in Flanders or like Governor Tillman, of South Carolina, in advocating anarchy and repudiation. If they have to put up with temporary inconvenience or annoyance, they are wont to laugh it off altogether too easily. A New Yorker will endure without murmur things that Londoners or Parisians would not stand for five minutes, as affecting comfort and getting the value of their money.

Coming to the question of the quality of the service, we do not hesitate to characterize it as good, and as being generally of remarkable excellence. We say this after testing kindred service in most of the cities in this country and several cities of Europe. On the pro rata basis, a subscriber can now limit his expenditure to the exact number of calls, and anybody who really needs a telephone can afford to put it in.

ELECTRICITY DIRECT FROM COAL.

LACKING one year it is just three-quarters of a century since Seebeck demonstrated that an electric current is generated by heating the junction of two dissimilar metals. When one stops to consider that this discovery antedates Faraday's discovery of magneto-electric induction by nine years, and when one contemplates the vast extent to which the latter has been applied in practical work, one is impressed with the fact that the germinating power of ideas is subject to wide fluctuation. We are not unmindful of the fact that theoretical considerations have limited the activity in the field of thermo-electric work, but even this would scarcely serve to explain the slow advance which marked its progress from the beginning. Happily the work of the last twenty years in other departments of electricity has again given a stimulus to the search for a method of direct production of electricity from coal or other forms of fuel derived from it, and indications are not wanting that substantial advances have been made, if not towards a general utilization of some of these methods, at least in their adaptation to many useful and important applications involving the use of electric current.

The type of apparatus which may be said to be advanced farthest beyond the laboratory stage is the thermo-electric generator of Mr. H. B. Cox, already noted in our columns, and the description which we give in this week's issue of the factory constructed for its manufacture in England is sufficient evidence of works backed by faith. The salient feature of the Cox generator is the nature of the joint between the dissimilar metals, which has invariably been the weak point in previous constructions of this nature. The length of time during which some of Mr. Cox's generators have been at work may well be taken as good evidence that the question of durability and power to stand up to its work is disposed of.

The question which naturally forces itself to the front in the application of a new apparatus designed to replace older types is, "What will it cost to operate?" On this point the figures given by Mr. Cox shed considerable light. Taking the 12½ watt generator to consume 2½ cubic feet per hour, 1,000 cubic feet of gas, would, therefore, furnish 5,000 watt hours. With ordinary city gas at $1.25, this figures out at 25 cents per 1,000 watt hours, or 1 cent for 40 watt hours. This rate, while not as low as that obtaining in some cities, nevertheless compares favorably with that charged in many smaller towns, and when it is considered that producer gas, costing far less than $1.25, and oil, may be employed, instead of the more expensive illuminating gas, the possibilities of the new thermo-cell are at once apparent. The comparison of cost of current just made refers, of course, only to current generated by steam power. When we take into account the many uses to which galvanic batteries are still put and compare their cost of operation with that of the thermo-generator, the difference is so striking in favor of the latter that no special calculation is necessary to demonstrate it. As to the cost of Cox thermo-generators we are informed that a horse-power equipment could be installed at a price not exceeding that of a steam engine and dynamo equipment of like power. Of course we are here giving the figures and data furnished us by the inventor, who is perfectly willing to stand or fall by them. Taking them as they stand, however, we may yet hope to see electricity direct from coal well realized before the close of the century.

EDISON TELEPHONES.

IT is rumored that Li Hung Chang is anxious to get telephones and phonographs from Mr. Edison. If this be true, there is little doubt that the inventor is ready and willing to supply the needed commodities. Phonographs he has, we all know, and unless his right hand has lost the cunning which enabled him to turn out the two or three hundred types of telephone, of which specimens were shown at the Lenox Lyceum six years ago, he should be well able to furnish telephones as well. Mr. Edison by this time should also be free from the old contracts that checked his ardor and literally threw him out of the telephonic business.

Thermo-Electricity.

THE COX THERMO-ELECTRIC GENERATOR.

It is now about eighteen months ago that The Electrical Engineer first described[1] a type of thermo-electric generator devised by Mr. Harry Barringer Cox, of Hartford, Conn., in which that gentleman had embodied the results of many

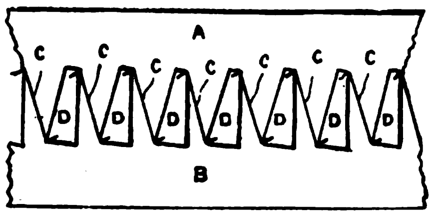

Fig. 1.—Mould for Casting Cox Thermo-Elements.

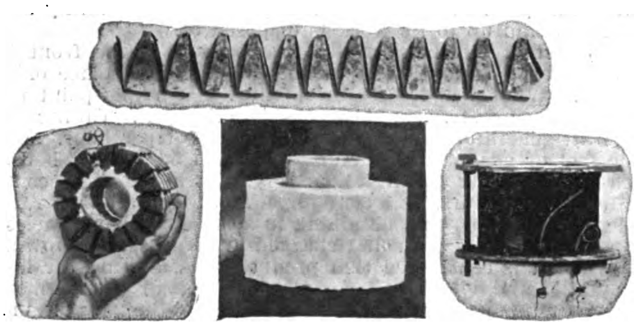
years of study and experiment and which far surpassed in efficiency and economy anything which had theretofore been accomplished in the direction of thermo-electric current generation. Although the invention was worked out on American soil, circumstances, the details of which need not be entered into here, have led to the establishment of the first factory for the manufacture of the Cox thermo-electric generators in England, and a brief description of the Cox laboratory and works at St. Albans, Herts, will, without doubt, prove of interest, as it represents the largest individual works of the kind in the world devoted to the manufacture of thermo-electric generators.

Before proceeding to describe the process of manufacture, it may be well to recall that Mr. Cox has achieved his present success chiefly by recognizing and overcoming the main difficulty heretofore encountered in thermo-electric generators, namely, oxidation at the joint, with its attending increase in resistance with lapse of time. In the Cox generator this defect is overcome by having practically no real junction point. This is brought about by graduating or shading the two alloys composing the element into each other so that there is practically



Figs. 2, 3, 4 and 5.—Cox Thermo-Electric Element in Various Stages of Construction.

no definite point of junction. Oxidation of such a junction is evidently impossible, and hence is explained the constancy of its action after a use, in some instances, of five years.

Mr. Cox employs in his generator a couple, one element of which is an alloy of antimony and zinc, and the other of copper and nickel, each couple giving .08 volt. A sufficient number of couples to form one ring or tier in the generator are cast together in a mould of peculiar construction. The mould is made in two parts, A and B, Fig. 1, each half being a steel plate with pointed teeth on one of its edges. When the two parts of the mould are placed together, the teeth intermesh as in toothed gearing, and grip the short copper plates, C, which form the positive elements, between their bearing surfaces. The clearance left between the back of one tooth and the face of the tooth next following, forms the moulds or cavities, D, into which the antimony alloy forming the negative element, is cast. The ends of each copper element are bent round so as to lie across the ends of the cavities into which the antimony alloy is poured.

The fused antimony thus comes directly in contact with the copper plates, but this would not be sufficient to make a good joint if the metal were allowed to cool in the ordinary way. Since the fusing temperature of the antimony alloy is about 300° and of the copper 1,000°, a strong welded or alloyed joint could evidently not be secured at the lowest fusion temperature. The desired result is effected, however, and a true welded point produced between the antimony and the copper by heating the steel moulds to a high temperature before casting, and maintaining them at this temperature for a considerable time thereafter. A gradual process of alloying thus takes place between the fused antimony and the copper at their surfaces of contact; a certain percentage of copper penetrating into the antimony, and a certain percentage of antimony into the copper. The stratum of metal which forms the junction of the two elements varies uniformly in composition from that of the positive element at the one side to that of the negative element at the other.

The element after it leaves the casting mould is shown in Fig. 2; in this form it undergoes a careful annealing until the antimony alloy, which, after casting, is quite brittle, becomes tough and can be readily handled without danger of breaking.

After the annealing process is complete each strip is tested

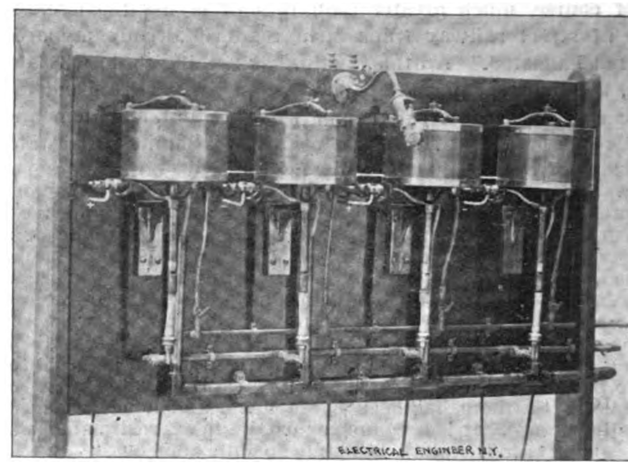


Fig. 6.—Fifty-Volt 5-Lamp Outfit of Cox Thermo Generators.

for resistance, and a variation of but one-thousandth of an ohm, indicating a defect in casting or annealing, leads to the rejection of the strip.

The straight strip or series of couples, after passing the resistance test satisfactorily, is bent into circular form, in the manner shown in Fig. 3, each such ring of elements constituting a tier in the finished generator. In order to prevent corrosive and disintegrating action of the gas flame, the rings of elements, together with their connections, are covered with a vitreous enamel, the element having then the appearance shown in Fig. 4.

The enamel coated cell is then surrounded by a copper cylinder and flanges, insulated from the main body, as shown in Fig. 5, and this constitutes the water back for cooling the outer terminals of the elements. The illustration shows the water back with the outer cylindrical casing removed.

The standard form of generator adopted by Mr. Cox is shown in Fig. 6, which illustrates the five-lamp set, designed for lighting a house of moderate size. This set consists of four generators, 7 inches in diameter by 5 inches high. The

Fig. 7.—The Cox Laboratory, St. Albans, England.

interior of each generator is heated by a Bunsen flame rising through the central opening. The heat is deflected towards the sides of the elements by a series of discs which increase in diameter from the bottom upward. The deflectors become

[1] The Electrical Engineer, May 1, 1895.

red hot and serve to effect the complete combustion of the fuel supply. In the case of oil, these deflectors prevent the formation of soot and obviate the disagreeable odor of burning oil.

The standard capacity of the element adopted by Mr. Cox is 12½ watts, and instead of building generators of various sizes as was done in the early stages, the required capacity is obtained by coupling up a sufficient number of the standard elements. Thus one size of elements has an output of 5 amperes and 2½ volts on closed circuit; on open circuit the e. m. f. is 5 volts. This result is obtained with a consumption of 2½ cubic feet per hour of ordinary illuminating gas. With pure water gas a higher result is obtained, and with oil a still better result has been noted.

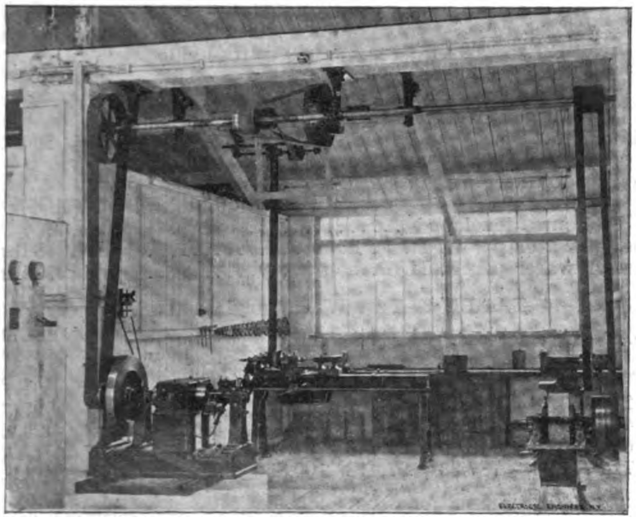

Fig. 8.—Machine Room, Cox Laboratory.

The generators are built, as stated above, to a standard size and coupled up like batteries. The voltage of the generators for different purposes can be varied from ½ to 12 volts by changing the form and size of the thermo-couples, the external dimensions of the element remaining the same. In the earlier types of his generators, Mr. Cox also employed a water back with continuous circulation of water. The circulation has been found to be unnecessary; all that is now required is the refilling with water of the back at intervals of about six months.

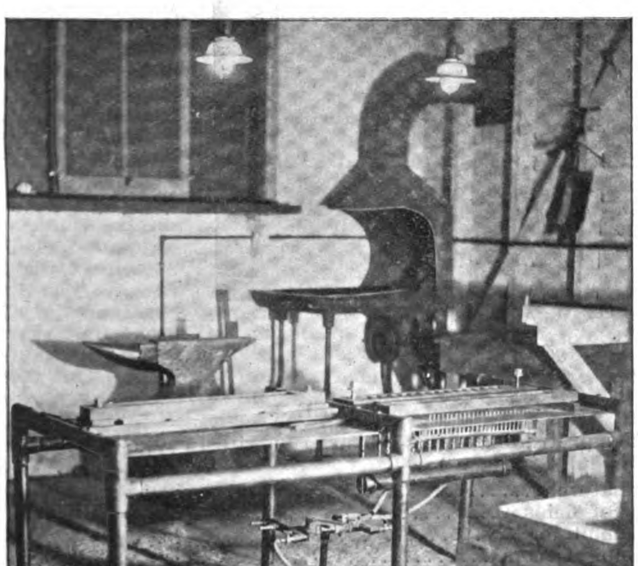

Fig. 9.—Moulding Department, Cox Laboratory.

The Cox laboratory, an exterior view of which is shown in Fig. 7, is admirably equipped for the economical manufacture of thermo-generators. Our illustrations, Figs. 8 and 9, represent, respectively, the machine and moulding rooms. One of the means for saving labor in handling is the overhead electric crane, illustrated in Fig. 10, the chief point of interest in connection with which is the fact that it is operated by current derived from thermo-generators. We believe that this is the first instance on record of apparatus of this kind driven by current generated in this manner.

At the St. Albans works the current generated in testing the thermo-generators is turned into a storage battery, a special switch being employed for the purpose. The battery is capable of giving 112 volts. Where the current demand is not continuous, as in house lighting, a storage battery is usually added to the thermo-generator equipment, the batteries being charged in parallel with the generators and discharged in series.

As regards the actual use to which the Cox thermo-generators have been put we may recall their employment as far back as two years ago in the office of the Commercial Cable Company, in New York, with excellent results and greatly increased economy over batteries. The generators have also been tested by the British Post Office electricians, who, we understand, were able to detect an increase of only .02 ohm in a 1-ohm generator, after six months' hard usage.

Mr. Cox is sanguine in the belief that with his generators any work of an isolated nature ranging from 1 to 2 horsepower, such as house lighting, the running of pumps, fans, small machinery, X-ray apparatus, etc., is feasible and economical. We understand that the English company is thriving and that an agency will soon be established in the United States. If Mr. Cox's statements are true, and we have no reason to doubt them, a large field awaits him in this country.

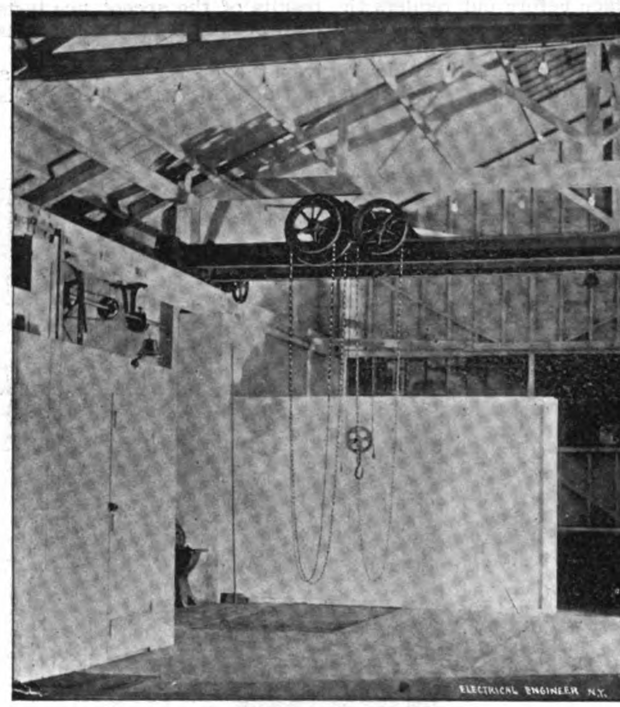

Fig. 10.—Electric Crane Driven by Thermo-Generated Current.

A Cox thermo-generator can be seen in operation at the offices of The Electrical Engineer, which will be gladly submitted to the inspection of those interested.

PHOTOGRAPHY UP TO DATE.

The following advertisement is clipped from the London (Eng.) "Standard" of Aug. 8: "The New Photography.—Owing to the success Mr. Henry Slater has personally achieved with the New Photography, he is prepared to introduce same in divorce matters free of charge. Offices, No. 1 Basinghall street, city." Mr. Slater, as a detective, is evidently up to date. We presume he uses the X-rays to discover the skeleton which every closet is said to contain. Ability to do the detective act without squinting through a keyhole is regarded evidently as one of the recommendations of the rays, which themselves prefer darkness rather than light.

THE HIGHEST POSSIBLE COMPLIMENT.

Mr. Harry Linwood Tyler writes us: "I enclose you check for The Electrical Engineer for another year. In stating that the publication is as interesting as ever, I believe that the highest possible compliment is paid you."

ELECTRIC LIGHTING.

TEST OF A 300 H. P. DE LAVAL STEAM TURBINE IN THE TWELFTH ST., NEW YORK, EDISON STATION.

THE New York Edison Electric Illuminating Co., whose stations and methods of working were described in extenso in our issue of Jan. 8, 1896, have always been in the vanguard of progress in the application of improved methods and devices, and as a result their new stations represent the highest types of modern electrical engineering. In the description of the company's work above referred to, mention was made of the fact that the Twelfth street station then in course of erection was to be operated by dynamos driven by De Laval steam turbines. This is the first instance of the use of this type of engine for regular commercial purposes in this country and hence the results obtained with it are not only of special interest to central station managers but to all power users as well.

Through the courtesy of the Edison Company we are enabled to place before our readers the results of the acceptance tests made on one of these turbines, two of which have been thus far installed.

The data marked Table 1 gives the operating data of a six-hour test under conditions of full load, while Table 2 is a résumé of some tests under partial load when operated with 2, 4, 6 and 7 steam jets, each test lasting one hour. The brake horse-power was obtained from the electrical horse-power by assuming that the commercial efficiency of the 100 kilowatt dynamos was 90 per cent.

Table 3 gives the temperature readings.

The 300 horse-power steam turbine on which these tests were made, which is illustrated in the accompanying engraving, was built by the Maison Bréguet, of Paris, for the Société de Laval. Each 300 horse-power turbine drives, by means of gearing, two 100 kilowatt Desroziers dynamos, one on each side of the turbine shaft. Operating with a steam pressure of 145 pounds to the square inch and a vacuum of 26 inches, the steam consumption, operating condensing, was to be not over 18.7 pounds per brake horse-power hour.

The turbine disc has a diameter of about 0.75 meter (29.5 inches) and a thickness through the blades of about 10 millimetres (.4 inches). The turbine disc runs at a speed of about 9,000 revolutions per minute; the dynamos at 750 revolutions per minute. The total equipment, comprising steam turbine, gearing and dynamos, occupies a space 4.05 meters (159 inches) long, 1.97 meters (77⅝ inches) wide, and 1.31 meters (51 inches) high.

TABLE 1—Full Load Test.

Average of readings:

+	+	—	—
127.25 volts.	692.48 amps.	128.26 volts.	709.18 amps.

127.25 × 692.48 = 88,118.080 watts + side
128.26 × 709.18 = 90,959.427 " – side

Avg. watts... 179,077.507 " both sides

179,077.507 is 90 per cent. of 198,975.01 watts = 266.72 h. p. × 6 = 1,600.32 h. p. hours.

Weight of water discharged from air pump, 6 hrs. = 27,763 lbs.

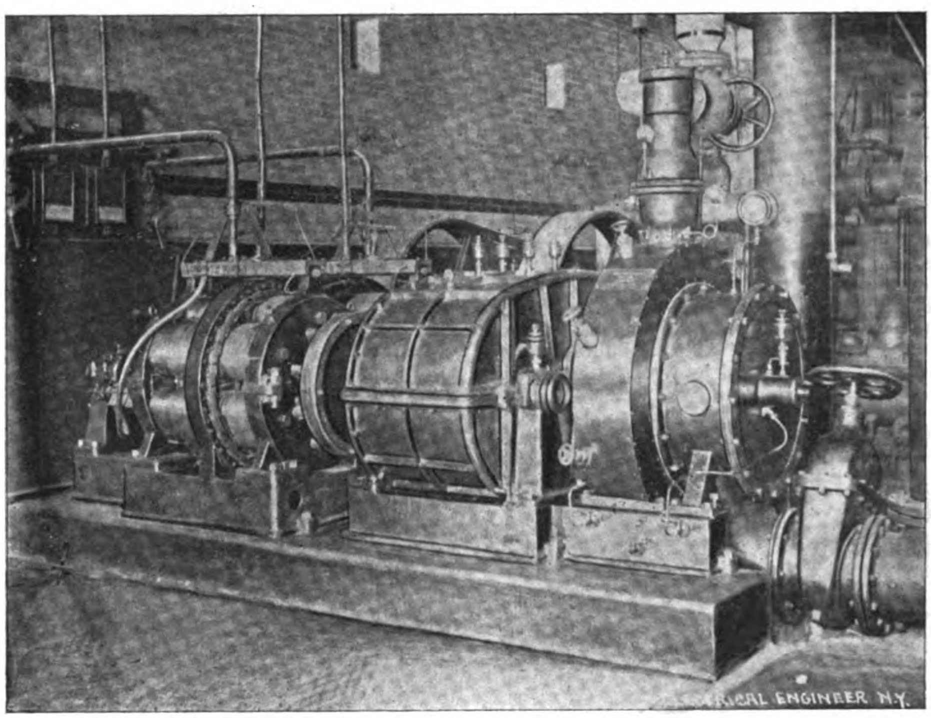
H. P. hours developed .... 6 hrs. = 1,600.32

Lbs. of water per B. H. P. hour .... 17.348 lbs.

Lbs. of water per E. H. P. hour .... 19,275 lbs.

TABLE 2—Test With Varying Load.

No. of jets used.	Average load. + Amps.	– Amps.	Average watts. +	–	Per cent. of full load.	Vacuum.	Lbs. of steam per B. H. P.
2	153.78	147.15	18.707	18.283	18.50	27.	27.35
4	433.60	455.80	54.156	57.886	56.02	26.43	20.22
6	700.85	718.65	87.746	91.268	89.51	26.07	19.75
7	771.94	787.33	97.418	100.856	99.14	25.79	19.95



300 H. P. DE LAVAL TURBINE IN NEW YORK EDISON STATION.

TABLE 3.

Temp. Readings after 6 hours run with Load as indicated.

	+ Dynamo.	— Dynamo.
Armature	120° F.	129°
Av. of fields	98°	107°
Commutator	144°	132°

Temp. above room arm	38°	47°
Temp. above room fields	16°	25°

MR. H. S. JACOBS, the American mining engineer, has applied to the Mexican department of encouragement for the right to dam the Amacusac or Grande River, near its confluence with the Barranquillo, for the purpose of securing water power to operate his mill at Huautla, Jojutla District, State of Morelos and to generate electricity for transmission from the falls for use in Mexico City for power and lighting.

ELECTRIC TRANSPORTATION.

LONG DISTANCE AND HEAVY DUTY ELECTRIC RAILWAYS.[1]

BY F. W. DARLINGTON.

THIS subject may be treated at length from two standpoints, the scientific and commercial, either of which, to fully discuss, would take up more of your time than I feel justified in doing to-day. I will therefore occupy you with glances at both sides of the subject, and call your attention to a few of the important thoughts which I deem pertinent to the times, and of supreme interest to all of you who have roads, suburban, interurban, and local, to operate and earn dividends therefrom.

There are already in operation many long distance and also some heavy duty electric railways. The majority of these roads do not fairly come within the scope of this paper for the reason that they have been built as ordinary trolley roads, with road-beds insecure and unsafe for high speeds. Our subject refers more properly to roads designed to supplant the steam locomotive both for high speed and heavy freight service.

Some few roads have been built, which, though not longer than ten or twenty miles, and consequently not long distance roads, yet are convincing proofs of the ability of the electric motor to perform all work demanded of a steam locomotive. These roads have been installed as experiments and by such corporations as the P. R. R. Co.; the N. Y., N. H. & H. R. R.; and the B. & O. R. R.; and with all the success obtained on these, the corporations named are yet unconvinced of the advisability of adopting electricity for their entire systems.

This incredulity is not prejudice in favor of steam, as asserted by many writers, for the men at the helm of affairs in these big companies are too broad-minded and too alert for the companies' interests to be blinded by prejudice. Their slowness to be convinced is to be attributed more to the lack of proofs of its desirability from their point of view, as handlers of heavy traffic.

The first electric railway motors were designed to supplant horses in street railway work. And from this point the advances have been made by meeting and overcoming difficulties long since met and overcome by the steam railroadman. For it must not be forgotten that the first railroads were horse roads and when the steam locomotive was put upon them it had to undergo changes, and its use necessitated alterations in the construction of cars and roadbed. Does it not seem absurd, therefore, to ask steam railroad men to go backward some fifty years and begin over again, for this was the proposition advanced when they were asked to take hold of the subject in the shape it was only two years ago. It is to the method in which the question has been taken hold of by these men that is due the credit of the advanced position the electric motor holds to-day as a rival of the steam locomotive.

So far as the motor alone is concerned there is no longer a possibility of doubting its ability to do the work of a steam locomotive. It can make a car move as fast and faster. It can pull heavier loads by reason of its power being supplied from some exterior source, and hence, having practically an unlimited supply, it can climb steeper grades, and it can reduce expenses. Can more than this be asked of it? I think not!

There remains, however, the question of how to transmit the electricity from the stationary engine and boiler plant to the motor on the car. It has been proved beyond doubt that power can be developed in a stationary power house at a very large saving of coal and other expenses. Of this fact, and that of the ability of the motor to do all the work demanded of it, there is no difficulty in convincing the steam railroad man. But the inability to prove beyond a doubt that the power can be transmitted satisfactorily for long distances is where the failure lies. This is the one point to be worked out and demonstrated before there will be any general adoption of electricity for long distance roads.

There have been many theories advanced and systems proposed, but as yet but an insignificant number of them have been tried, and they only for very short distances.

This question must be solved, and all are looking for the solution in the alternating current system, but whether this or the direct current system is the solution is still an open question. There are many who think that the only solution is to come from the alternating current, but in the meantime devices are being added to the art that tend to making the direct current more and more of a success in overcoming long distance. Ultimately, no doubt, the ideal alternating current system will be at our service, and by the ideal system I mean that one requiring no actual current-carrying contact between the car and the track; in other words, some modification of the induction system. But unless this system is developed and made practical before long it will find the older direct current system so well established and so generally in use that it will be difficult to have it adopted except for new roads, for it must be borne in mind that the depression in the financial situation for the last two years is the reason more than any other that steam roads have not been changed to electricity. So that with the country enjoying even moderate prosperity there is sure to be extensive and widespread experiment in this line, and it is not too much to say that in five years' time there will be such a change in the minds of financial and railroad men that there will be a rush to obtain the benefits of the reduced operating expenses to be derived from using electricity.

This assertion may seem wild and romantic, but any close observer of the thought and the attention given this subject by the large steam railroad companies, will bear out this statement. It does not mean that people will go wild over it, for that period in electric railroad history is past, and all should be thankful for it. But it does mean that with money available there will be a general start to equip both long and short roads, and the start once made, the work will be pushed, on increasing numbers of roads, which, taken altogether, will constitute the equivalent of a rush.

The same conclusion is reached when it is remembered that the very conservatism of the steam railroad man, of which so much is said in electrical circles, will keep him and has kept him from adopting electricity until that same wonderful power shall have demonstrated its ability to do, and do continuously and satisfactorily, all of his work. This demonstration once having been made, and made in the manner those engineers abreast of the times are confident it will and can be made, that is, to prove beyond all possibility of doubting that money can be saved by discarding the steam locomotive for the electric motor—even when such change requires an enormous outlay of new money—then the conservatism must give way to progress, and all will be only too anxious to obtain the advantages to be gained.

What has all this to do with suburban and interurban railways as existing to-day? It is a question of vital interest to all those companies operating such roads. For all managers of local roads, whether they be running between towns or are purely local, if they in any measure parallel steam roads, have this fact staring them in the face, that it is only a matter of time, and a short time at that, before they will have real competition from those same roads whose territory they so profitably invaded.

They (the local managers) must know that a trunk line supplied with such power as it will require, can be tapped at any point to run a local road or branch line, at but small expense in comparison with that required to operate the local road independently. Then, too, let him think what it would mean to him to have a competing line with frequent service, and maintaining high speed on safe roadbeds.

All these things must be faced sooner or later, and while the above statement may seem alarming, yet it need not be so to the wise manager who will keep his eyes open and prepare himself in the time at his disposal.

Just what this preparation consists of will have to be worked out by each individual. But it is very safe to say here that one of the most important points he will have to consider will be that of expenses; he will have to reduce coal bills and bills all along the line. He will also have to guard well his policy of management, but as this point is not included in the scope of this paper it will not be elaborated upon, though there are interesting points for discussion which might be brought out.

The question of expenses is mentioned here for the reason it is safe to say that at least seventy-five per cent. of the electric railroads in this state are paying too much for their power. By power is meant available power at the car axle. Some develop power cheaply and waste it on the line; others may develop it at high cost while they distribute it, and utilize it economically; while others again may be losing at only the motor end of the line. Then again, some roads may be so full of heavy grades that they may be eating up their earnings in maintaining them.

At any rate, the fact remains that few, if any, are paying dividends, and many are in the hands of receivers, when it would be possible to make all pay, excepting, of course, those wildcat schemes floated to fleece people of their good dollars. The sooner these latter are weeded out or reorganized on a more reasonable basis, the better it will be for all. There is one thing very sure and that is that there is no excuse for any electric road, not saddled with interest for imaginary money

[1] A paper read at Altoona, Pa., before the Pennsylvania Street Railway Association, Sept. 2, 1896.

spent, to spend more in expenses (which includes salaries and interest) than its receipts amount to.

The reports obtained from many roads vary to such an extent that it is impossible to assume any given amount at any given place without knowing the conditions existing there. It might be stated here that a car mile should be produced for a given number of cents, based on these reports, and nothing of real value towards the solution of the question at hand would be gained, for all the calculations and reports made on power questions have been based on results at the power house, or at the switchboard, which is only a part of the proof, for they take no account of interest or line losses and motor repairs, which are all necessary for determining definitely as to the cost of a car mile. For of what use is it to calculate your power in kilowatt hours at the power house and in that calculation consider only your coal, water, supplies and labor, when you omit all account of your interest except as a lump sum? And of what use is it to define your motor repairs and car expenses in car miles when here, too, you lose sight of interest?

How can you tell how these several items compare unless you base them all on the same unit? This unit should be in car miles, for expenses of every description, and when they are so calculated you have the true basis, for all expenses are incurred for the one object of propelling cars a certain number of miles.

By this means the manager can determine the value of each department under him, and when economies must be undertaken he knows exactly where to turn to accomplish them. It would also enable the manager to tell at all times in what shape his engineering force was, whether his engineer was competent, and if he was attending to his duty. Again, he would be able to calculate to a nicety what each improvement would cost and in what way it would benefit him. His receipts, being readily reduced to earnings per car mile, would enable him at a glance to determine the prospects of his road.

All these points are of importance to know in order that the manager may keep himself posted as to the working of his system as a whole. The managers who do this are not many, and why they do not is to be attributed to the fact that the necessity for so doing has not been made clear to them. There are many who keep elaborate books with the expenses divided up into different classes, when they are principally only of value to keep the bookkeeper busy, and really do not enlighten anyone as to the scientific conditions of the road.

This association can broaden its scope of usefulness to its members and at the same time advance the interests of all electric roads by appointing a committee to gather data from its members and tabulating them, by numbers, not names, for it is not wise or of value to publish the names of roads making reports, and it is not necessary.

This committee can then digest the reports and each year draw impersonal conclusions for the benefit of all. This same method is employed by the National Electric Light Association, and though it has been in use only a few years it has proved a great benefit to those desiring to avail themselves of its lessons.

It will be well to return once more to the subject of grades and curves, to say that both are expensive luxuries, not only because they cost more to maintain than straight level roads, but also because they are more expensive to operate, and are the cause of greater original investment. And as we have seen in the case of the Columbia & Donegal R. R., they may be the source of many and expensive damage suits.

Suppose A and B each build a road from X to Y, and A builds his with long radius curves and as little grade as possible, say a maximum of 1 per cent., while B does not appreciate the gain in this method and so has some heavy curves and some heavy grades. What will be the result? It is well known that it takes more power to climb the hill than to run on a level, but you say that the motor on the level averages the same power for the whole round trip. That is true, but here is the point, for A can do his work with smaller motors which will be running more continuously and will be calling for a more even supply of power from the power house, which in itself will be a source of economy both at the motor and at the power house. B will be drawing power intermittently and creeping up the hills to rush down the other side at great risk. B's motors will cost more than A's because of their larger size, and B's engines and generators will have to be larger. His feeders must be larger. Just what these several items will amount to can be determined, and I maintain that they should be calculated before a road is built, and the economical grades figured out.

When it comes to competing with the steam roads as they exist to-day, the electric road attracts local travel because of its cars being run at frequent and regular intervals, whereas a traveler must consult a time-table before taking a train on a steam road. Again, in summer time the electric road offers the additional inducement of a cool, clean ride, while on the steam road if one opens the window for fresh air he is treated to a shower of coal dirt, cinders, and dust, to such an extent that when the journey is over the passenger is more uncomfortable than when he started.

All this is destined to change, however, for the undoubted tendency of steam railroad travel between large cities is to move trains at more regular and more frequent intervals. This is indicated by time-table records for some years back. The clean travel will come when electricity is adopted.

The question of the real meaning of the difference in number of trains running on competing roads is shown very clearly on the roads operating between Philadelphia and New York. Of these two roads the Pennsylvania gives by far the most trains and the result is that it gets the most of the travel. This is natural for the reason that a man bound to New York from Philadelphia will buy his ticket by the route that will give him the greatest choice of times to start on his return. Carrying the comparison farther, suppose an electric road was built between the two cities and built so that it could land pasengers in New York as quickly as the steam roads and a train service every fifteen minutes or a half hour be maintained, there is no doubt that it would get the bulk of the travel.

As for speed, if a speed of seventy-two miles an hour can be obtained on a road seven miles long and maintained for three miles, as has been done on the electric road installed by P. R. R. Co., in New Jersey, it certainly would be no more difficult to obtain a speed of eighty to ninety miles an hour on such a roadbed as possessed by the P. R. R. on its Philadelphia-New York line. As for the length and weight of train, the same road has demonstrated that it can handle a train of three cars, i. e., motor car and two regular Pennsylvania day coaches as trailers and fulfill its schedule requirements.

I have observed with interest the fact that the majority of trains leaving the Broad Street Station, Philadelphia, are composed of a combination car and two or three trailers and that trains of more than four trailers are not frequent. It therefore seems to indicate that a motor car of sufficient capacity to draw these trailers at the desired speed could be made a standard and do all the work. This might necessitate making two sections of the through trains, but this would prove a benefit to the traveler, especially if the two trains were scheduled to run at different times.

Right here it might be interesting to consider what we are to have in the place of the steam locomotive. It can be demonstrated conclusively that when we discard the steam locomotive, the most economical and convenient method will be to put the motor under a baggage or combination car, for if we attempt to follow steam railroad practice and carry enough weight on an electric locomotive to provide traction for a train, we will have to add useless weight, and one of the chief sources of economy of the electric system over the steam is from the reduction of the weight of train. The weight can be done away with because of the fact that the even pull, at a tangent to the circumference of the motor armature, produces an apparently greater possible traction effort per ton of weight, and in addition reduces the tendency of the wheels to slip at starting.

This feature of the electric motor is the one above all others that establishes the fact that it has come to stay, no matter what developments may be made in air, gas, or other motors which have to convert a reciprocating into a rotating motion.

And the fact that an electric motor supplied directly from a central power house gives to that motor a practically unlimited supply to draw from, puts it far ahead of any motor which carries its supplies on its back, whether it be in air tanks, storage batteries, oil reservoirs, or coal and water bunkers. Any storage reservoir must be refilled and this takes time. And all time used in this way is dead loss and means that the motor can not make as many miles in a day.

One more point in favor of the electric motor is that where they are equipped with double motors and two controllers, there is no one thing that can happen to prevent the motorman from getting his train to its terminus, for with the modern apparatus he can cut out the motor or line giving trouble and proceed with one motor. To be sure his speed will be decreased, but still he will be able to move his train, whereas in any of the above cases there are a number of accidents, and trivial ones, that may happen to cause the train to wait for a new motor. Of course, the question of the supply line, or feeder system, is ignored in this statement; but with the advent of electricity on steam roads, will undoubtedly come a feeder system practically impossible to interrupt.

The question arises when considering cars for high speed work as to what kind of motor trucks should be used.

The advocates of maximum traction trucks refer to the steam locomotive as their model, but there are some principles in use on the steam roads which we must avoid, and this is

one. The steam locomotive is of necessity a maximum traction machine, but it has been demonstrated that a car can be started and propelled with less power when the trucks have a motor on each axle (i. e., four motors on an eight-wheeled car), than where equipped with a motor on each pair of axles (i. e., two motors to an eight-wheeled car), and this too when the four motors are of greater weight than the two larger motors.

These so-called maximum traction trucks with one pair of small wheels are lately provided with some kind of device to hold down the small wheels to keep them from jumping the track. This deprives the truck of most of the efficient traction obtained by putting the weight nearer the axle of the larger wheels, so that the results obtained are practically no better than were the light wheels made the same size as those carrying the motor and the weight of the car placed centrally over the truck.

It will be noticed, too, that a maximum traction truck rides more roughly than a regular truck; this for the reason that the car support is placed more over one axle than the other and thus gets practically the same hammer motion that the motor does and does not get the relief given by equalizing and dividing the motion of both axles as found on regular trucks. In this question of trucks as we approach nearer the practice of steam roads in other respects, we will find it to our advantage to be guided by their experience and not attempt to drag with us the crude ideas heretofore held. It is only just to say here that most builders of trucks have recognized this point since the building of these roads mentioned at the beginning of the paper, and have been trying to educate their customers to this belief, and with some measure of success.

In closing, I will remind you that the era of long distance, high speed and heavy duty electric railways is at hand. The first experiments have been made and steam railroad men are awake to the facts. And those of you having roads that must come in competition with them must bear in mind that the steam railroad man will bring to the subject an experience of great value and that there are certain matters in connection with your roads that will bear your closest inspection, such as power house, distributing system, motor repairs, track, grades and trucks.

I have only outlined the bearing of these subjects on your work on account of the limited time at my disposal.

BALTIMORE'S LAST HORSE CAR TO GO.

The last horse car in service in Baltimore will soon make its final trip. This car runs on Ann street, between Band and Thames, on a track of the Baltimore City Passenger Railway Company, and only on market days during market hours. Col Walter S. Franklin, president of the road, says that a contract has been made with Mr. Frank H. Sloane, electrical engineer, to make it an electric line.

MR. C. D. HOTCHKISS has been elected vice-president of the Chicago North Shore Electric Railway Company, succeeding J. E. Montrose, resigned.

THE HARDIE COMPRESSED AIR STREET CAR MOTORS IN NEW YORK.

DURING the past two months a number of compressed air locomotives have been in operation on the 125th street cross-town line of the Third Avenue Railway Company, and numerous articles have appeared in the daily press dilating upon the great benefits to the public and the saving to the railway company which would accrue by the equipment of the entire line with these motors, and hints have been thrown out that it was but a question of a short time when the Third Avenue Railroad would adopt the system and abandon its present system of propulsion by cable. At about the time these cars first went into operation one of our contributors, Mr. Robert Lundell, showed by a critical analysis the fallacy of assuming that economy could be obtained by this method of propulsion, as compared with electricity, and thus far no figures of actual tests of the cars in operation have been forthcoming to indicate that the compressed air motor cars give the economy claimed for them by the company operating them. It may be well to state here also that the compressed air cars running on 125th street are operated entirely at the expense and risk of the American Air Power Company. The Third Avenue Railroad Company has assumed no responsibility whatever for their operation, it has not indorsed the system, and it has no data before it yet upon which to base any opinion whatever of the practicability of the system for the whole, or any part of its railroad system; and so far as the Third Avenue Company's changing its system over from cable to compressed air, as has been hinted at in some quarters, the statement is characterized by officers of the company as absurd in the present stage of affairs.

FIG. 1.—HARDIE COMPRESSED AIR MOTOR.

Before entering into a description of the plant, it may be stated that the compressed air motor cars are operated on a practically straight and level road, from the Fort Lee ferry on the Hudson River to the foot of 125th street and the East River. The conditions therefore are in a sense ideal. As for the compressed air motor cars attempting to climb the grade on Amsterdam avenue, that has so far only been done once, in an experimental trip, successful but not conclusive.

The plant for furnishing compressed air to the motor cars consists of two compound Norwalk 75 horse-power compressers, working under a steam pressure of 140 pounds, compressing the air to 2,250 pounds to the square inch. The compressed air is stored in a reservoir consisting of 30 Mannesmann steel tubes, Fig. 2, 20 feet long by 8 inches inside diameter, and ⅝ths of an inch thick. The capacity of these tubes at 2,250 pounds is about 31,500 cubic feet. Trouble was at first experienced in the packing of the connections, but this was overcome by using red fiber washers. From these storage cylinders the air cylinders on the car are filled, each car having a capacity for taking one-fifth the capacity of the station reservoir, that is, about 6,000 cubic feet at 2,250 pounds pressure. The time required to charge a car is 6½ minutes.

The compressed air is admitted to the cylinders of the car

engine, which are 6 inches in diameter, with a stroke of 16 inches, the pressure being reduced from 2,250 to 150 pounds to the square inch. The air in passing from the air cylinders on the car to the working cylinder on the engine is heated to 350 degrees Fahrenheit. This is done in order to prevent freezing and the formation of ice in the working cylinder, and valves and at the same time effects an economy in reducing the volume of air required. Each car is calculated to make a run of sixteen miles with a single charge. The engine on the car,

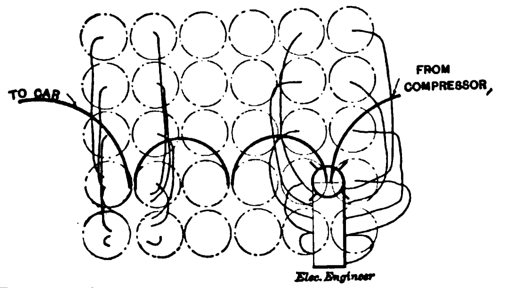

FIG. 2.—ARRANGEMENT OF COMPRESSED AIR TANKS.

which is illustrated diagrammatically in Fig. 3, is patterned after the usual steam engine with an oscillating crank, but is deprived to a certain extent of the power of using the compressed air expansively, and the air is admitted for the full stroke of the cylinder. The result is that the cars now are recharged after each trip of four miles.

The weight of the car complete is 18,000 pounds. Of this, 6,000 pounds is chargeable to the car body, 500 pounds to hot water for heating the air, 500 pounds to the compressed air stored in the tanks, and the remainder to the truck, motive equipment and air cylinders.

There are no less than four levers required to control the car. One handle operates the main air valve which admits the air to the engine cylinders and controls the speed. A second

inder so as to accelerate the starting of the car. A fourth handle acts to cut-off entirely the supply of air from the tank. At the end of each trip the motorman removes all four handles and transfers them to the other end of the car to corresponding positions.

The car which is illustrated in our engraving, Fig. 1, taken from "Compressed Air," is 28 feet long over all, with a 20-foot car body, and 4-foot platforms. Its seating capacity is 28 persons.

As to the operation of the cars themselves, it may be said that starting and stopping are not accomplished as smoothly or

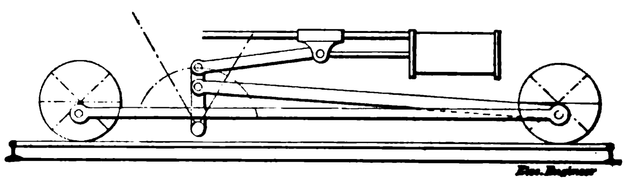

FIG. 3.—DRIVING GEAR OF COMPRESSED AIR ENGINE ON CAR.

as well as is the case with cable and electric cars. In fact, a dead stop cannot be made at all, and in case of emergency it has been demonstrated that the cars cannot be stopped within ten feet, while with electric and cable cars almost a dead stop can be made within a distance of five feet.

THE RIKER ELECTRIC VEHICLE.

WE illustrate herewith the electric vehicle, for pleasure purposes, designed recently by Mr. A. L. Riker, and built by the Riker Electric Motor Company, of Brooklyn, N. Y. It has been entered for the "motorcycle" races at Providence, and whatever be its success it must be allowed to have many noteworthy features of merit. It weighs 1,500 pounds, and can be fitted with extra batteries when needed, bringing

RIKER'S ELECTRIC CARRIAGE FOR FOUR PERSONS.

handle operates the reversing gear and controls the cut-off by operating the link motion. A third handle controls the air brake. By throwing this same lever over to another position, air at higher pressure than normal can be admitted to the cylinder so as to accelerate the starting of the car.

its weight up to about 1,800 pounds. It will carry four passengers, two fronting ahead and two astern. The body of the vehicle is black, the wheels and gear are a bright, cheerful red. The wheels are of the bicycle type ,with stout wire spokes, and

pneumatic tires, and were furnished by the Crawford Wheel and Gear Company, of Hagerstown, Md. The under shafting that carries the body is built of tubular steel. Two Riker motors of 3 horse-power each and weighing 180 pounds each, are mounted so as to gear each side upon the gear wheels on the rear axle, and in this way motion is imparted. The motors are ironclad and are very tightly inclosed so as to insure protection against dirt or damage. The pinions and gear wheels are also protected. The rate of reduction of the speed of the motor is 5 to 1. There is a strap brake, operated from the front seat, the use of which on a band wheel on the motor shaft obviates the necessity of applying a brake to the wheels themselves.

The carriage is steered by a tiller projecting from the dashboard towards the riders, and so contrived as to work with a right and left motion. The wheels are pivoted at the hub and are locked in position in an instant by pressing down on the tiller. Four speeds are obtainable by the corresponding four dispositions of the storage batteries that supply the current. The changes are effected by means of the small handwheel at the side of the carriage within easy reach of the driver. This wheel is on the shaft of a controller placed horizontally under the front seat, and the successive steps are like those with a street car controller. The speeds are 5, 10, 18 and 25 miles an hour. The wheel is turned forward for forward motion of the vehicle and reversed for a backward motion.

Current is obtained from 32 cells of a special make of chloride accumulator furnished by the Electric Storage Battery Company, of Philadelphia, each giving 100 ampere hours. The weight is about 800 pounds, and the batteries are inclosed in boxes so as to prevent spilling of the acid. On the average road the batteries will furnish power enough to run the carriage not far short of 50 miles at 10 miles an hour. They also furnish current for an electric gong and for two strong lights of the usual carriage lamp character.

The carriage is admirably contrived and balanced, and while light to look at moves with wonderful steadiness. It turns easily, moves forward or backward at a touch, and by having two motors is able to get along very well even if one of them should break down. The battery is also arranged in such a way that sections can be wholly cut out if desirable. Altogether, one has only to see this vehicle run, and to watch its smooth, swift motion, or to enjoy a ride on it, to become convinced that a great future awaits carriages of this class, not only for pleasure, but for all the innumerable uses of trade and intercommunication. Mr. Riker does not hesitate to say that he looks forward to the early development of a great electrical industry in this field.

SOCIETY AND CLUB NOTES.

FIFTH ANNUAL CONVENTION OF THE PENNSYLVANIA STREET RAILWAY ASSOCIATION.

The fifth annual convention of the Pennsylvania Street Railway Association met in the theatre at Lakemont, Altoona, Pa., on Sept. 2. Mr. John Lloyd, of Altoona, introduced Hon. Martin Bell, who made the address of welcome. Hon. B. F. Meyers, president of the Wilkesbarre and Wyoming Valley Traction Company, responded. Both addresses were entertaining and interesting and were heard with great attention.

Following this, papers were read on "Long Distance and Heavy Duty Electric Railways,"[1] by Mr. F. W. Darlington; "Construction and Maintenance of Electric Railway Tracks," by Mr. George H. Neilson; "Transfer Tickets," by Mr. J. H. Stedman; "Street Railway Law," and "Liability Insurance" were the topics next introduced for general discussion. Addresses on these subjects were made by E. C. Felton, of Harrisburg; G. S. Larzelier, of Norristown; E. H. Davis, of Williamsport; and President B. F. Meyers, of Harrisburg.

A committee of five was appointed by the chair to take charge of the matter of new legislation on the subject of street railway corporations. This committee is composed of E. C. Felton, of Harrisburg; E. H. Davis, of Williamsport; Richard Koch, of Pottsville; G. S. Larzelier, of Norristown; B. F. Meyers, of Harisburg; and John Lloyd, of Altoona.

At the afternoon session the discussions on "Street Railway Law" and "Liability Insurance" were again taken up and continued at some length, after which the annual election of officers took place as follows: President, John Lloyd, of Altoona, first vice-president, Albert Johnston, of Allentown; second vice-president, Robert Wright, of Allentown; secretary, S. P. Leight, of Lebanon; treasurer, W. H. Lanius, of York; executive committee, John Lloyd, B. F. Meyers, S. P. Leight, John A. Rigg and E. C. Felton.

[1] See page 255, this issue.

Allentown was selected as the next place of annual meeting. A vote of thanks was tendered the local traction companies for courtesies extended, and to the officers of the association for the thorough manner in which they had attended to their respective duties.

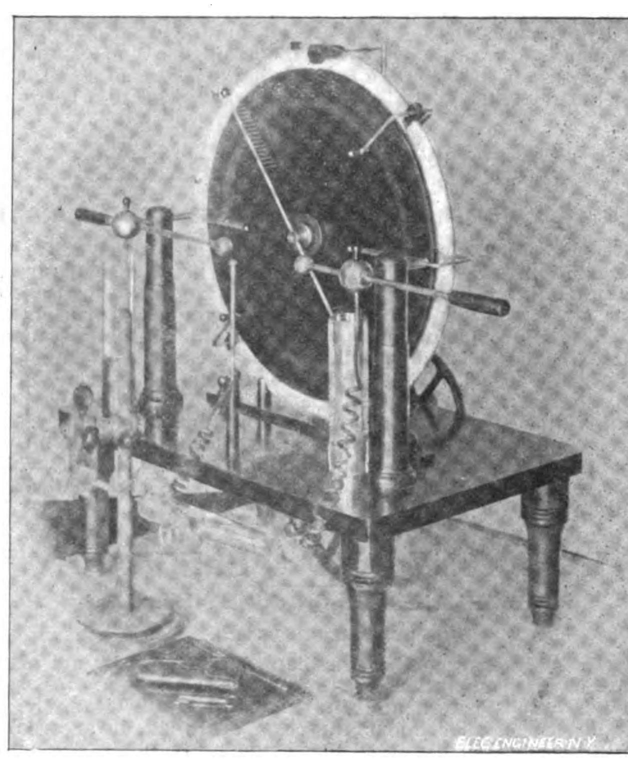
The following programme was observed on Sept. 3: Visit to the electrical department of the Pennsylvania Railroad shops; excursion to Wopsononock, train leaving Juniata at 9.30 a. m.; trolley ride over lines of the Altoona and Logan Valley Electric Railway Company; banquet, Mountain House, Cresson.

The new Edison electric light plant in Altoona, lately extended and remodeled, was visited also by the delegates on Sept. 2, under the escort of Mr. E. B. Greene, the general manager and electrical engineer.

ROENTGEN RAYS.

THE PRACTICABILITY OF THE STATIC MACHINE FOR X-RAY WORK.

THE first X-ray experiments on record were made with a Ruhmkorff coil and naturally other experimenters used coils. It was found that the larger the coil the better the results, but at present the general opinion of those having practical experience seems to be that coils of 8-inch or 10-inch spark length give fully as satisfactory results as larger ones. The time of exposure is not enough shortened nor are the



FREI STATIC MACHINE FOR X-RAY WORK.

details brought out so much better as to justify the expense of very large coils.

Only a few of the large number of experimenters looked upon the static machine as a substitute for the more expensive coil; some met with success, others failed. The failures were due mostly to one of three causes:

1. The machines being of the school type, pretty enough to look upon but flimsily constructed, could only be run a few minutes at a time without a breakdown.
2. The machines were too small or run too slowly to give the required spark length or rapidity of discharge.
3. The operators did not use them properly.

Those that succeeded found that a machine of given spark length will do better work than a coil of the same spark length and that the definitions obtained with the static ma-

chine, both the Wimshurst and the Toepler-Holtz, are much clearer and that the tubes lasted much longer.

Messrs. Frei & Co., of Boston, recognized the importance of the static machine for X-ray work and have placed upon the market a Toepler-Holtz machine which, neat in design, combines strength and durability with a low price. The No. 2, or double plate machine, answers all requirements of the average surgeon. The stationary plates are of glass, 20 inches diameter and the revolving plates 17 inches diameter, are of hard rubber especially vulcanized for the purpose. The latter are mounted upon ball bearings and can be revolved at a speed of nearly 2,000 revolutions per minute, the ratio of transmission being 1:18. All the metal parts are nickel plated and the whole is mounted upon a mahogany base. A mahogany case with glass front is furnished with each machine. While it cannot be denied that the average static machine is influenced by the weather, this can easily be overcome by keeping the machine in a case and by placing a dish of calcic chloride or other absorbing agent within the case. At any rate this new machine has never been known to fail in any kind of weather when treated in this way. To make the machine completely independent of the atmospheric conditions the manufacturers are experimenting now with a special drying apparatus to be attached to the base of the machine. One of the most important parts of this machine is the spark gap post which is placed half way between the dischargers so that it can be used from either rod as may be found convenient. One terminal of the tube is connected to one of the discharging rods and the other terminal to the spark gap; the distance between the second discharging rod and the spark gap post is then regulated to suit the requirements of the tube.

To those who will make an unprejudiced comparison between the static machine and the Ruhmkorff coil it must be obvious that the former has a number of points in its favor. There is no danger of its ever burning out; a burned-out coil is practically a complete loss. There are no running expenses; even if the machine is run by a power motor of one kind or another the expense is smaller than the running expenses of a coil; and, last but not least, there is its comparatively low first cost.

REPORTS OF COMPANIES.

RECEIVER FOR THE KINGS COUNTY ELEVATED ROAD.

General James Jourdan has been appointed receiver for the Kings County Elevated Railroad, Brooklyn. The company has defaulted interest on its bonds, owes the city taxes for three or four years, and has found it difficult to get coal to run its engines, unless paid for in spot cash. In 1892-3 the passengers numbered 50,000 a day, but the past year the average has been only 40,000. The total receipts last year were $767,338, against $564,074 total expenditures. The failure of the road is broadly attributed to the competition of the trolley. The receiver is one of the heaviest stockholders in the company. The total indebtedness reaches about $12,000,000, of which nearly the whole is in various forms of bond and bonded liability.

TELEPHONY AND TELEGRAPHY.

CABLE LANDINGS ON CONEY ISLAND.[1]

BY JAMES R. BEARD.

A FEW years ago the Brazilian Government by act of its Parliament authorized the purchase of the cables operated by the Western and Brazilian Telegraph Company, an English corporation, along the coast of Brazil, in accordance with the concession granted that company in 1873. The act of Parliament provided that the income derived from the operation of the cables, when purchased by the Brazilian Government, should be used to pay the interest on the cost of purchase and provide a sinking fund to retire the bonds issued for such purpose. It was expected that the Brazilian Government would have no difficulty in floating a loan on this basis, but just at the time Brazil proposed to negotiate this loan, the English cable managers caused the English Government to seize the island of Trinidad with the apparent intention of using it for the establishment of a rival submarine cable to be laid in two sections between Buenos Ayres and the island of St. Vincent, now connected by cable with England.

The island of Trinidad was practically a telegraph post in mid-ocean so conveniently placed that it divided this proposed rival cable into two sections of about 1,800 miles each. Were it not for Trinidad, a cable 3,600 miles in length would have been necessary, and its cost would have been too great. So you see the island of Trinidad was used as a scarecrow to defeat the proposed loan of the Brazilian Government and served to continue the English monopoly of cables on the coast of Brazil.

Practically the same thing has been done on our shores within the past few months. A foreign cable company has landed a cable on the coast of Coney Island without even asking permission from the United States Government. This cable is to connect with a French cable which has a monopoly to connect the West India Islands and the northern coast of Brazil. It is currently reported that our Government officials hold to the opinion that there is no law to prohibit foreigners from landing cables on the shores of the United States.

It has always been understood that the marine league was for national defence. A submarine cable in the hands of foreigners, silent and secret in its operation, is certainly as dangerous as a battery built by foreigners within that marine league. This marine league has been invaded by a foreign cable company, and it seems strange that no action has been taken by our Government.

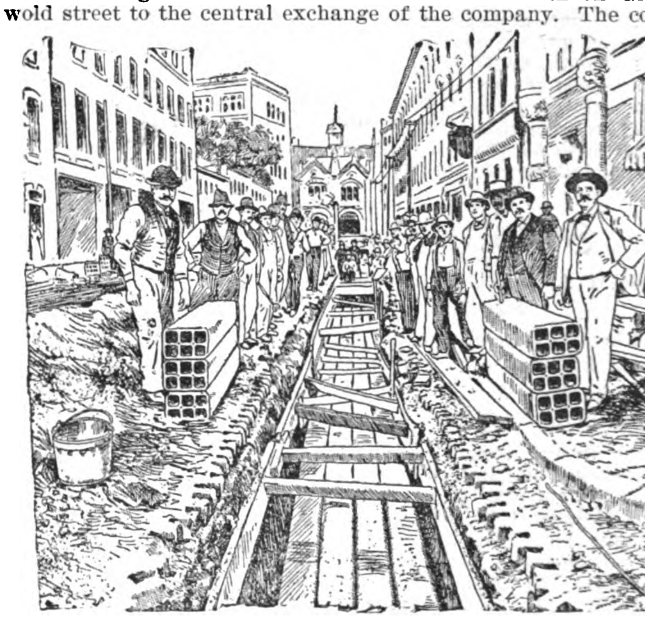
The courageous action of Brazil in obliging the Englishmen to surrender the island of Trinidad is a good object lesson for our Washington officials. Undoubtedly the executive has full power, in the absence of Congress, to prevent such invasion of the coast of the United States by foreigners. Certainly the executive has police power in this matter under the constitution, which also provides for the regulation of commerce with foreign countries, the courts of the United States having decided that telegraphy is commerce.

[1] New York "Sun."

UNDERGROUND CONDUCTORS AND CONDUIT OF THE DETROIT TELEPHONE COMPANY.

IN our last issue we gave some details in regard to the extensive work now being done by the Detroit Telephone Company, of Detroit, Mich. This is one of the largest of the companies organized in opposition to the old Bell system, and is spending nearly $500,000 on its plant, in order to serve the 5,000 subscribers which it is understood to have enrolled.

We now give a view of the work being done by the company on its underground wires. The illustration shows the conduit being laid from Grand River avenue north on Griswold street to the central exchange of the company. The con-



LAYING McROY TERRA COTTA TELEPHONE CONDUIT IN DETROIT.

duit used is that of Mr. J. T. McRoy, of Chicago, and is of vitrified terra cotta which has abundantly proved its value in electrical subway construction. This conduit is made up in 2, 3, 4, 6 and 9 duct sections, and in the cut the 6 duct type is seen. Into this conduit cable made by the Standard Underground Cable Company is being drawn.

The underground cable for the Detroit Telephone Company, ordered so far from the Standard Underground Cable Company, consists of 80,000 feet of Standard double wrapped dry paper, lead covered, 50 and 100 pairs, No. 19 B. & S. G. This quantity is already in hand and about as much more will follow.

The American Bell telephone instrument statement for the month ended August 20 shows a gross output of 9,675, against 11,009 in 1895. Returned, 7,856, against 8,730; net output, 1,825, against 2,279.

SYNOPSIS OF CURRENT ELECTRICAL LITERATURE.

EDITED BY MAX OSTERBERG, E. E.

Alternating Currents:

CHANGING FREQUENCY. By Ludwig Gutmann. Description of a method for changing the frequency after transmission. "Elec. Eng'r," Sept. 2, '96.

Electro-Chemistry:

ELECTRICITY IN METALLURGY. By W. Borchers. The importance of electricity for direct working of metals at high temperatures and in connection with prěliminary preparation of the ores before melting is pointed out. The various processes for reducing and separating metals are presented in tabular form.—"Zeitschr. fur Elektrochemie," Vol. II., p. 368, in abstract. Lond. "Elec. Rev.," Aug. 21, '96.

Isolated Plants:

ELECTRICAL PLANT OF DUQUESNE STEEL WORKS AND BLAST FURNACES. Details of power house, generators, switchboard, pumps, cranes, etc. Two 500 horse-power, 250 volt, direct current generators, and six 60 light arc dynamos; six 50 horse-power shunt motors and one 45 kilowatt single-phase alternator form the electrical outfit of the plant.—"Elec. Eng'r," Sept. 2, '96.

Lighting:

MANCHESTER LIGHTING REGULATIONS. A revision of supply of current regulations was required owing to the departure of using 200 volt supply in certain districts with a three wire system having 400 volts between the two outside wires.—Principle clauses to be found in Lond. "Elec. Eng'r," Aug. 21, '96.

LIGHTING OF RAILWAY TRAINS. By Carl Kriz. After tracing the historical development of railway train illumination and presenting statistics of the number of oil, gas and electric lamps used on one of the Australian roads, author gives the following results:

The total cost per lamp hour per candle power was, for

Oil lamps consuming........	.02 kg. per hour,	3 c. p. =	.0016c.
Oil gas "	.2 c. m. "	4 c. p. =	.00125c.
Regen oil gas "	.023 c. m.	6 c. p. =	.00096c.
" (2 flames) consuming	.03 c. m. "	9 c. p. =	.00083c.
Incandescent lamp, 23.5 volts,	2.5 watts, per	6 c. p. =	.00120c.

—"Zeitschr. für Beleuchtungswesen," Aug. 20, '96.

LIGHT OF THE FUTURE. By E. Hospitalier. In a short article author gives the following figures relative to the quantities of heat given off by combustion of gas in different burners, and also by acetylene and electric lamps:

Gas candle	413	B. T. U. per c. hour.
Flat flame burner..................	252	
Bengel "	206	
Welsbach "	41	
Denayrouze "	20	
Acetylene "	31	
Incandescent lamps (not pushed)....	11	
Incandescent lamps (pushed)........	8	
Ordinary 10 amp. arc...............	2	

—"Progr. Age," Sept. 1, '96.

Power Transmission:

COTTONWOOD POWER TRANSMISSION, UTAH.—Detailed description of plant with illustrations. Generating plant consists of four 450 kilowatt three-phase 60 cycle generators separately excited connected to 60-inch Pelton wheels. The line is over seventeen miles long and has an efficiency of over 68 per cent.—"Elec. Eng'r," Sept. 2, '96.

Railways:

BEHR'S HIGH SPEED RAILWAY. The single railroad mentioned in Synopsis, Aug. 26, is referred to and the points claimed by Mr. Behr to be an improvement on the system are enumerated.—"Elec. Eng'r.," Sept. 2, '96.

TWO HUNDRED HORSE-POWER LOCOMOTIVES. The Westinghouse-Baldwin Locomotive Works have completed this large mining locomotive. Detailed items of sizes are presented in "Elec. Eng'r," Sept. 2, '96.

MUNSON ELECTRIC CONDUIT RAILWAY. Two diagrams illustrating this system with a short description appeared in "Elec. Eng'r," Sept. 2, '96.

ELECTRIC RAILWAY SYSTEM OF THE NORTHERN COAST OF NEW JERSEY. Description of the two recently built electric railways connecting the seaside resorts on the northern portion of the New Jersey coast line. Total length 24 miles measured as single track. Seventy pound 4½ inch T rails. Tandem compound direct connected engines and 400 kilowatt Westinghouse generators. Three batteries of boilers, two of 325 horse-power each, and one of 250 horse-power.—"Street R'way Journ.," Sept., '96.

ELECTRIC RAILWAY OF ROME, ITALY. The line purchases its current by meter from the sub-station of the Tivoli-Rome Transmission plant. In addition to the transformers used for lighting purposes, a set has also been installed in which the alternating current is transformed down to 400 volts. At this pressure it enters the collector rings of a number of rotary converters, and issues from the commutator side, direct current at about 550 volts. The equipment of the sub-station is completed by an extensive battery of Tudor accumulators, 304 in number, with a capacity of 1,000 ampere hours. This is in parallel with the trolley circuit and is divided into line groups of 26 cells each. For further details see "Street R'way Journal," Sept., '96.

STREET RAILWAY OF HANOVER. By C. O. Mailloux. Short description of this combined battery and overhead line. Equipment consists of three water tube safety boilers of 175 horse-power each, 145 pounds pressure; two horizontal compound engines, 200 horse-power each operating the generators. —"Street R'way Journ.," Sept., '96.

ORGANIZATION AND OPERATING METHODS OF THE METROPOLITAN STREET RAILWAY COMPANY OF NEW YORK.—This article gives the history of the company, details of organization, working force, general traffic conditions, how traffic is handled, transfer system and statistics. Four hundred and twenty-five cable cars and 35 electric cars are in regular and special operation over the entire 32 miles of trackage, cars being thus spaced at an average distance of 365 feet at maximum service.—"St. R'wy Journ.," Sept., '96.

GROWTH OF ELECTRIC RAILWAYS IN SOUTHERN NEW ENGLAND.—Some abstracts of the statutes of the various States, showing the conservative lines on which roads must be constructed and managed. Also the following statistics of street railways in Massachusetts, Rhode Island and Connecticut:

	Mass.	R. I.	Conn.
Number of miles operated.	1,087	143	317
Number of cars operated...	4,426	636	896
Passengers carried	259,794,308	32,618,473	38,037,474
" per capita.	112	94	50
Gross receipts	$13,246,372	$1,624,281	$2,232,051

—"Stret R'way Journ.," Sept., '96.

Roentgen Rays:

REGULAR OR SPECULAR REFLECTION OF THE ROENTGEN RAYS FROM POLISHED METALLIC SURFACES. By O. N. Rood. A series of carefully prepared experiments show that metallic surfaces which are highly polished for ordinary light are only imperfectly polished for the X-rays, and all the experiments detailed in this paper are in harmony with the idea that X-rays consist of transverse waves like those that constitute ordinary light, differing from them only in being shorter.—"Am. Journ. of Science." Sep. '96.

PERSONAL.

MR. J. MIYAKE, a graduate of the Engineering College of Japan, is at present in this country studying electrical plants and methods. He comes with letters of introduction from Mr. Fujioka, the well-known electrical engineer at Tokio.

MR. A. DAVIDSON, late electrician on the steamship Minia, has been appointed assistant cable engineer to the Central and South American Telegraph Company, with headquarters at Lima, Peru. He left Monday, the 31st, to take up his duties.

Mr. F. B. COOK has resigned the position of Chief Engineer of the Central Union Telephone Company after seventeen years connection with that corporation; during this time he has filled probably every technical position in the company's service. Mr. Cook's experience in the telephonic field has been of a wide scope, and many of the telephonic labor-saving devices in use in the United States to-day are of his production. Mr. Cook is succeeded by Mr. S. G. McMeen.

HON. JAMES D. REID, the veteran telegraph superintendent and U. S. Consul at Dunfermline, Scotland, arrived by American liner "St. Paul" last week in good time to attend the telegraph meetings of this season.

INVENTORS' RECORD.

CLASSIFIED DIGEST OF U. S. ELECTRICAL PATENTS ISSUED SEPT. 1, 1896.

Alarms and Signals:—

TOWER STRIKER. F. W. Cole, Newton, Mass., 566,843. Filed July 24, 1894.
Adapted for fire alarm use.

ELECTRICAL SELECTING INSTRUMENT. A. Duppler, Jersey City, N. J., 566,896. Filed Feb. 12, 1895.
Details of construction.

SIGNALING DEVICE. H. L. Webb, New York, 566,951. Filed March 18, 1893.
Adapted for use in connection with telegraphs and telephones to indicate to the different stations on the line when the same is occupied by the transmission of a message.

ELECTRICAL COMMUNICATION. J. A. Sullivan, Cincinnati, O., 567,112. Filed July 15, 1893.
A combination in an electrical instrument in a circuit of a permutation wheel having an armature mounted thereon and attached thereto, the wheel being in such relation to a magnet that the attraction of the magnet causes the rotation of the wheel, a magnet and a battery.

Secondary Batteries:—

PLATE FOR SECONDARY VOLTAIC BATTERIES. J. G. A. Rhodin, Clifton Hill, England, 567,044. Filed Oct. 7, 1895.
Consists of a perforated frame plate, in combination with plugs composed of a bundle of lead wires filling the perforations of said frame plate and producing permeable plugs to the interstices of which the electrolyte has access.

PLATE FOR SECONDARY VOLTAIC BATTERIES. J. G. A. Rhodin, Clifton Hall, England, 567,045. Filed Sept. 25, 1895.
Similar to above.

Distribution:—

ELECTRIC-DISTRIBUTION MACHINE. W. E. Sinclair, Milwaukee, Wis, 566,874. Filed July 25, 1895.
Comprises a series of automatic quick break knife switches, each of which is for incorporation as part of an electric circuit, a power shaft, a counter shaft in gear with the power shaft, and a series of rotarily adjustable switch closing cams carried by the counter shaft.

Dynamos and Motors:—

ELECTRIC MOTOR. J. Bram, Decatur, Ill., 566,889. Filed Sept. 5, 1895.
Capable of operating with either a continuous or an alternating current.

ELECTRIC MOTOR. R. Eickemeyer, deceased; R. Eickemeyer, Jr., executor, Yonkers, N. Y., 567,119. Filed Dec. 31, 1890.
Combination of an armature, carrying coils connected in series; an inside field coil; separate or isolated coils conforming to and massed with the field coil, and one or more outside, or counter field coils, connected in series with the field coil.

Electro Metallurgy:—

APPARATUS FOR EXTRACTING GOLD AND SILVER FROM ORE. P. Danckwardt, New York, 566,894. Filed June 8, 1896.
Consists of a revolving barrel having amalgamated copper lining to form a negative pole, with a pair of heads, and with a series of insulated inclined blades secured to such heads and having overlapping edges to form the positive pole.

CYANID PROCESS OF EXTRACTING PRECIOUS METALS FROM THEIR ORES. R. Keck, Denver, Colo., 566,986. Filed July 3, 1895.
Consists in dissolving said metals in a cyanid solution and extracting them therefrom by electrolytic precipitation upon an aluminum cathode.

Lamps and Appurtenances:—

REGULATING SOCKET FOR ELECTRIC LAMPS. C. A. Chute, Chicago, Ill., 566,892. Filed Feb. 8, 1896.
Details of construction.

ELECTRIC LIGHT HANGER. J. F. Diehl, J. F. Diehl, Jr., and D. Diehl, Pittsburg, Pa., 567,022. Filed Feb. 11, 1896.
Details referring to a mast having a laterally projecting arm, with a movable trolley.

Miscellaneous:—

ELECTRIC HEATER. F. L. Pruyn, Albany, N. Y., 566,795. Filed Aug. 1, 1895.
Comprises an insulating support with spirally coiled conductor encircling it.

ELECTROMAGNET. A. Le Blanc, New York, 566,918. Filed Oct. 16, 1894.
Consists of an outer casing, a core inclosed within the casing both of magnetized material, two coils wound between them, one at each end and separated from each other, thereby forming a double magnet, one at each end, in combination with a movable plate-armature at each end.

Railways and Appliances:—

ELECTRIC RAILWAY SYSTEM. J. M. Murray and A. F. Pierce, Danbury, Conn., 566,786. Filed Sept. 10, 1895.
Sectional conduit system.

MAGNETIC TRACTION APPARATUS FOR MOTOR CARS. W. Robinson, Boston, Mass., 566,800. Filed Oct. 12, 1891.
The combination of a car axle and its wheels, a motor arranged to drive the same and coils of insulated wire surrounding the hubs of the wheel and arranged to magnetize the same.

ELECTRIC RAILWAY SYSTEM. W. Robinson, Boston, Mass., 566,801. Filed Dec. 19, 1894.
Embodies a magnet included in a continuously closed circuit and operated without actually opening the circuit of the magnet, a transformer arranged to energize the circuit with a current of low voltage and means for demagnetizing the magnet by short circuiting.

DETECTOR FOR RAILWAY SWITCHES. W. H. Berrigan, Jr., Brooklyn, N. Y., 566,887. Filed April 26, 1895.
Embodies an insulating contact and a latch for forming part of an electric circuit which controls means to lock or unlock the switching mechanism.

ELECTRIC CAR BRAKE. A. B. Roney, Chicago, Ill., 566,939. Filed April 2, 1895.
The combination with a motor, a screw-threaded shaft driven thereby, and a yielding connection between the shaft and the armature of the motor, of a nut working on the shaft and held against rotation, and a brake rod connection with, and actuated by the nut.

ELECTRIC RAILWAY. R. M. Hunter, Philadelphia, Pa., 566,984. Filed Feb. 3, 1896.
Consists of a current collector embodying a trolley and a guide wheel adapted to keep the trolley in place.

TROLLEY. F. W. Canales, Portland, Me., 567,118. Filed Jan. 22, 1896.
Details of construction.

Regulation:

ELECTRICAL CONSTRUCTION, REGULATION AND DISTRIBUTION. T. H. Hicks, Detroit, Mich., 566,860. Filed Feb. 1, 1895.
Designed for employment with a gas engine.

AUTOMATIC STARTER FOR ELECTRIC MOTORS. J. E. Putnam, Rochester, N. Y., 566,936. Filed Feb. 29, 1896.
Comprises variable resistance contacts, operating lever and contact lever provided with a lug, the springs on the lever, and suitable means driven by the motor for operating the lever according to the speed of the motor.

AUTOMATIC CIRCUIT CONTROLLER FOR ELECTRIC PUMPS. D. W. Dunn, Wrentham, Mass., 567,023. Filed May 1, 1895.
Comprises the piston of a pump which is exposed to the pressure of the air in the reservoir and a switch whose moving member is moved up to a dead point by power stored up during its motion up to the dead point.

Switches, Cut-Outs, Etc:

ELECTRIC SWITCH. J. L. Hornig, St. Louis, Mo., 566,760. Filed Feb. 26, 1896.
Comprises a rotating disc, conductor plates passing through the disc and a spark arrester consisting of non-conducting elastic material so positioned as to engage yieldingly against the periphery of the disc.

Telegraphs:

ELECTRIC SELECTOR. A. Le Blanc, New York, 566,914. Filed Oct. 3, 1893.
Adapted to be operated by the transmission of electrical impulses sent out by the ordinary telegraph key or a pair of keys so arranged as to be capable of transmitting currents of opposite polarity.

ELECTRIC SELECTOR. A. Le Blanc, New York, 566,915. Filed Nov. 11, 1893.
Similar to above.

SELECTING DEVICE. A. Le Blanc, New York, 566,916. Filed Jan. 16, 1894.
Similar to above.

ELECTRICAL TRANSMITTING INSTRUMENT. A. Le Blanc, New York, 566,917. Filed Oct. 16, 1894.
Details of construction.

TELEGRAPHY. J. M. Joy, New York, 566,985. Filed June 17, 1895.
A closed circuit system for printing telegraphs.

Telephones:—

VILLAGE OR HOUSE TELEPHONE SYSTEM. E. G. Hovey, Chicago, Ill., 566,762. Filed May 4, 1895.
A signaling device adapted to be sounded when the subscriber has neglected to return the plug to its individual switch socket.

SELECTIVE SYSTEM. A. L. Merrick, J. Merrick, administratrix, and H. Brooks, Springfield, Mass., 566,784. Filed Sept. 16, 1892.
Means by which a signal may be given from one station to any one of several other stations in one electrical circuit.

TOLL-BOARD APPARATUS FOR TELEPHONE EXCHANGES. V. Wietlisbach, Bern, Switzerland, 566,829. Filed Feb. 1, 1895.
Details of construction.

TELEPHONE TRANSMITTER. N. L. Burchell, Washington, D. C., 567,077. Filed Sept. 5, 1895.
A two-diaphragm transmitter, employing granular conducting material.

OBITUARY.

J. T. RIDGWAY.

Col. Joseph T. Ridgway, Superintendent of the Trenton Electric Light Company, shot himself in the head on Sept, 3 at his home in Trenton, N. J. Col. Ridgway underwent an operation in Philadelphia several months ago, and since then his mind has not been strong. He went to Tuckerton for his health, but returned home recently. He acted queerly and was watched by his family. He managed to elude his watchers and killed himself. Col. Ridgway was a civil engineer, and was at one time a member of the Trenton Board of Public Works. He served in the U. S. Navy during the War of the Rebellion. Several years ago he was the superintendent of the now defunct Star Rubber Works. He was over sixty years of age.

H. J. TUCKER.

A news dispatch from Colorado announces the death at Denver of Mr. H. J. Tucker. He was well known to the mining men of that district from being connected with the Marvin Electric Drill Company, of Canastota, N. Y., one of the plants of which was placed in operation by Mr. Tucker at the Columbine-Victor Tunnel on Squaw Mountain. He was a young man and possessed more than ordinary ability as electrical engineer. He graduated from Brown University and the Massachusetts Institute of Technology and had a most promising future in the electrical field before him. His friends were much pained and surprised to learn of his death. The deceased's former home was Pawtucket, R. I., where his mother and sister still reside.

Trade Notes and Novelties

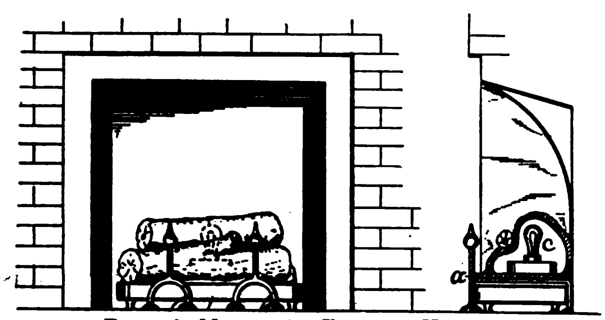
AND MECHANICAL DEPARTMENT.

DEWEY'S ILLUMINATED ELECTRIC HEATER.

ONE of the chief reasons for the continued existence of the old-fashioned open fireplace is its cheerful appearance, which is lacking in the case of electric heaters of the usual pattern. To overcome this deficiency, Mr. Mark W. Dewey, of Syracuse, N. Y., has invented an attachment for an electric fireplace which will have all the advantages of an open grate while avoiding the dust and dirt incidental to this manner of heating. The "stove" itself may consist of any form of electric heater in addition to which illuminated artificial fuel is used to supply the deficiency in appearance.

The device provides a heating apparatus for rooms that may be placed in an ordinary fireplace and which will not only radiate heat but light. The heater is also so constructed that it resembles the appearance of fuel when light is radiated from it.

The illustration represents an ordinary open fireplace where coal or wood is burned. Upon the grate or andirons there is an inclosure. The bottom and back, and ends in some cases, may be made of metal or wood, and are made to fit the walls



DEWEY'S METHOD OF ELECTRIC HEATING.

of the fireplace. The cover for this box, which includes the top and front, and in some cases the ends, is constructed of a transparent or semi-transparent material, as glass or mica. This cover is removable from the box and resembles ordinary fuel, as coal or wood, in a state of combustion when the light is radiated through it, and may also be made to resemble the same materials when not in such state when light is not radiated through it. This cover is made of glass so as to give the general shape that coal or wood would be placed in for a good fire. The interior surface is made smooth and the exterior surface rough. Within this cover are incandescent lamps, as shown in the illustration, the bulbs of which may be colored so as to produce any desired tone of illumination. The illuminating heater may either be used alone or in connection with any type of electric heater.

SALES OF THE BALL ENGINE CO.

The Ball Engine Company, Erie, Pa., report an encouraging increase in orders during the past few weeks for engines for electric work. Shipments for the past month are as follows: Bradford Electric Railway Company, Bradford, Pa., one 200 horse-power cross compound engine; village of Willmar, Minn., one 100 horse-power engine; Fox Pressed Steel Company, Pittsburg, Pa., one 100 horse-power engine, direct-connected to Westinghouse generator; Henry Sonneborn & Co., Baltimore, Md., one 25 horse-power engine, direct-connected to General Electric dynamo; Rogers, Peet & Co., store building, Broadway, New York City, one 25 horse-power engine and one 100 horse-power engine; National Galvanizing Works, McKeesport, Pa., one 175 horse-power engine; National Tube Works, McKeesport, Pa., one 175 horse-power engine, direct-connected to Crocker-Wheeler dynamo; Iowa Agricultural College, Ames, Iowa, one 60 horse-power engine; J. Q. Howe's Sons electric light plant, Phelps, N. Y., one 100 horse-power engine; Cambridge Fuel Company, Byersville, Ohio, one 125 horse-power engine for electric mining; Institute for Blind, Janesville, Wis., one 40 horse-power engine; Bertha Mineral Company, Bertha, Mo., one 70 horse-power engine; Crook, Horner & Co., Baltimore, Md., one 35 horse-power engine; Gobierno del Distrito Federal, Mexico City, one 80 horse-power and one 30 horse-power engine; H. V. Phelps, Nitta Yuma, Miss., one 25 horse-power engine; Toledo Glass Company, Toledo, O., one 100 horse-power engine.

BURHORN & GRANGER.

Burhorn & Granger, 136 Liberty street, New York City, are at present installing three Woodbury engines in this vicinity, including one 9 x 12 direct connected to Eddy generator, at the Merritt apartment house, Eighty-first street and West End avenue; one 9 x 12 for the Safety Insulated Wire and Cable Company, 229 West Twenty-eighth street, and one 9 x 12, at Schneider's building, Union Hill, N. J. They also report the following recent installations: One 9 x 12 direct-connected to Fort Wayne generator, for the D. Jones Brewing Company, Forty-fourth street and First avenue, this being the combination which attracted such favorable notice at the recent Electrical Exhibition; one 12 x 14 and one 9 x 12 direct-connected, at the new Hotel Mathewson, Narragansett Pier, R. I.; one 7 x 10, at the Highland Spring Brewery, Boston; one 7 x 10, for G. M. Angier & Co., Boston; one 8 x 12 for the old Colony Brewing Company, Fall River, Mass.; one 11¼ x 14, Western Electric Company, Chicago , Ill.; two 13 x 16 Irondequoit Park Railroad, Rochester, N. Y., and a large consignment for the Osaka Electric Light Company, Osaka, Japan, including three 8 x 12, one 9 x 12, one 14 x 18, one 9¼ x 14, 14 x 14 tandem compound, and three 13½ x 23 x 16 tandem compounds.

The machine shops and the boiler shops of the Stearns Manufacturing Company, Erie, Pa., the builders of the Woodbury engine, are well filled with work on hand at the present writing.

NEW ENGLAND NOTES.

THE JOHN BECKER MANUFACTURING COMPANY, of Fitchburg, have made a huge success of the Becker vertical milling machine, and are now working thirteen hours a day to fill orders. The Becker miller was brought out only a few years ago, but has gained wonderfully in patronage, and now that Mr. Becker has added some larger sizes, he is taxed to the utmost to fill orders. All manufacturers desiring a thoroughly satisfactory milling machine, which can perform an amazing variety of work, should send to Fitchburg for a descriptive circular.

NEW YORK NOTES.

CHAS. J. BOGUE, 206 Centre street, has a busy shop at present, rewinding armatures and refilling commutators which are his specialties. Mr. Bogue manufactures carbon holders for all types arc lamps, also arc lamp supplies, American system, and will take pleasure in sending prices, etc., on application.

C. A. ECK, formerly of 116 Wooster street, New York, has removed his factory, and is now located at 159-161 Oraton street, Newark, N. J. Mr. Eck manufactures electric motors, dynamos, electro-plating machines and rheostats, and will be pleased to mail circulars and prices, etc., on application.

MR. EUGENE E. BOGART announces that he has bought out the old business of the late Abraham L. Bogart, 22 Union Square, in electric, gas lighting and other well known specialties, and that it will be actively continued. The practical and mechanical departments will be in the able hands of Mr. A. L. Bogart. Both gentlemen have the heartiest good wishes of a large circle of friends.

H. B. COHO & COMPANY have been appointed New York agents for the Translucent Fabric Company, of Quincy, Mass. This company manufactures a translucent fabric which can be used as a substitute for glass chiefly in skylights. This fabric is impervious to the weather, unaffected by heat, cold, expansion or contraction, flexible, durable and unbreakable. Electrical engineers in designing modern central stations should investigate this material before deciding on glass.

THE PHOENIX GLASS COMPANY, 42 Murray street, have been awarded the contract to fit up the new Manhattan Hotel, Forty-second street and Madison avenue, entire, with specially designed silver etched electric shades. They have also the contract for the entire City Hall, Philadelphia. The electric lights are furnished with their cut globes and boles ground on inside. The Masonic Temple, Detroit, Mich., is also installed with specially designed goods of this firm's make.

WM. A. ROSENBAUM, electrical expert and patent solicitor, Times Building, reports that although general business may be dull, there is an indication in the patent business that people have not given up hope of better times. While there are comparatively few applications being filed in the patent office at this time, there is now a growing disposition by those operating under patents to have thorough examinations made to determine the exact status of the patents they control. Mr. Rosenbaum thus finds himself busy almost entirely in making validity searches and reports and in furnishing general advice to many of his clients as to what can and what cannot legally and properly be manufactured and used.

STORAGE BATTERIES IN FIRE ALARM WORK.

The growth of the application of storage batteries in fire alarm work, displacing gravity cells, is indicated by the fact that during the past two years, 10,422 chloride accumulators manufactured by the Electric Storage Battery Company, have been installed in that service. Forty-seven cities are now equipped with the storage system. The Gamewell Fire Alarm and Police Telegraph Company is installing chloride accumulators wherever conditions permit.

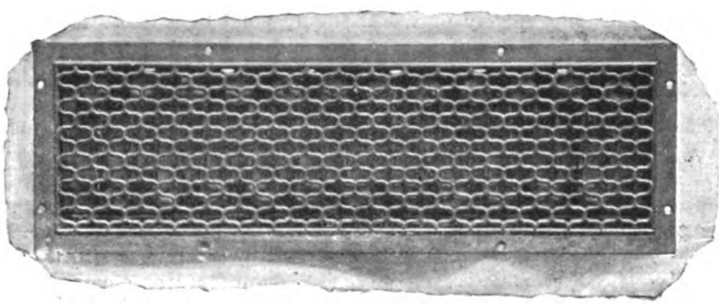
"THE MINERAL INDUSTRY."

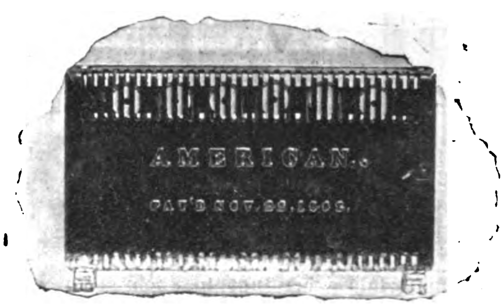
There is nothing equal to this book as an encyclopedia of all that relates to the condition of the mineral industries of the world. It is issued annually by the Scientific Publishing Company, of 253 Broadway, and we are glad to learn that Vol. IV. is now ready. The price is $5 per volume. The work is always well bound, clearly printed, and usefully indexed. The present volume, like its predecessors, contains several special articles.

ELECTRIC CAR HEATERS.

THE AMERICAN ELECTRIC HEATING CORPORATION, of Boston, Mass., who are exclusively engaged in the manufacture of all kinds of electric heating apparatus, are now preparing to push their styles of street car heaters, two of which we illustrate in the accompanying engravings. Fig. 1 represents a panel heater for side seat cars, designed to be placed with its front flush with the riser under the seat, giving the effect of a furnace register. This heater is but 3 inches deep (from front to back), and has ample space for free circulation of air to and from the coils, thus insuring the uniform heating of a large amount of air to a moderate temperature as well as providing for considerable direct radiation from the coils. It is finished in gold bronze.

Fig. 2 illustrates the type E heater, which is designed for long cars with cross seats, where it is desirable to have a larger number of heaters of smaller capacity than those used in shorter cars. This heater is furnished to fasten to the floor or suspend from the seat frame, and will fit under the shortest cross seats. Type E heater is finished in black enamel.





FIGS. 1 AND 2.—ELECTRIC HEATERS OF AMERICAN ELECTRIC HEATING CORPORATION.

PRESIDENTIAL FACTS AND FIGURES.

This is an unusually interesting year in politics, and one in which facts and figures are peculiarly desirable. The Central Electric Company, of Chicago, shrewdly aware of this, has issued a very neat and handy little manual about the presidential candidates and about the votes in previous years, both of the people and of the electoral college. A valuable feature also is the inclusion of the two platforms, those of the Republican and the "Democratic" parties.

150 HOUR ARC LAMP—A CORRECTION.

In our issue dated September 2, the advertisement of the General Incandescent Arc Light Company read: "Bergmann Long Life Lamp, 50 Hours," but should have read 150 hours. These lamps are in growing demand and meet with unqualified approval by reason of the saving in labor and annoyance their long life effects.

THE ELECTRIC APPLIANCE CO. is carrying a large and well-assorted stock of the celebrated "Electra" imported carbons, which are recognized as a very high grade article. They have an exceptionally long life, owing to the fact that almost the entire carbon is consumed, the amount of dust being reduced to a minimum. Prompt shipments are made from Chicago stock.

WESTERN NOTES.

J. HOLT GATES has removed his office from 311 Dearborn street to suite 1143 Marquette Building, Chicago, where the agencies of the Walker Company and the C & C Electric Company will henceforth be.

THE AMERICAN STORAGE BATTERY COMPANY has been formed in San Francisco, with a capital stock of $25,000, of which $50 is paid up. The incorporators are W. T. Bell, T. Z. Hardee, E. M. Massey, B. H. Bancroft and C. S. Preble.

THE ELECTRIC APPLIANCE COMPANY has been successful during the past month in closing some large deals for "O. K." weather-proof wire. Several orders for good sized complete new plants have been booked, together with some large orders for extensions for already existing plants.

MR. F. P. LEUTHER, former manager of the Western Electric Heating Company, St. Paul, Minn., has been appointed Chicago manager of the American Electric Heating Corporation, of Boston, with an office at 1644, the Monadnock Block, where he will carry a full line of their goods to supply the Western trade.

MR. CARTER H. FITZHUGH, 1634 the Monadnock Block, Chicago, will continue to represent the American Electric Heating Corporation in that section as agent for the sale of their make of electric heaters for street cars. Mr. James I. Ayer, general manager, the American Electric Heating Corporation, Boston, was a Chicago visitor last week.

THE LONG DISTANCE ELECTRIC TELEGRAPH CO. has filed articles of incorporation in St. Louis, Mo. The business the new firm will engage in is the manufacture, use, and sale of mechanical appliances, transmitters, receivers and devices connected with linotype or other type-setting machines. The company incorporated with a fully paid-up capital stock of $100,000. The stock is owned as follows: Joseph Riefgraber, 991 shares; Clarence P. Connolly, 5 shares; Charles Lenz, 2 shares; Jacob Handelmann, 1 share; Julius Friedman, 1 share.

ADVERTISERS' HINTS.

ATTENTION IS CALLED by the General Electric Company to their slow and moderate speed generators and motors. They carry as many as fourteen sizes in stock ranging from 2½ to 75 kilowatts.

THE CROCKER-WHEELER ELECTRIC COMPANY have made a special study of the equipment of factories with electric power. Among other large plants they have thus installed may be mentioned the Baldwin Locomotive Works, Philadelphia, and the Cambria Iron Works, Johnstown, Pa., and in all cases the most satisfactory results have followed.

THE COLBURN ELECTRIC MANUFACTURING COMPANY are now extensively represented in the United States. Their agents are Baker Bros., Toledo; Missouri Electric Repair Company, St. Louis; Illinois Electric Company, Chicago; and C. P. Hutchinson, Salt Lake City. They make an excellent machine for electro-plating.

THE AMERICAN ELECTRIC HEATING CORPORATION are selling an electric stove with cord and plug for $4. The stove requires two amperes on a 110 volt circuit.

THE S. & B. ELECTRIC COMPANY are stocking a very full line of supplies and novelties, their catalogue of which, with discounts, they will mail on request.

THE CUTTER ELECTRIC AND MANUFACTURING COMPANY illustrate an "I-T-E" mercury contact circuit breaker for use on motor circuits. These circuit breakers are now recognized as standard.

THE CENTRAL ELECTRIC COMPANY are offering a three inch, iron box, snap cover bell at twenty-two cents. This is not their only bargain.

Department News Items will be found in advertising pages.

THE
Electrical Engineer.

Vol. XXII. SEPTEMBER 16, 1896. No. 437.

POWER TRANSMISSION.

THE NEVADA COUNTY (CAL.) ELECTRIC POWER CO.

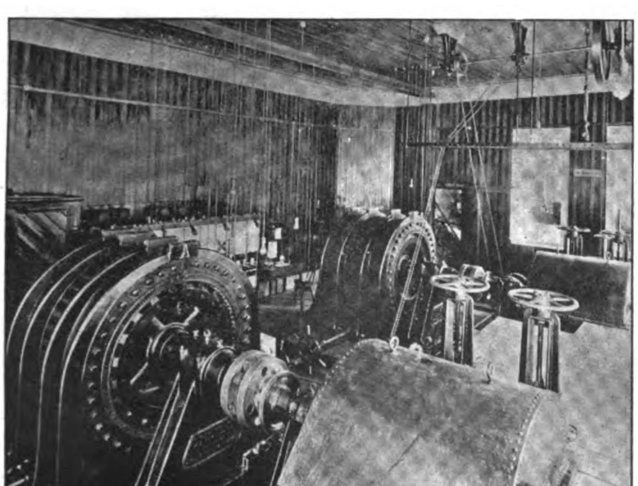
Mountain Pole Line.

A LITTLE more than one year ago work was commenced on the plant of the Nevada County Electric Power Company. To-day it is giving twenty-four hour service to 3,400 incandescent lamps and 32 horse-power in motors, with contracts ahead for 450 horse-power in synchronous motors. The plant has been in operation since Feb. 5, and has given commercial service from the start. Till June 12 the service extended from 4.30 p. m. to 9 a. m.; since that date the plant has been in continuous operation.

On the South Yuba River, 1½ miles above Purdou's bridge, is built a log crib dam, 28 feet high and 150 feet on the crest, which diverts water to the flume 6 feet wide and 5 feet high, which with a grade of 10 feet per mile follows the windings of the canyon for 18,000 feet. The rugged nature of the country and the difficulty of the work is well shown by the accompanying engravings.

At the end of the flume a head of 206 feet is attained and the water is carried to Pelton wheels through 300 feet of 48-inch, 44-inch and 42-inch pipe, giving in round numbers about 2,500 horse-power.

The power house is a stone, wood and corrugated iron building, 28 feet by 40 feet, having one large room with 20-foot ceiling, in which are installed at present two 340 kilowatt Stanley two-phase, 5,000 or 2,500 volt generators connected by special insulating couplings, shown clearly in the engravings,



INTERIOR OF POWER HOUSE.

to two 34-inch Pelton wheels running at 400 revolutions per minute; two Crocker-Wheeler 5 kilowatt bipolar exciters belted to two No. 5 Pelton motors; one No. 3 Pelton motor running at a constant speed to drive the differential governors; and a suitable switchboard.

Current is delivered to the line at 5,000 volts direct from the generators, saving the loss of power and extra complication of step-up transformers. It may be of interest to note that

FLUME LINE ON SOUTH YUBA RIVER.

there has not been a moment's trouble with, or the least item of repairs to, the generators thus far.

The pole line is very substantial and carries two complete circuits of four wires each on triple petticoat porcelain insulators. No. 3 bare copper wire is run to a point 4 miles from the power house where the circuits branch. No. 6 bare copper is run from here one mile to Nevada City, and four miles to Grass Valley. In both towns all wire is insulated.

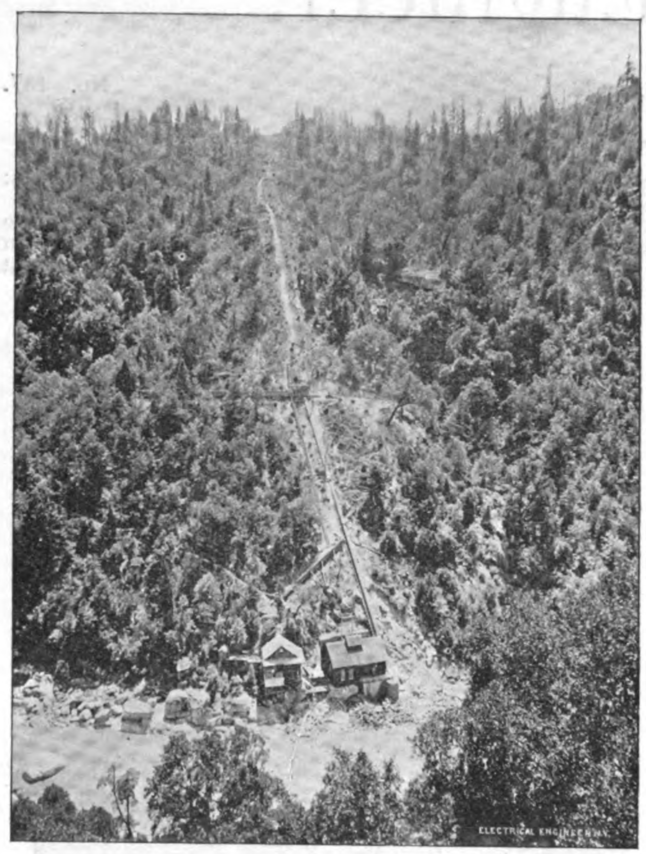
A No. 6 iron wire, run on the tops of the poles and grounded at every other pole, was intended to protect the system from lightning, but it has been found entirely inadequate and Wurts non-arcing metal arresters have been installed at the power house and at the terminals of all branches.

At both towns sub-stations have been established with elaborate switchboards and step-down transformers which reduce the line pressure to 2,000 volts for lighting and small power distribution. There are furnished now 1,600 incandescent house lights, 58 25 candle-power series incandescent street lights and four alternate current arcs in Nevada City; and 1,800 incandescent house lights and 40 arcs for street lighting in Grass Valley.

The motor business is very promising, but mining men are slow to adopt the new power till they see it in successful operation elsewhere. The first mine to adopt electricity for both lighting and power near Nevada City was the Red Hill, Limited, which is using a 30 horse-power Stanley two-phase induction motor to drive a Griffin mill, which has been running successfully since June 12. The second installed was a 2 horse-power Stanley two-phase induction motor for driving a concentrator and pump working the tailings from a large mine, and has been in almost constant service since the latter part of June. The third motor to be installed is a 120 kilowatt synchronous motor to drive an air compressor at the Gold Hill mine, near Grass Valley, where it was decided to

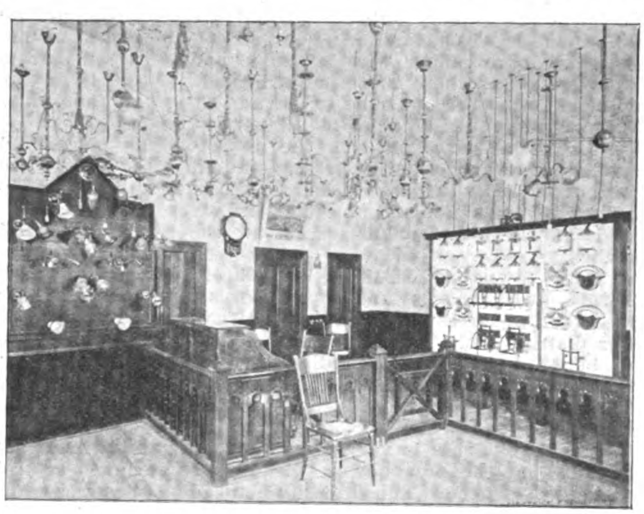
use compressed air in order to utilize the engines already installed; it is also intended to use the steam boiler already in place as a receiver and reheater as well as reserve in case of accident to the electric machinery; this motor will start up in a few days.

For about three months it was necessary to run at 2,000



Power House, Flume and Penstock.

volts, which was very easily accomplished by changing the connections on the generators and cutting out the step-down transformers. With this arrangement, however, it was found difficult to keep the phases balanced, but it was accomplished very well by means of an iron wire inductive resistance. Since changing back to 5,000 volts no trouble has been experi-

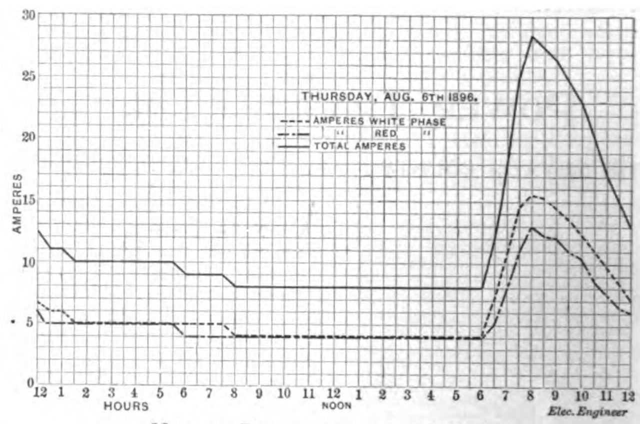


Grass Valley Office, Showing Sub-Station Distributing Board.

enced with unbalanced phases, and the difference in voltage between the two towns has been very little, even when the heaviest load is in, in fact it is often two volts higher (on the 100 volt circuits) at Grass Valley than at Nevada City.

One hundred volt 3.6-watt lamps are used exclusively for house lighting and the Edison base has been adopted as standard for them. For the few 50 volt lamps it is necessary to use the Thomson-Houston base has been adopted. The accompanying diagram shows the load curve as taken from the power house reports of August 6.

The conception of the plant is entirely due to the superintendent, Mr. A. Fregidgo, and the success of the enterprise is due to the energy and ability of the general manager, Mr. E. J. de Sabla, Jr. The consulting engineers for the installation were Messrs. Hasson & Hunt and Mr. W. R. Eckert, of San Francisco. The machinery was installed by Mr. Jno.

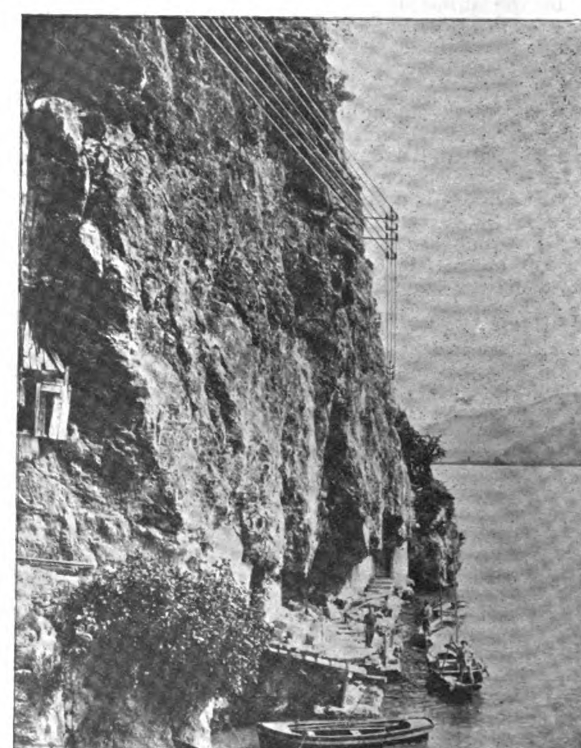


Nevada Power Plant Load Curve.

Martin, Pacific Coast agent for the Stanley Electric Manufacturing Company, who were represented in the field by Mr. E. E. Stack. The electrical portion of the plant since starting has been under the direction of Mr. L. M. Hancock.

ELECTRIC POWER ON THE GARDA LAKE, AUSTRIA.

ONE of the main beauties of electric power is its flexibility of application, rendering easy and economical the performance of work which, with any other methods would be difficult and expensive, if not impossible. A plant recently in-



Three-Phase Electric Power Transmission on the Garda Lake, Southern Austria.

stalled by the Oerlikon Works, Zurich, Switzerland, affords a good illustration of the handiness of the electric motor. The cut herewith shows the plant in operation on the Garda Lake, Southern Austria, the line being seen at the top of the bluff and the work going on along the water's edge. The system

used is three-phase at 2,000 volts, and the apparatus is answering its purpose very satisfactorily.

THE ELECTRICALLY DRIVEN MILLS OF THE PELZER MANUFACTURING CO., PELZER, N. C.

THE advantages incident to the driving of textile mills by electricity instead of by belt or rope drive from a steam engine are perhaps nowhere more emphatically demonstrated than in the great cotton mills of the Pelzer Manufacturing Company, at Pelzer, N. C. This company, organized in 1860, had gradually increased its manufacturing facilities until in the spring of 1894 it had not less than 53,500 spindles in operation in the three mills which it had located on the Saluda River. The entire power of the river at that point it then utilized to drive two of the mills. Mill No. 3 was driven by a belt from a 400 horse-power engine of Corliss type.

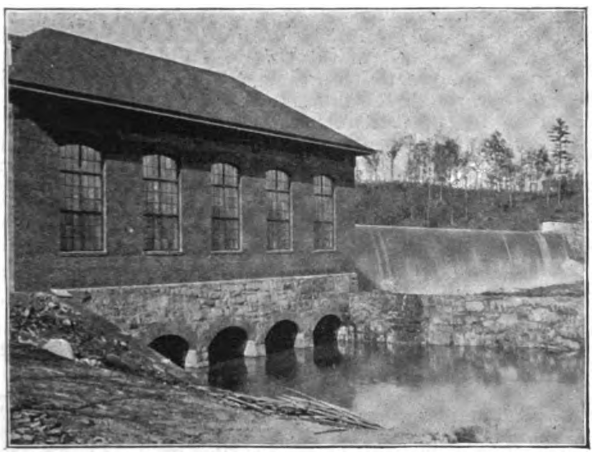


FIG. 1.—POWER HOUSE AND DAM, PELZER COTTON MILL PLANT.

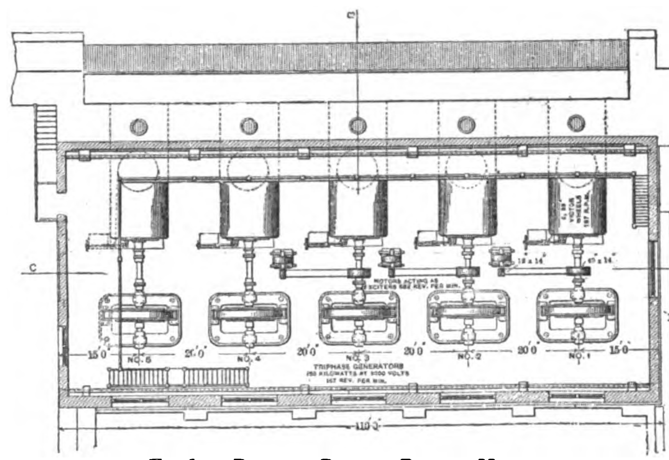

FIG. 2.—PLAN OF PELZER POWER HOUSE.

The Pelzer Company owned a large tract of land immediately adjoining the mills, and upon this it had erected besides the three mills just mentioned, three churches, schools, stores and the factory village, the whole property being controlled and supervised by the president, Capt. E. A. Smythe. The village is located about three-quarters of a mile from the Columbia and Greenville branch of the Southern Railroad, and a spur track is run from the line to the village. The corporation controls the Saluda River for several miles on each side of the Pelzer village, and in this distance owns a number of undeveloped water powers, in addition to those it had already utilized. The growth of the business of the Pelzer Company rendered an increase in the manufacturing plant necessary, and in 1894 plans were drawn for a new 55,000 spindle mill. The question of driving the mill, and consequently, its location, became the most serious it had to consider. A magnificent undeveloped water power existed not three miles down the stream from the present village, but if the new mill were to be erected by the side of this water power, it would be necessary to duplicate the mill village, etc., and would entail the cost of additional supervision, the distance between the two villages being too great to bring the new mills under direct supervision of the mills 1, 2 and 3. The formation of the land adjacent to the water power was also unfavorable to the erection of a mill at that point, unless at great expense. It would have been necessary to lay very heavy stone founda-

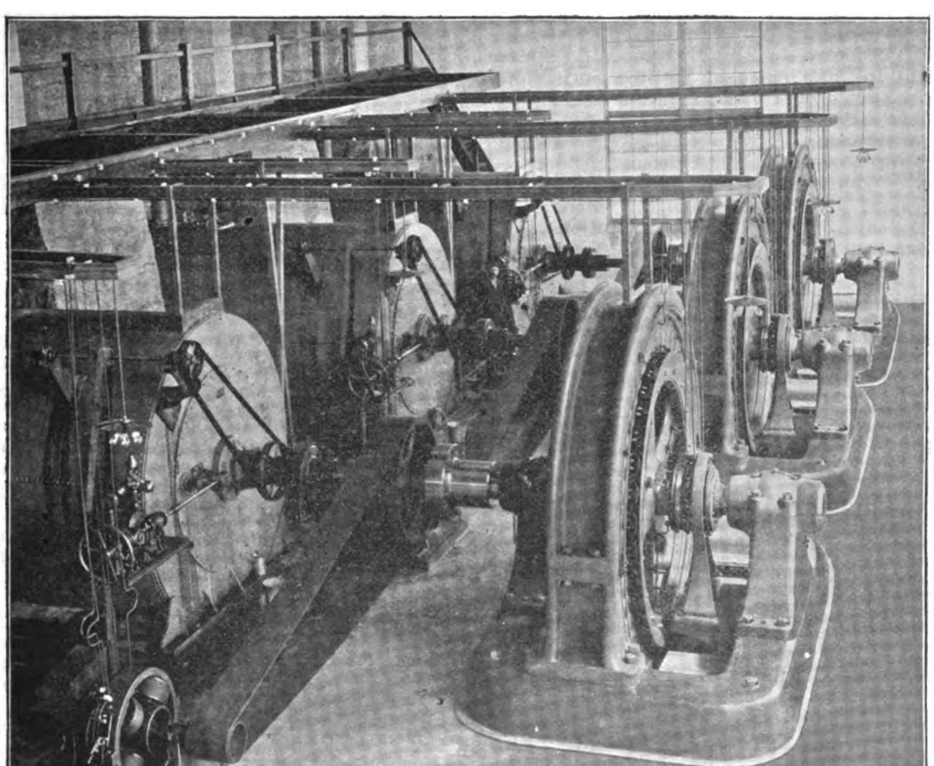

FIG. 3.—GENERATING PLANT, PELZER COTTON MILL POWER TRANSMISSION.

tions under the entire building, which had been planned for 505 feet in length and 128 feet wide, as well as to extend the railroad track from the old to the new village. Before the magnitude of such a project even such enterprising mill owners as the Pelzer Company recoiled.

A little before this time the owners of large cotton mills at Columbia, S. C., had decided to use electricity to drive their machinery. Their plant was already in operation and giving

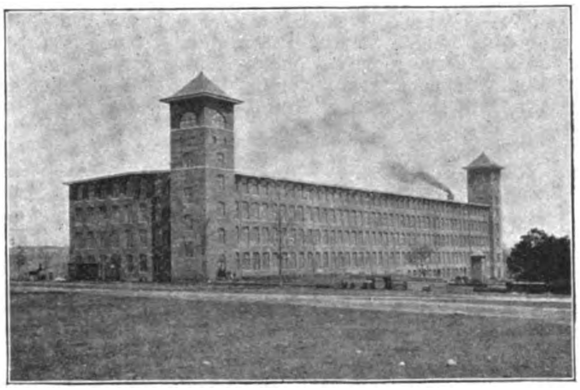

FIG. 4.—NEW NO. 4 PELZER MILL OPERATED ELECTRICALLY.

satisfaction, and the Pelzer Company, after an exhaustive examination, made a contract with the General Electric Company, in October, 1894, for an entire electrical three-phase generating and insulation motor equipment for the new mill, and a synchronous motor equipment for mill No. 3.

The plans were altered accordingly to comprehend a power house only at the site of the water power, and the erection of mill No. 4 itself in the vicinity of mills 1, 2 and 3. The new mill is 505 feet long by 128 feet wide, four stories high and contains 55,027 spindles. To obtain the necesary fall with a sufficient storage of water, a dam of solid masonry 32 feet high and about 450 feet long was thrown across the Saluda River, a spillway 300 feet long being provided in view of occasional heavy spring freshets. The available power is set down at 5,500 horse-power. The power house is of red brick, laid on masonry foundations, the walls being waterproofed for three feet above the top of the stone. The dam and power house were constructed by William Chapman & Company, Providence, R. I., and the water wheel plant by the Stilwell-Bierce and Smith-Vaile Company, of Dayton, O. Wheel pits and feeders are provided for five pairs of 29-inch horizontal Victor wheels, each of which, under the available head, will develop 1,000 horse-power. Three pairs of wheels only have been installed, but the other two will be put in as soon as the increase in the demand for power warrants the extension.

Each pair of turbines is connected to the armature shaft of a 1,000 kilowatt three-phase generator, delivering current at 3,300 volts when turning at a speed of 167 revolutions per minute. The exciters are multipolar dynamos of the General

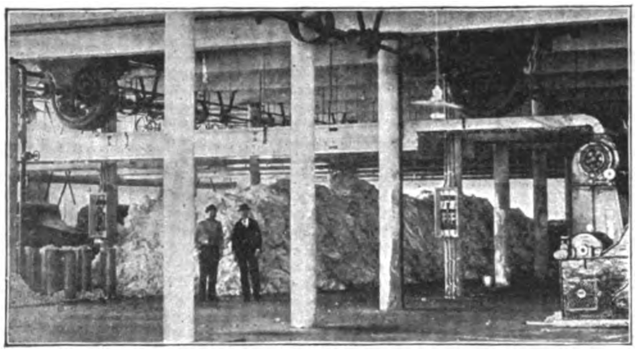

FIG. 5.—PICKER ROOM, PELZER MILL, WITH CEILING MOTOR.

Electric slow speed type, and are directly driven by belts from the turbine shafts. The switchboard of the skeleton type located in the gallery, carries the special high tension switches the synchronizers and usual rheostats and measuring instruments, the busbars receiving the current direct from the generators without transformation. The high tension wires rise from the board to a small monitor on the dam side of the power house and pass out through this to the special glass insulators on the poles. These carry four cross arms. The top one carries two wires acting as lightning conductors grounded at every third pole; the second, third and fourth cross arms carry the generator circuits, while on the lowermost are strung the pressure and telephone wires. The total length of the pole line is 2⅝ miles. Three-quarters of a mile from mill No. 4 the wires for the synchronous motor in mill No. 3 branch off from the main line.

A small tower erected immediately in front of the new mill receives the high tension wires which are carried down the interior and proceed into the basement of the mill by an underground tunnel. In the tower are contained the lightning arresters. The transformer room adjoining the repair shop in the basement receives the wires through porcelain lined holes in the wall, on a skeleton board carrying the necessary switches. The transformers are nine in number, three of which have a capacity of 265 kilowatts, and six of 275 kilowatt capacity. They are of the G. E. air blast type, in which the principle employed to keep them cool is to send a constant current of air through the laminations by means of two electric blowers. In the transformers the pressure is reduced to 200 volts, at which pressure the current is brought to the motors. There are also two transformers reducing the current to 114 volts for the 1,200 incandescent lamps used to light the establishment.

The motor equipment of the new mill aggregates 2,080 horse-power, divided into twenty-four motors, all of the G. E. induction type and located throughout the building as follows: Two of 50 horse-power each in the basement to drive the

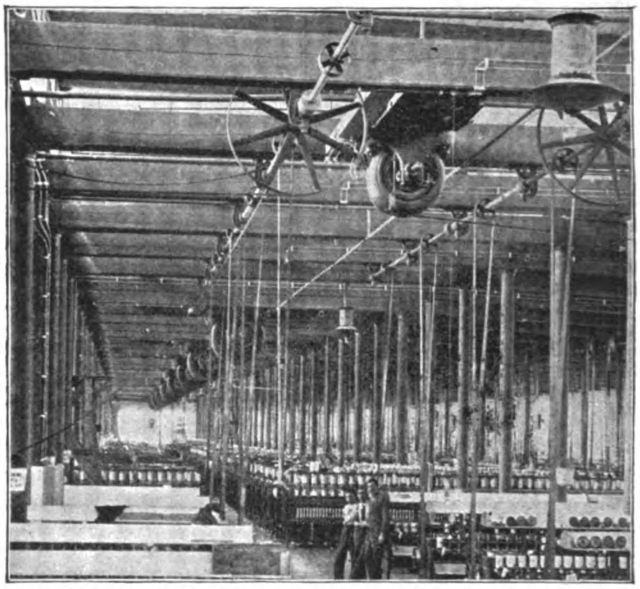

FIG. 6.—SPINNING ROOM, PELZER COTTON MILL, MOTORS ON CEILING.

blowers for ventilating, heating the repair shop, etc. Four of 75 horse-power each in the picker room on the first floor. These are directly connected to the shafting in the same manner as at the Columbia, S. C., mills, and run at 600 revolutions per minute. Four of 110 horse-power each, driving 720 looms on the first floor and 680 on the second floor, as well as five slashers. Three of 110 horse-power each, driving the carding machines of the third floor. Eight of 110 horse-power each, driving the machinery in the spinning room on the fourth floor. One of 20 horse-power operates the spoolers in this room and four of 5 horse-power supply power for the operation of the pumps. All of the above motors are non-synchronous, and are of the inverted type. They are suspended from the ceilings of the rooms in which they are employed. They have neither brushes, collector rings nor commutators, and consequently there is no sparking. The principal advantage presented by these motors is that they necessitate no attention whatsoever beyond that given to the bearings, and so long as these are kept properly lubricated, the motor will satisfactorily perform its duty. They are self oiling and are provided with oil glasses, by which the attendant can readily determine the amount of oil in the oil chamber. By fastening these motors to the ceiling a great saving in floor space is effected, and they are there beyond interference from curiosity, carelessness or accident.

To drive the machinery, each motor is, as far as possible, connected by four belts, two overhanging pulleys being keyed to each end of the motor shaft. From each end

the two belts lead in opposite directions to the shafting driven by the motor. This method of driving reduces to a minimum the amount of friction, while equalizing the strain upon the bearings and shaft. In cases where two belts only are driven by a single motor the pulleys are placed on one end of the motor shaft only, and the belts are led in opposite directions to the machinery shafting.

A glance at the economy induced by the adoption of electricity shows that the erection of this plant cost very little more than it would have done had the mill been located at the dam, on account of the expensive stone foundations which would have been required, the duplication of the mill village and the extension of the railroad. The mill instead of being located on low lying land near a river, is on a high, dry tract, where it receives the best light and ventilation. A considerable saving was effected in both shafting and belting. The widest belt in this mill using 2,200 horse-power is only 8 inches wide—the largest shaft 2 15-16 inches in diameter. The saving in first cost of shafting and belting compared with that in a mill of identical proportions driven by mechanical methods, can be set down at about $10,000. The omission of the belt tower, and its accompaniments, resulted in economizing a sum between $3,000 and $5,000. In mill No. 3, substitution of the 400 horse-power synchronous motor for the steam engine will do away with an annual expenditure for fuel of $10,000. The steam required for heating and slashing in this mill is supplied from the boilers in Nos. 1 and 2 mills, and thus the entire cost of fuel used in No. 3 mill will be saved by the substitution of the synchronous motor. This saving would more than equal the entire operating expenses, including interest on the electric plant driving both No. 3 and No. 4 mills, and lighting the latter. In other words, the cost of power for these two mills and the cost of lighting one of them would be no more than if the steam engine had been retained in No. 3, and No. 4 had been erected near the water power to be driven therefrom mechanically. All of the advantages of concentration, subdivision of power, more favorable transportation facilities, better light, and better ventilation are obtained without adding anything to the cost of manufacturing the output. On the other hand, it is obvious that they must result in a very material reduction in its cost.

ELECTRIC TURRET GEAR FOR FRENCH WARSHIPS.

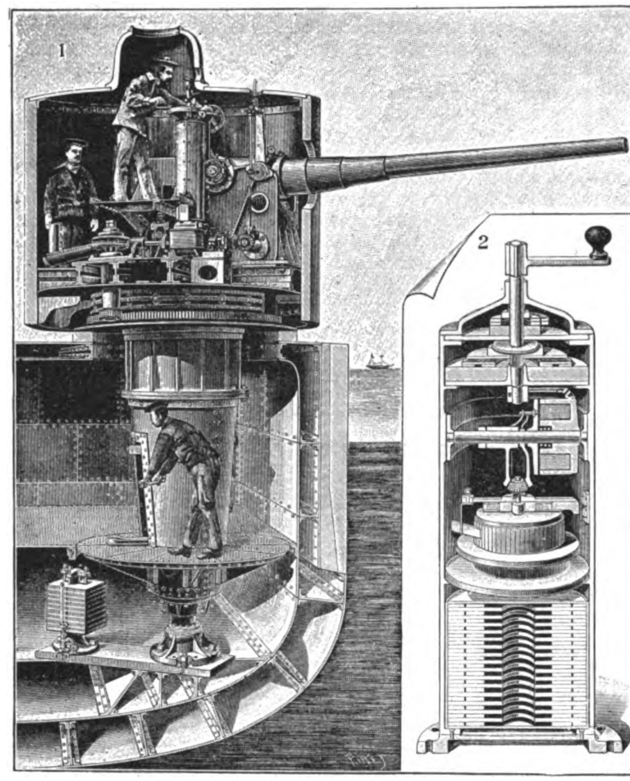
NOWADAYS when so much depends upon the rapidity with which the guns can be handled in naval warfare no pains are spared to apply the latest improvements to this department of naval ordnance. An arrangement for the rapid handling of guns, adopted in a number of French warships, is that illustrated in the accompanying engraving taken from "La Nature." As will be seen, the turret and the gun carriage are placed on a platform which revolves on rollers, the whole resting on a vertical column, which, in turn rests on a hydraulic pivot placed close to the keel of the vessel. This hollow column encloses the apparatus for raising the ammunition to the gun from the magazine below.

Two men operating a crank and revolving the pinion which gears with the circular platform on which the gun rests, can turn the gun and turret, but this method is only employed in emergency, as it is much too slow for regular work. The actual manipulation is carried out by means of a controller, shown in an enlarged view in the illustration. By means of this controller the turret can be revolved at any desired speed by a simple turn of the handle which introduces more or less resistance into the circuit. This movement suffices for the rapid traversing of the gun.

It is also necessary, however, to be able to stop quickly in any desired direction. This is also carried out by the displacement of the handle, which transforms the motor into a generator, thus acting as a brake and stopping the movement of the turret suddenly. A special arrangement then permits of giving the turret a very small angle of rotation to the right or left, so as to give the gun its final range.

Finally, in order to prevent all shocks, it is necessary to provide for the automatic stopping of the turret at the extremities of its movement. This is done by means of a magnetic gear. This provision is necessary in case the gunner is killed or wounded while the turret is revolving at full speed in one direction or the other. The controller does not operate for giving a vertical range to the gun. This is done directly by hand without much difficulty, and is very easily accomplished, as the masses to be moved are almost in complete equilibrium.

Electricity is also employed for raising the ammunition from the magazine below. The power required for this class of work is very small. For a turret containing a 24-centimetre (10-inch) gun, the motor requires 15 horse-power nominally, but it does not normally require more than 10 horse-power, and a 12-centimetre (5-inch) gun turret takes only 3 horse-power.



ELECTRIC GEAR FOR GUN TURRETS.

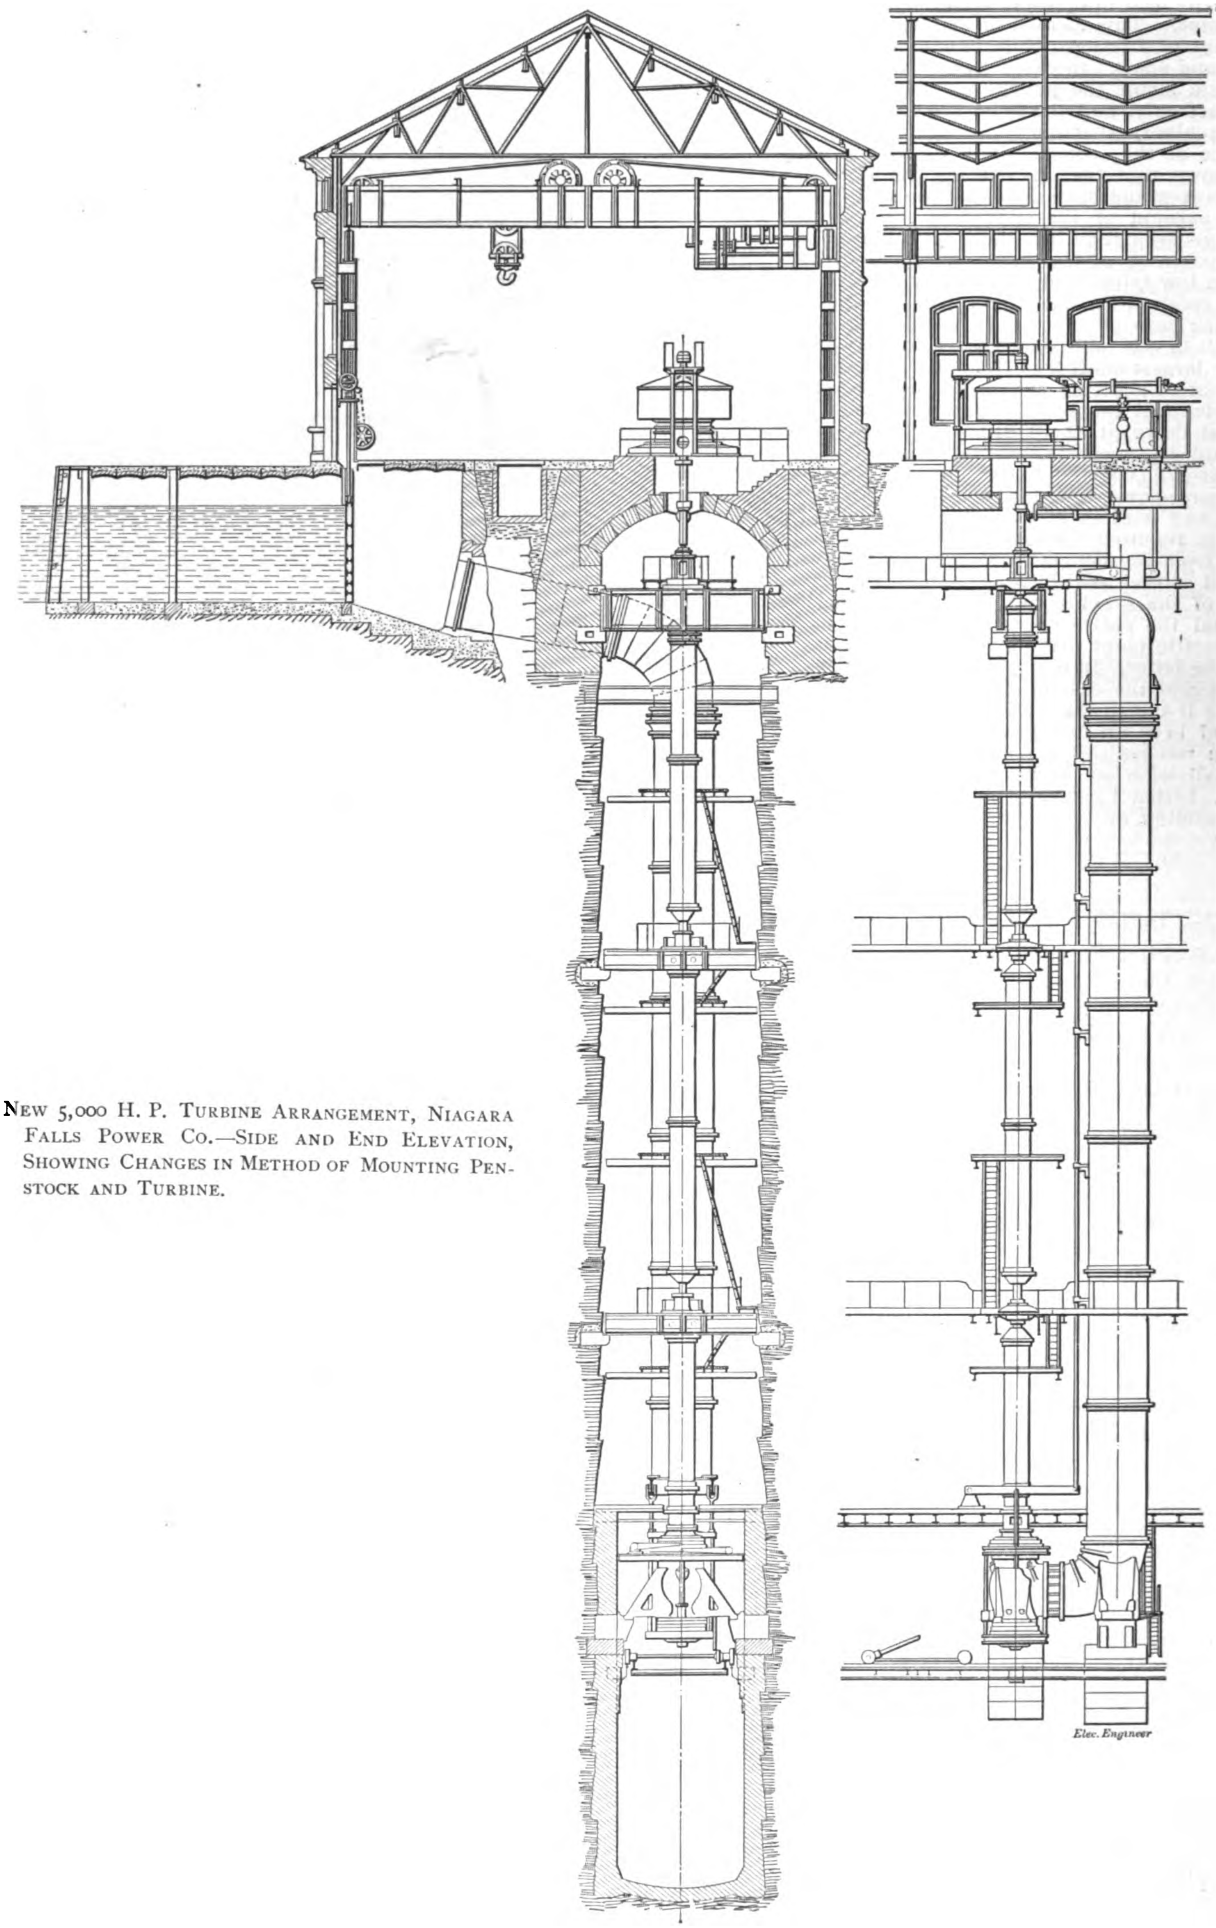
EXTENSION OF THE NIAGARA POWER HOUSE.

BY ORRIN E. DUNLAP.

THERE is much, very much, in the extension of the wheel-pit of the Cataract Construction Company that is of the highest and best encouragement to more than one branch of engineering science, and in addition to this there is still to be found much credit for the men, who, as capitalists seeking profitable investment, or as engineers and authorities, have contributed in any manner to the success which has been attained in making available for the use of mankind a comparatively small, yet intrinsically enormous amount of the force of a wonderful and mighty river. Humanity has perhaps become too matter of fact to stop in this day of electrical and scientific progress to congratulate itself upon the availability resultant from a new development of ideas or power, but on the contrary the present day ambitions of men lead them to contemplate more and more each day the possibilities of the future, and it is this anticipation of accomplishment which encourages and develops new projects and gives greater force to those now under way.

It was on October 4, 1890, that the first sod in the Niagara tunnel work was turned by Capt. C. B. Gaskill, and the few years which have passed since then have witnessed an electrical development which not more than a decade before was almost if not entirely beyond conception. To the success attained at Niagara Falls in this wonderful plant of the Niagara Falls Power Company, electrical, civil and hydraulic engineering owe much. Not that man's ambition did not turn to other water powers, but for the reason that at Niagara the greatest possibilities in the whole world were presented, and where such possibilities are found, there, too, are found the greatest results if success be attained.

It must indeed have been a proud moment for the engineers connected with the Niagara installation, when on the morning of April 4, 1895, Mr. Rudolphe Baumann, a Swiss engineer, moved the small wheel controlling the initial turbine, giving motion to the field of the generators. Since then other turbines and generators have been installed to the full capacity of the

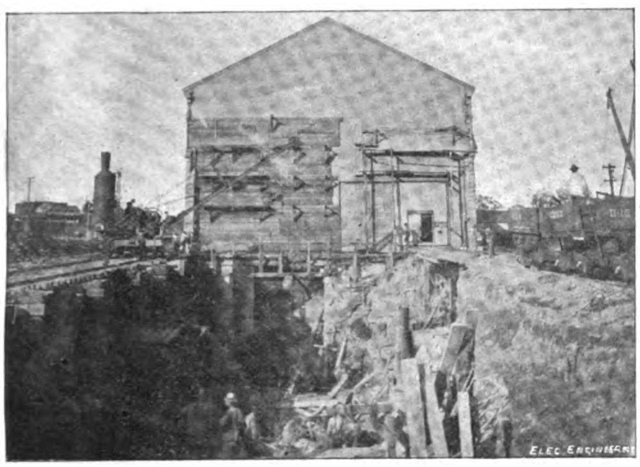


New 5,000 H. P. Turbine Arrangement, Niagara Falls Power Co.—Side and End Elevation, Showing Changes in Method of Mounting Penstock and Turbine.

present wheel-pit and power house, and now a further installation is proposed by the Cataract Construction Company.

The pictures and drawings published in connection with this article well illustrate the scene of the wheel-pit and power house extension, while they also make clear some of the notable changes to be made in the new installation as compared with the present. The contract for the wheel-pit extension is in the hands of E. D. Smith & Co., of Philadelphia, they having sublet the contract for masonry to J. S. Patterson, of Chicago, Ill. Mr. William A. Brackenridge, chief engineer of the Cataract Construction Company, is in charge of the work. Mr. Brackenridge was connected with the original work, and his great familiarity with all parts of the work is invaluable at the present time.

The contract held by E. D. Smith & Co. calls for the extension of the wheel-pit for a distance of 294 feet, making the total length of the pit 434 feet, which will allow room for the installation of seven more turbines, making ten in all in the pit. The depth of the wheel-pit will be 179 feet. The power house foundation will be carried to a point opposite No. 10 inlet, which covers space for the complete power house. It has not, as yet, however, been definitely determined whether the superstructure of the entire power house will be erected, or whether the new portion of the superstructure will only cover the space of three additional turbines. The average width of the wheel-pit will be twenty feet, which is increased at the top to make room for masonry walls six feet wide. The walls are to be carried down to solid rock, the width between them to be 21 feet. One of the changes in the method of construction of this new portion of the wheel-pit as compared with the original portion of the pit is that all the new penstock mouthpieces, seven in number, will be built in the wall, the idea being that when dynamos No. 7 to 10 inclusive are installed, no masonry will be necessary, it having been completed in advance. Still another change is that the openings directly under the dynamos are to be increased. The new method is shown of supporting the girders in the wheel-pit. In the present portion of the pit the girders are built right into the wall, but in the new pit they are to be supported on castings placed in the walls.



Work on Extension of Niagara Power House.

It will be seen that the wheel case and lower penstock elbow will have projecting ribs supporting them on castings without any girders. This is a notable change from the present construction, as girders are used to support the three turbines installed. The supports of the ribs referred to will be bricked into the walls, as is made clear in the illustration.

At present, current exciting the fields of the generators is obtained from 200 kilowatt rotary transformers located at one end of the switchboard structure, but with the completion of the new installation it is proposed to do away with these exciters and four small turbines will be placed in the wheel-pit to operate four exciters located on the power house floor. This change is not because the present method has not proved efficient, but because it is felt the new method described will be in the line of improvement and give an absolutely independent source of supply for the exciters.

A new conduit is provided for on the west side of the power house to carry light and power cables. This will be 7 feet 6 inches by 4 feet 4 inches. The main subway is to be extended. The expense attending the wheel-pit extension will be over $300,000, and it is expected the work will be completed by May, 1897. The alteration in the arrangement of the turbines was suggested by Dr. Coleman Sellers, who is chief engineer of the Niagara Falls Power Company.

The scene of the work is very lively. Messrs. Smith & Company have erected a very efficient plant in order to hurry the contract as rapidly as posible. They have a large force of men at work and good progress is being made. The point of operation is in the rear of the present power house and alongside the inlet canal, as will be seen by the illustration. The method of working is somewhat different from what it was on the original section of the pit. Dynamite is not used in quite such heavy quantities. Channelling machines cut the rock, which is blown out in benches, care being taken that nothing shall occur to injure the installation now doing service. The muck from the excavation is loaded into dump cars and carried over the tracks of the Niagara Junction Railway to the wooden trestle of the same road beyond Echota, where it is used to fill in beneath the trestle and make a firm roadbed. This work of itself will be a notable improvement. The muck of the first section of the wheel-pit and also of the tunnel was used for filling in the company's land under water and thus many acres were reclaimed, on some of which factories to-day stand.

MISCELLANEOUS.

THE TESTING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY'S WORKS.—II.

BY THEO. STRAUS.

THE power for testing is supplied by four engines, three of which are located in building No. 12 and one in the new building. The three in the former consist of one Improved Greene engine, built by the Providence Steam Engine Company, of Providence, R. I., which is a tandem compound. The cylinders are 17½ inches and 28 inches in diameter, the stroke 48 inches and the speed from 60 to 100 revolutions per minute. It is rated at 750 horse-power. The remaining two are Straight Line engines, built by the Straight Line Engine Company, of Syracuse, N. Y. One engine has a 16-inch stroke and 15-inch diameter of cylinder, and the other is of 16-inch stroke with cylinder of 14-inch diameter. Both make 118 revolutions per minute and are rated at 125 horse-power. The engine located under the gallery in the centre of the southern side of building, No. 11 (Fig. 4), is the Lawrence engine, built by Armington & Sims, of Providence, R. I. Its cylinder is 14¾ inches in diameter and it has a stroke of 13 inches, making 260 revolutions per minute and being rated at 150 horse-power.

Steam is supplied to these engines from the central power station, at initial pressures of 120 and 160 pounds per square inch. Belted to the Greene engine is a 4-pole 500 kilowatt railway generator running at 325 revolutions per minute and at 500 volts. Besides supplying power to the different sections of the new building, it runs the two 200 kilowatt 4-pole, 500-volt motors, each of which is belted to the ends of the counter shaft located in the southeastern section of the new building. The shaft being fitted with pulleys of all sizes and

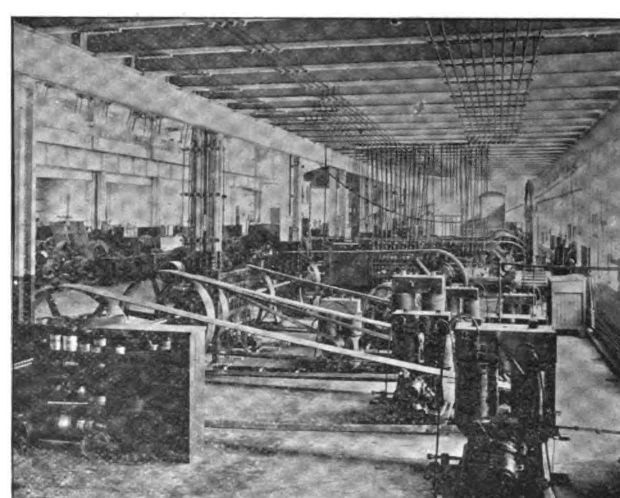


Fig. 4.—The Exciter Plant.

friction clutches, it is an easy matter to connect up a machine and make a test. The two Straight Line engines are also connected to a counter shaft arranged in the same manner. These engines are used in cases of emergency, and are always kept in reserve.

In the Testing Building No. 11, the Lawrence engine is belted to a counter shaft, which runs the exciting dynamo plant. (Fig. 4.) This plant consists of the following apparatus:

Two 4-pole 25 kilowatt generators running at 1050 revolutions per minute, one of 125 volts and the other of 500 volts.

Four 4-pole 17½ kilowatt generators running at 1,100 revolutions per minute, two of 125 volts, one of 250 volts and the remaining one of 500 volts..

Three 30 kilowatt Edison bipolar generators of 125 volts each.

One 45 kilowatt Edison bipolar generator of 500 volts.

These are so arranged that one can obtain any desired voltage from the plant. Although the aggregate horse-power amounts to 1,150, and at times the machines in test have an output over that of the engines, it is seldom the full capacity of the engines is utilized. This is accomplished by the excellent methods and schemes for testing which are used. The principal method for saving power is known at these shops as "pumping back," being an adaptation of the Hopkinson method of testing dynamos. This is carried out by connecting two machines of approximately the same size, so that they will tend to run each other, but having an external supply to overcome all the losses due to friction, hysteresis, eddy currents, slipping of belts, excitation current, etc. To accomplish this, the two machines, one used as a motor and the other as a generator, are belted together, and their armature circuits and that of the loss supply, are connected in parallel. The special part of the test requiring care, is to arrange the conditions suitable for starting. Referring to the diagram, Fig. 5, with the following brief explanation, one can readily see how this is accomplished:

The voltage of the three machines is regulated by rheostats, R, introduced in the field circuits. In the circuit between the loss supply and motor, B, are located an ammeter, A, and starting rheostat, S, and between the motor, B, and generator, D, an ammeter, A, and a switch, C, are connected. The loss supply being brought up to voltage the motor, B, is started. This necessarliy runs the armature of the generator, D, and the machine picks up, generating the field current. The field rheostat, R, is then regulated so that the voltage across the brushes of the generator, D, is about 3 volts higher than that of the motor, B, and the loss supply. When this has been accomplished, the speed being correct, and the voltage across the switch, C, has become about 3 volts, the switch, C, is thrown in, and the machines pump their current back on each other. Then to bring the machines to the required load, the motor field is weakened.

It is not absolutely necessary to use an electric loss supply. In most instances, some mechanical source, such as a countershaft is belted to both of the machines. All types of direct current machines may be tested in this manner by varying somewhat the conditions to suit each case. From actual observation, machines of 2,100 kilowatt capacity have been run at full load, with the expenditure of only 400 horse-power from the engines.

The work at the different shops being so very accurate, it has been found by experience that there is no necessity to put the separate parts together until the machine is erected in

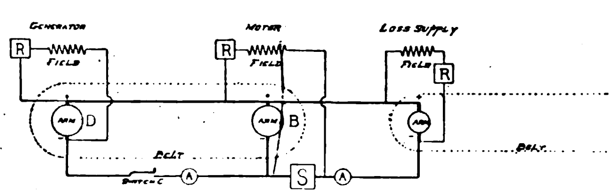

FIG. 5.—METHOD OF TESTING GENERATORS.

the testing building. When a test is to be made, the tester considers the mechanical and electrical parts imperfect and defective until to his own satisfaction he disproves his assumption. A person testing under these conditions is wide awake at all times, and on the lookout for any defects in construction. The testing staff is divided into two classes, the "regular" men and the students. The regular men are those of practical experience, having been with the company for years, and are thoroughly conversant with every machine built by the company. These are ably seconded by the student corps, who, after securing their theoretical education at some college or university come to these shops to gain that important factor in electricit, "practical knowledge." Necessarily the men must be very careful as records of high accuracy only are allowed to pass through the office. The accuracy of the test is doubly insured by the personal inspection of the foreman and engineering corps, and by the frequency with which all the instruments used are calibrated.

A laboratory, used solely for standardizing purposes, is located at the remotest corner of the grounds, far removed from the surrounding buildings. An interior view of this is shown in Fig. 6. It is here that all the instruments used for testing are calibrated and repaired. No instrument is used in a test, if it has not been calibrated at most a few days before.

The instruments are sub-divided, so that only part of them

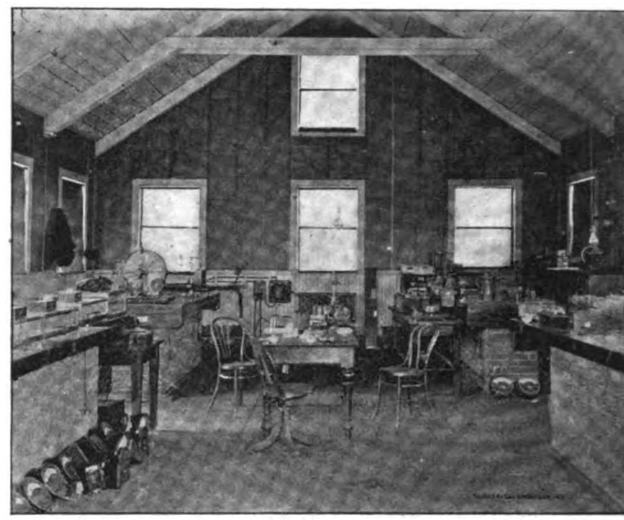

FIG. 6.—STANDARDIZING LABORATORY.

are at the laboratory at one time. Having the curves or constants of the instruments, accurate readings are thus secured and the percentage of error is thereby made very small. The instruments now in actual use amount to 298 and are mostly of the General Electric and Weston types.

These are divided as follows: Direct current ammeters, 85; direct current voltmeters, 80; alternating current ammeters, 40; alternating voltmeters, 20; wattmeters, 25; dynamometers, 13, and tachometers, 35.
